The disposal of manufacturing waste by dumping into streams is now causing more or less friction between the manufacturers and the communities in which they operate. Consequently in addition to the financial inducement of reconverting this waste lime into lime would be the satisfaction to the manufacturer of removing a source of contention with his neighbors. Where lime waste is pumped on low ground by the manufacturer, or is carted away and dumped, this represents a direct expense which its conversion into lime would do away with.

In the manufacture of caustic soda there is carried off with the lime sludge a certain small amount (½—1 per cent) of caustic soda, and if this sludge is converted into lime this soda is recovered, adding to the saving to be effected by the process.

So far as I know, no attempts were ever made to burn waste lime by moulding the material into bricks and burning these in an upright kiln. The rotary kiln employed by the cement industry, however, offered a means of burning the waste lime and its use here was naturally suggested by the fact that it had been employed for burning fresh water marls which resemble alkali waste in physical properties.

The attempt to burn alkali waste in a rotary kiln began about 1900 and the kiln was first employed in connection with dryers. This installation had been already tried on wet materials in the cement industry and proved a failure. The use of dryers in recovering waste was soon abandoned and the employment of long kilns following the cement practice was substituted. This, in connection with various schemes for thickening the waste sludge so as to reduce the water to be evaporated have made the reburning of the waste lime commercially profitable.

Among those industries in which lime is being recovered at one or more plants may be mentioned the manufacture of caustic soda, sugar, wood-pulp and soap. These plants have generally proved successful. Naturally, as I have said, the early attempts to convert this sludge into lime met with some mishaps, largely owing to a lack of knowledge on the part of the experimenters as to the fundamental principles of rotary kiln operation and design, but the process has been worked out on a practical basis and where lime is being purchased at a cost of over $3 per ton it will generally prove economy to put in a lime recovery plant, provided the quantity of sludge obtained is not too small.

As received from the caustic soda plant the lime sludge usually contains a large quantity of water, as we have said. It will be practically an impossibility to burn this material in this condition economically owing to the amount of water which would have to be evaporated. If this sludge is allowed to settle for twenty-four hours it is possible to drain off much of the water and the resulting thickened sludge or slurry will contain about an equal weight of water and of carbonate of lime and may be burned with an expenditure of about 800 lbs. of coal for 1 ton of lime. Should it be desired to reduce further the quantity of water there are a number of very satisfactory mechanical filters on the market and these may be employed to do this work. The installation of a continuous drum filter, the product from which would fall directly into the kiln, would prove efficient and labor saving.

In small lime recovery plants (10 to 15 tons of quick lime per day), the item of labor will usually amount to more than that of fuel and it will prove more economical here not to thicken the sludge beyond the point where it can still be handled with a pump. It is possible to handle a mixture of 55 per cent of carbonate of lime and 45 per cent of water successfully with a centrifugal pump and the mixture of half and half can be easily handled. If it is burned in this condition the material may be pumped directly into the kiln, using a valve to control the flow and allowing the excess to circulate back into the feed tank, thus keeping the consistency uniform.

Where the plant is large, however, better results will be obtained on the score of economy if thickeners such as the Dorr and suction filters of the continuous type are installed and as much water as possible is drawn from the lime sludge. By this means the water in the sludge may be reduced to 30 per cent, which will reduce the quantity of fuel required for burning to 600 lbs. of coal per ton of lime produced.

We have seen statements to the effect that lime sludge could be burned with about 500 lbs. of coal to 1 ton of lime. This figure is entirely too low and I do not know of any concern which is burning with this amount of fuel—600 to 700 lbs. of coal per ton of lime is nearer the correct figure.

Generally producer gas is used for burning lime sludge. Where available and cheap, however, natural gas or fuel oil would be superior fuels and would reduce the labor by one man per shift. Between 9,000 and 11,000 cu. ft. of natural gas (950 B.t.u. per cu. ft.) are required to burn a ton of alkali waste or from 60 to 80 gals. of oil.

The capacity of a rotary kiln burning alkali waste will vary largely with the condition of the waste when fed to the kiln as regards its water content. If properly installed, a 6 ft. in diameter kiln 100 ft. long will burn at least 30 tons of quick lime per day when working on a waste containing 45 per cent water. An 8 ft. x 125 ft. kiln on the same material will have a capacity of at least 75 tons of lime per day.

The cost of burning lime, including interest on the investment necessary and depreciation on the plant will vary between $2 and $3 per ton, depending on the quantity of waste to be recovered and the cost of fuel.

To operate the plant there will be required per shift one man to take care of the producer, one man to attend the kiln and if mechanical filters are installed from 1 to 2 men to look after these. If the slurry is pumped directly to the kiln, the first two men only are needed and indeed in very small plants one man alone may be trained to do the work with the occasional assistance of another man to place coal in the bunkers and wheel away the ashes from the producer.

The power required by the plant will amount to about 15 kilowatt-hours per ton of lime produced. That is a plant producing 25 tons of lime per day will require about 375 kilowatt-hours per day. The repairs will amount to about 15 cents per ton of lime produced and will consist chiefly of relining the lower third of the kiln about once a year and the lining of the producer about as often. Owing to the slowness with which the kiln revolves repairs and renewals to the carriers and driving gear are infrequent. The producer will require from 300 to 400 lbs. of steam at 60 lbs. pressure per ton of lime produced.

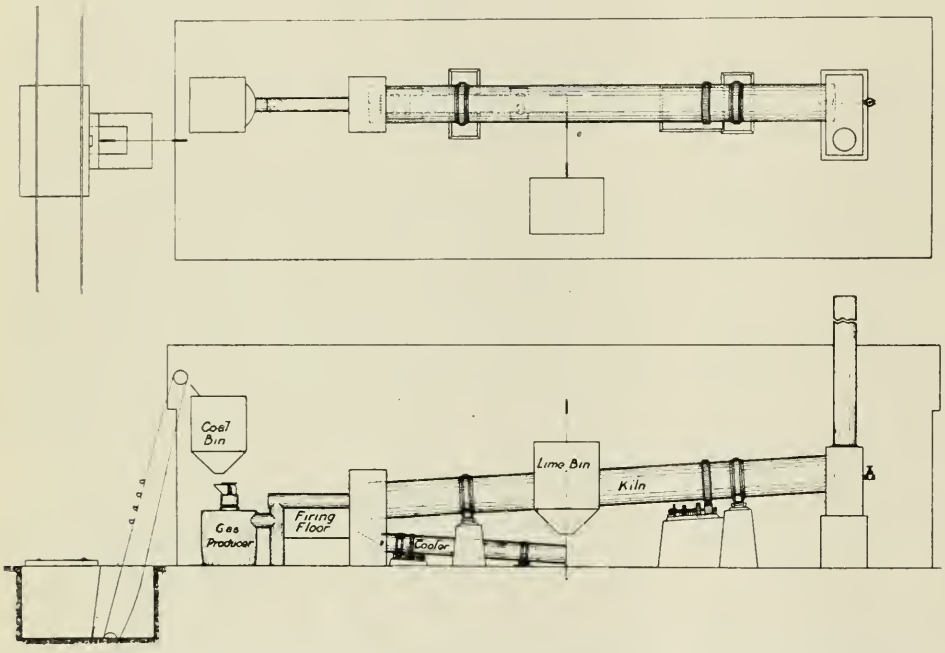

FIG. 1—PLANT FOR THE RECOVERY OF LIME FROM WASTE CARBONATE OF LIME AND LIME SLUDGE

Fig. 1 illustrates a small plant for the burning of lime sludge, which we have designed. In this plant the percentages of water in the waste is reduced to as low a percentage as will permit of the pumping of this latter. This is done by allowing the waste to settle in two large tanks (not shown in this drawing) provided with a movable syphon tube. The contents of one tank is allowed to settle while that of the other is being fed to the kiln. The sludge is allowed to settle 24 hours when the water is drained off. The slurry is then agitated by means of compressed air to remove the more solid portion at the bottom and to make it of uniform consistency, when it is pumped into the kiln by means of a small centrifugal pump. A valve controls the flow of slurry to the kiln and this valve is opened and closed by a mechanism which may be operated from the firing end of the kiln. The excess slurry goes back into the tank and serves to keep the contents of the latter agitated. The rotary kiln is of the ordinary type and if desired Z-bars may replace the fire brick in the upper end of the kiln.

The lime is obtained from the kiln in the form of small round nodules resembling very much a bird's egg in appearance and these are usually slightly colored from impurities in the lime. The lime drops from the kiln into a rotary cooler and is cooled by a current of air passing through the latter. This air is used for combustion and hence the lime in cooling serves to preheat the air.

The lime should be elevated from the cooler into a bin and it may be dumped from this into barrows and wheeled to the caustic soda plant or preferably the lime bin may be located in the caustic soda building and the material conveyed from the cooler to this by means of an elevator and screw conveyors.

The gas producer may be located at any convenient point, but should not be further away from the kiln than is absolutely necessary owing to radition losses. For a large kiln two 10-ft. gas producers may be necessary. In order to save labor the coal for the gas producer should be lifted by a bucket elevator into a steel bin above the producer and drawn from this bin to the latter as needed. This latter should be sufficiently large to hold twenty-four hours' run for the producer or if the plant is small at least a carload of coal.

The cost of a plant for the recovery of lime sludge will vary entirely with the size plant to be erected, fuel employed, class of construction used, etc. A small plant may be put up for about $12,000 to $15,000, which will have a capacity of about 10 tons of lime per day. A plant for 25 tons per day will cost about $17,000 to $20,000 and one for 40 tons of lime per day approximately $20,000 to $25,000. If oil or natural gas are to be used for a fuel the cost will be materially less, while the cost will be increased somewhat by the installation of continuous mechanical filters, etc.

Recovered lime consists of small, slightly oval lumps ranging in size from that of a walnut down to dust. The color is usually slightly yellowish or greenish. The lumps slake slightly slower than rock lime and consequenty causticise somewhat slower, but this is made up for by better settling of the precipitated carbonate of lime due to its coarse grain. The lime will pick up some slight impurities from the process and also from the kiln lining, so that it is not possible to burn the same lime over and over indefinitely. Instead of starting with a fresh lot of lime, therefore, it is the general practice to introduce a small quantity of fresh lime into the system at regular intervals. From 5 to 10 per cent is sufficient in most cases. The recovered lime, if burned at all skillfully, will contain fully as much caustic lime as the best lump lime made from limestone. The kiln used for recovering lime waste may also be used to burn lime from limestone provided this latter is crushed to pieces ½ in. and under.

Baltimore, Md.

The Arizona Copper Co. produced during January 1816 tons of copper, some of which was from an accumulation of partly treated material.

Solution Control in Ferric-Chloride Leaching of Sulphide Copper Ores

BY F. N. FLYNN AND ROGER H. HATCHETT

Smelter Superintendent and Smelter Metallurgist of Arizona Copper Co., Ltd.

Determination of Iron and Copper in Chloride Solution

When chalcocite is decomposed by ferric chloride as a solvent, the resulting solution may contain ferrous and ferric iron and cuprous and cupric copper, according to equations (1) and (2) representing theoretical reactions.

(1) $Cu_2S + 2FeCl_3 = 2FeCl_2 + 2CuCl + S$

(2) $Cu_2S + 4FeCl_3 = 4FeCl_2 + 2CuCl_2 + S$

It is apparent from these equations that a comprehensive laboratory investigation of the action of ferric chloride as a leaching agent for sulphide ores of copper, and the subsequent treatment of the resulting liquor, requires that the chemist be able at any stage of the operation to determine in what condition the iron and copper salts exist in the solution.

A scheme for estimating these quantities, and that served as a guide in conducting leaching experiments, was worked out in the laboratory of the Arizona Copper Company, Ltd., Clifton, Ariz. Experiments were not carried far enough to prove that the method gives exact or quantitative results. Details of procedure are given for anyone interested in this work who has no better scheme, and who may have time and apparatus to determine the limits in which the method is trustworthy.

Total Iron

To a measured quantity of the neutral solution to be tested add a little hydrochloric acid. Boil with test lead to precipitate copper and reduce iron. Filter and titrate the iron in the filtrate with a standard solution of potassium permanganate or potassium bichromate as desired, preparing the solution accordingly. This titration gives *total iron* in the solution.

Ferrous and Ferric Iron

To a second measured portion of the cold neutral solution add an excess (2 or 3 grams) of precipitated calcium carbonate and stir vigorously for two or three minutes. Ferrous iron remains in solution, but all the ferric iron is precipitated as ferric hydroxide thus:

$$2FeCl_3 + 3CaCO_3 + 3H_2O = 2Fe(OH)_3 + 3CaCl_2 + 3CO_2$$

Filter and thoroughly wash the precipitated ferric hydroxide. The precipitate and filtrate are separately prepared for titration by reducing the hydrochloric acid solution with test lead, and the iron contents determined by the method used for total iron. The sum of the two titrations giving ferric and ferrous iron should equal the total iron previously found.

The separation of ferric and ferrous iron by precipitation with calcium carbonate and filtering must be done without heating the test. If the neutral solution is made hot, a precipitate usually appears before calcium carbonate is added. And, further, more copper is precipitated from a hot than from a cold solution. The copper thrown out increases the bulk of precipitate and makes it more difficult to filter and wash.

Total Copper

Determine total copper by any reliable method. A rapid scheme is to measure a third portion of original solution and completely oxidize it with potassium chlorate and hydrochloric acid. Neutralize with sodium carbonate, acidify with acetic acid, add two or three grams of sodium phosphate to precipitate iron. Now add three or four grams of potassium iodide and titrate with a standard solution of sodium thiosulphate as in the ordinary titration for copper. This titration gives *total copper*.

Cupric and Cuprous Copper

A fourth measurement of sample is acidified with hydrochloric acid, three or four grams of potassium iodide added, diluted, and the total oxidizing power determined by titrating the liberated iodine with a standard solution of sodium thiosulphate (1 cc = 5 mg Cu, or 4.40 mg Fe). This titration measures the ferric iron and cupric copper together. From the burette reading, subtract the equivalent of ferric iron already determined, and calculate the difference as copper, which is copper present as *cupric chloride*.

Sometimes the end point is not permanent in the thiosulphate titration for iron and copper. To check the result another sample may be measured and the total reducing power determined by titrating in a sulphuric acid solution with a standard solution of potassium permanganate (1 cc = 10 mg Fe, or 11.37 mg Cu). This titration gives cuprous copper and ferrous iron together. The equivalent of ferrous iron already found is deducted from the burette reading and the difference calculated as copper, which is the copper present as *cuprous chloride*.

Known quantities of the purest salts obtainable were weighed and mixed in solution and the results of separating the iron are given in Table I.

TABLE I

Test No.	Milligrams Weighed in Mixture: Fe as $FeCl_3$	Fe as $FeCl_2$	Cu as $CuCl_2$	Cu as CuCl	Milligrams Iron Found by Calcium Carbonate Separation: Ferric in Precipitate	Ferrous in Filtrate

11	...	125	...	125	9	116
12	...	125	125	125	14	111

Notes.—When iron salts alone are dealt with, the separation with calcium carbonate can be completed so quickly that oxidation from working in the atmosphere is inappreciable. If either cuprous or cupric salts are added to a solution of iron salts, some copper is usually precipitated with the iron, and filtration becomes retarded, apparently caused by oxychlorides of copper forming. The addition of ammonium chloride helps to make filtration quicker.

Mixtures made of known weights of chlorides of iron and copper show that cupric or cuprous chloride accelerates the oxidation of ferrous to ferric chloride, and cuprous chloride reduces ferric to ferrous chloride. The extent to which such reactions go on in solution in either direction before stable equilibrium of the system is reached is governed in some degree by the relative quantities of these substances present. This, no doubt, explains why weighed quantities of these salts were not recovered in the same condition in which they were mixed.

Tropical Agriculture.—The *Proceedings of the Third International Congress of Tropical Agriculture*, held last June in London, have just been published in form of volume of over 400 pages (London: John Bale, Sons and Danielsson, 10s. net). It contains the abstracts of the more than 150 pages presented and reports of the discussions, together with the address of the president, Professor Wyndham R. Dunston.

Notes on the Reverberatory Furnace

BY FRANCIS R. PYNE

Refinery Superintendent U. S. Metals Refining Co.

The reverberatory furnace is an apparatus for smelting ores or melting and refining metals on a suitable hearth. The heat required for this operation is obtained from the combustion of fuel within the furnace proper, the fuel being in the form of oil, powered coal, or gas, the latter being generated in a regular gas producer, or by the incomplete combustion of coal in an adjacent firebox.

The area of the hearth depends upon the size and nature of the charge it is desired to handle, some furnaces carrying a deep bath of small area, others a shallow bath of large area.

The length of the furnace is limited only by the ability to obtain the desired temperature at the uptake end, the width is limited by practical difficulties in building roofs that will stay up. The height depends upon the size of the cold charge and upon having sufficient space for the combustion of the gases.

The character of the hearth, walls and roof is dependent upon the nature of the charge and the temperature desired. An acid charge requires an acid lining, a basic charge requires a basic lining. When the temperature is high very refractory material must be used; with a lower temperature we may use less refractory and consequently less expensive material.

The radiating surface of the reverberatory being large, the heat lost by radiation may reach a considerable figure. Therefore all precautions should be taken to keep this radiation loss as low as possible. A good high-grade refractory is generally a poor insulator and should be backed up by some material which is a good insulator at the temperature of the outside of the refractory. It must be borne in mind, however, that if a refractory is used at a temperature near its softening or melting point, free radiation must be permitted else the refractory will be destroyed rapidly, in some cases even water cooling may have to be resorted to, to preserve it. Many materials which are good insulators at low temperatures lose this property and become good conductors at more elevated temperatures.

The temperature attainable in a reverberatory depends upon the calorific intensity of the products of combustion. Insufficient air to burn the fuel or an insufficient mixing of air and gas keeps down the temperature regardless of the amount of fuel burned; an excess of air has the same effect by diluting the products of combustion, thus lowering the calorific intensity.

In many cases when burning coal in an adjacent firebox attempts are made to cause complete combustion in the firebox. This causes an exceedingly high temperature locally which rapidly decreases towards the flue end of the furnace. The result is an inefficient furnace and frequent burnings out of the firebox. The fire should be handled so as to produce a large volume of combustible gases which are then completely burned in the furnace by admitting the required air. The grate area is, properly speaking, not a function of the hearth area but of the volume of the furnace; a grate that will have a satisfactory area for one furnace will not give satisfaction if the roof of the same furnace is raised several feet.

It should be borne in mind that the largest part of the heating is by radiation from the hot gases and not by actual contact. In the very short space of time taken by the gases to pass through the furnace only a very small part is in actual contact with the charge while the whole volume of the flame is radiating heat to the hearth, walls and roof.

In order for a reverberatory to properly perform its functions, its hearth, walls and roof must be heated up to or above a certain critical temperature. This temperature depends entirely upon the nature of the material being treated, and unless this temperature is attained no results are forthcoming. In an ore smelting furnace a temperature of say 2100° F. is required. If the furnace is so designed or the grade of coal is such that the highest temperature attainable is but 2000° F., nothing will occur save maintaining a large body of ore at 2000° F., no matter how much fuel is burned. And as one fuel gives so many hundred degrees more temperature than another, so is the first worth much more than the second.

Where a reverberatory furnace is used for melting and refining, it performs two separate and distinct operations. During the melting down period it furnishes sufficient heat to melt the charge and to make up for the losses by radiation. During the refining period it merely takes care of the radiation losses. Now all of this heat must be supplied at a certain definite temperature, so that if a furnace has but one source of heat supply, namely, one firebox, one gas port, or one oil burner, it is readily seen that if the furnace gets just sufficient heat from this source for melting, it will receive an excess of heat when merely keeping the metal molten by making up for the radiation losses, and any decrease in the rate of combustion will cause a lowering of the temperature. This indicates the desirability of having a plurality of sources of heat supply so that the temperature may be held constant while the amount

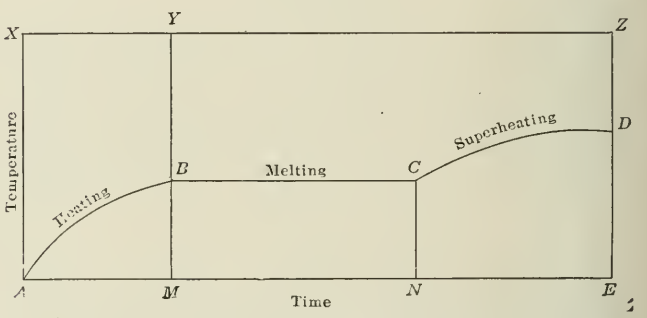

FIG. 1—THE TIME FACTOR IN REVERBERATORY SMELTING

of heat units is decreased to the desired point. This is not practicable with the coal fired furnaces, but can be applied to furnaces using oil, gas or pulverized coal.

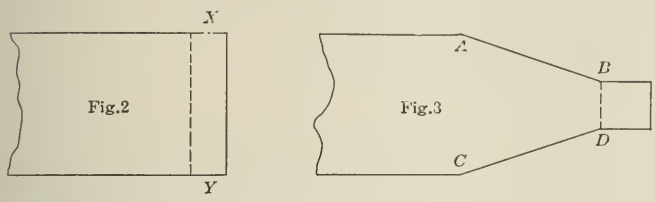
For rapidity of melting it is necessary that the furnace be designed to produce a temperature well above the melting point of the charge. The time factor may be illustrated by Fig. 1. Let XZ represent the furnace temperature. Now a charge of metal at temperature A will be gradually heated to the melting point B in time AM, at B the latent heat of fusion BC is absorbed during the time MN, at C the superheating begins and proceeds as per the line CD in time NO.

The amount of fuel burned is proportional to AO and if this can be decreased the result will be more available melting time for the furnaces. From A to B the heat absorption is rapid under the temperature head AX, but gradually decreasing as it approaches B where the head is only BY and at the point D it is still slower, the head being reduced to DZ. Now in order to reduce the time AO we must increase the temperature head AX, requiring a more rapid combustion of fuel. The attainable temperature is limited by the nature of the fuel and the material of the furnaces, but as long as the extra fuel consumption to increase AX plus the extra furnace repairs does not exceed the saving in time and labor, the furnace will be more economical when working at the higher temperature.

Many reverberatory furnaces do not work to satisfaction because proper attention is not given to the construction of the flue end. This results in the furnace being cold at this point, while the fire end may be over-heated.

If the flue end is square as at *X* and *Y* (Fig. 2), the metal will tend to chill in these corners, due to the great radiating surface presented. By making the end tapered as *AB*, *CD* (Fig. 3), this radiating surface is lessened and the metal kept hotter. The sides *AB* and *CD* should be well backed up with a good insulator to further decrease radiation. The amount of taper depends on the available space that can be given the furnace, but in all cases it is desirable to extend it as far as practicable without unduly reducing the capacity of the furnace.

There is another reason for the reduction in volume of the flue end. As the gases pass through the furnace they drop in temperature, thereby decreasing in volume.



FIGS. 2 AND 3—CONSTRUCTION OF FLUE END OF REVERBERATORY FURNACE

If the volume of the furnace remains constant for all sections, the velocity of the gases decreases as they become cooler. Heat is being continually lost by radiation, the velocity continues to decrease and in consequence the furnace begins to build up at the flue end as the metal cools. To prevent this more fuel must be burned, causing the furnace to become overheated at the fire end and increasing the fuel cost per ton of metal. An ideal furnace would have the combustion take place gradually throughout its length, thereby keeping all parts at the same temperature, but this ideal furnace does not yet exist in practice. Therefore, in order that the velocity may be kept sufficiently high to prevent this cooling the volume of the furnace must be reduced, and this is done by tapering the sides and lowering the roof.

That part of the roof which is lowered is called the hood and besides aiding to reduce the volume of the furnace and maintaining the velocity of the gases, it throws the heat down on the metal where it tends to be coolest, and this is an important point in keeping the flue end at the proper temperature. The height above the bath of the point where the hood joins the flue is a factor which varies under different conditions. A few inches one way or the other makes a great difference in the working of the furnace and can only be determined by experiment.

The question of draft enters largely into the working of a reverberatory furnace. Unless the draft is strong enough to give proper combustion the furnace will be run very uneconomically. Sufficient draft should be furnished so that there is always a good pull on the gases passing through the furnace, otherwise the furnace will not "clear" and give a good, sharp cutting flame which is the kind needed for melting.

With coal-fired furnaces forced draft is often used, but in such cases the forced draft should be carefully regulated and never permitted to reach such a degree that there is a pressure inside the furnace. When this condition exists flame may be seen coming through any crevices in the walls and roof, the furnace will not "clear" properly and the fuel consumption is increased.

If the furnace has waste heat boilers or other devices for utilizing waste heat, sufficient draft must be allowed for to take care of the increased resistance as the tubes become dust coated, a small amount of dust on the boiler tubes and flue having a marked effect upon the passage of the gas.

Chrome, N. J.

The Extraction of Carbolic Acid from Oils of the Distillation of Coal Tar

BY WILLIAM MASON

The method, used in many works for the extraction of carbolic acid, has been to treat the oils with a solution of caustic soda; in this way a sodium phenate solution is formed and separated from the oils. This sodium phenate is then decomposed by sulphuric acid. By this method, it is easily seen, the whole of the caustic soda and sulphuric acid are lost, which materials cost, at least 8d. (16 cents) to extract 1 gal. of carbolic acid.

The cheapest and best method is to treat the light oil with caustic soda solution of about 1110 sp. gr. whereby a sodium phenate is produced which may be separated from the light oil from which it has been extracted by subsidence. This sodium phenate solution is then treated with a current of carbonic-acid gas which forms sodium carbonate, and sets the carbolic acid free. The separated carbolic acid floats on the surface of the strong sodium carbonate solution which is drawn off from below the carbolic acid, and, being causticized with lime, is employed over again continuously.

The point, however, to be considered in this method is the production and purification of the carbonic acid. This gas may be produced in a coke furnace; but much care would have to be exercised in its construction and operation, since to obtain gases containing much carbonic acid would result in a higher temperature being obtained than the materials of the furnace would with-

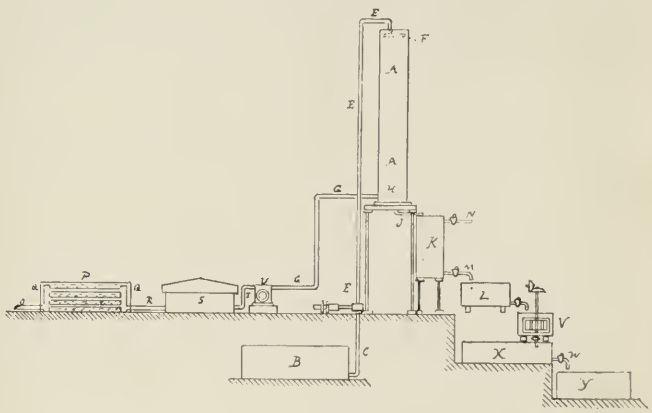


FIG. 1—THE EXTRACTION OF CARBOLIC ACID FROM OILS OF THE DISTILLATION OF COAL TAR

stand. With escaping gases containing only 6 per cent of carbonic acid, the initial temperature would be about 900 deg. C. These gases, too, would have to be purified and cooled.

Now, since tar and ammoniacal liquor are generally distilled in the same works, carbonic-acid gas may be obtained from the waste gases issuing from the sulphate of ammonia saturator. A typical gas liquor contains per 100 parts of liquor: 2.5 parts of NH_3 = 10 of $(NH_4)_2SO_4$; 0.5 of H_2S; 2.3 lb. of CO_2; or 10 lb. of sulphate of ammonia, 0.5 lb. H_2S; 2.3 lb. of CO_2, or 5.26 cu. ft. of H_2S and 18.7 cu. ft. of CO_2 (at 0 deg. C. and 760 mm) per 10 gal. Whence 1 ton of sulphate of ammonia would yield $5.26 \times 224 = 1180$ cu. ft. of H_2S and

18.70 × 224 would yield 4190 cu. ft. of CO_2, or a total quantity of 5370 cu. ft. of gas, and such a mixture would contain of CO_2 78 vol., and of H_2S 22 vol. per 100 vol. From these figures it is evident then, that in most works of this description there is much carbonic acid which might easily be utilized.

As the author has had practical experience with this method he will describe it by the accompanying drawing: *A* is a tower which is packed with stone, coke, or other similar materials, or provided with shelves of any suitable metal. *B* is a tank to which is supplied a solution of alkaline phenate, or cresylate obtained in the usual way. A pipe *C* connects the interior of the tank *B* to a pump *D* which is connected by means of a pipe *E* with perforations. The solution of alkaline phenate or cresylate is pumped from the tank *B* along the pipes *C* and *E* and escaping from the perforations formed in the pipes *F* flows slowly down the interior of the tower *A*. While flowing down the solution meets with the ascending carbonic-acid gas which is conducted to the base of the tower *A* by the pipe *G*, terminating within the base of the tower in pipe *H* provided with perforations through which the carbonic-acid gas escapes. The descending solution of sodium phenate or cresylate by being acted upon by the ascending carbonic acid gas is caused to become a mixture of sodium carbonate and carbolic acid. The mixed liquids on reaching the base of the tower *A* flow through the pipes *J* into a deep dividing or separating tank *K*, from which the sodium carbonate, as it separates from the carbolic acid, is run out by means of pipe *M*, fitted with a tap on the bottom of the tank, into a tank *L*, while the carbolic acid is run off by a pipe *N*, also fitted with a tap and near the top of the tank *K*. This carbolic acid is then made acid by sulphuric acid.

The carbonic acid used in this process is obtained from the waste gases in the manufacture of sulphate of ammonia from ammoniacal liquor which are conducted by means of a pipe *O* to a series of pipes *P* situated in a tank *Q* which contains water by which the pipes *P* are surrounded. Cold water is supplied to the tank *Q* in any suitable manner. By passing the waste gases formed in the manufacture of sulphate of ammonia from ammoniacal liquor through the pipes *P* nearly all the vapor of water and tarry matter are condensed and separated from the gases. The gases are then conducted from the pipes *P* by a pipe *R* to a purifier *S* which contains oxide of iron, similar to those used in the manufacture of coal gas and in this the sulphuretted hydrogen contained in the gases is extracted, and the remaining almost pure carbonic acid gas is conducted from the purifier by a pipe *T* to a pump *U* actuated in any suitable manner, by which the carbonic-acid gas is supplied through the pipe *G* to the perforated pipe *H* at the bottom of the tower *A*.

The above-mentioned sodium-carbonate solution is conducted into an agitator *V* of any suitable shape where it is causticised with lime, and after it has been so treated it is run therefrom by means of the pipe *W*, which is provided with a tap, into a settling tank *X*, in which the lime is separated. The solution is then run into the tank *Y* and contains from 2 to 3 per cent of caustic soda, and is of a suitable strength to treat a fresh quantity of tar oils. In this manner the process is made continuous.

This process has several advantages over the ordinary process for obtaining carbolic or cresylic acid in which sulphuric acid is employed: namely, no sulphuric is used; about 90 per cent of the caustic soda is recovered; also the liquor is utilized which in the ordinary process was difficult to dispose of, being a source of nuisance by polluting river streams and other waste courses.

Finally, there is one other matter which requires attention, and that is the condensed water from the coolers contains hydrogen sulphide in solution, which has to be dealt with before it leaves the works. In one works with which the author had experience it was allowed to run away into a sandy soil, and was thus got rid of. A much better method would be to dehydrate the gases as is done in the ammonia soda process, by placing a surface cooling coil between the still and the saturator at such an altitude that the condensed liquor could be syphoned back into the still, or the coil may be placed on the ground, and the condensed liquor collected in a closed vessel, may be pumped back into the still. In this way the gases issuing from the saturator would consist only of carbonic acid and hydrogen sulphide, and would, therefore, not require the large scrubbers and condensers usually employed for this purpose; besides, nearly the whole of the sulphur might be recovered in the purifier, and in works where carbonic acid is already being used, only inexpensive additions would be required, and the operations might be much quickened by using nearly pure carbonic acid.

Oxford, England.

The Non-Ferrous Metal Market

The trend of non-ferrous metal prices during April was distinctly upward. Copper was remarkably stronger and transactions were in fairly large quantities. Lead prices ranged higher early in the month, but fell off later owing to reduced export demand. Tin was the most erratic and fluctuated widely. Spelter continued at a high price in spite of a fairly large business.

Copper.—The market for this metal reached 16 cents on April 12, and ranged as high as 16.20@16.35. Domestic demand continued heavy, and as the statistical position is regarded as strong, prices are likely to range high.

Tin.—Since our last report the price for this metal has gone as high as 56@58 cents per pound, fluctuating widely on small transactions. Comparatively small business is being done. At last reports the market was unsteady at 55 cents.

Lead.—Exports of this metal continue to show an increase. The American Smelting & Refining Co. advanced the price to 4.20 cents, New York, on April 1, since which time it has remained at that point. St. Louis prices have been above the New York parity, owing to buying for export, but have again receded to 4.10@4.15 cents.

Spelter.—The unusual situation in this market continues, and prices are higher than a month ago. More buying has been done by domestic galvanizers. Spot metal continues to command a premium, while future deliveries are available at prices below the current quotations. About the middle of April New York spelter was quoted at 8.92½@9.67½ cents; St. St. Louis, 8.75@9.50.

Other Metals.—Aluminium has been quiet, with prices steady at 18¾@19 cents per pound. Business in antimony is quiet, owing to scarcity of supply. Prices range widely, according to brand, from 25 to 32 cents per pound. Quicksilver is unsettled. Prices have been as high as $67 per flask of 75 lb., New York, but about April 15 the metal was to be had at $62. San Francisco price was $64.50@$65.

A **welding flux** or compound patented by W. W. Hout, of Cortland, N. Y., contains boracic acid, iron or steel particles, furnace dross and calcined marble dust.

A Case for Copper Hydrometallurgy

Inexpensive and Efficient Treatment of Smelter Flue Dust and Carbonate Ore

BY GEORGE C. WESTBY

A small leaching plant of a Western copper smelter is an illustration of an adaptation of peculiar conditions to reduction of cost in the treatment of flue dust and incidentally of carbonate ores.

The flue dust which had been withdrawn from the flues in cleaning had weathered for a considerable period and contained much free sulphuric acid and soluble sulphates of copper and iron.

The former method of treatment had been to charge the flue dust into reverberatories and smelt it with the regular charges of calcined ore. There was a consequent cost for handling and serious loss through furnace draft and boiling due to the fine state of division of the material and the presence of sulphates, acid and moisture.

A former superintendent of the plant decided, in view of the composition of the flue dust, that a wet method of treatment might be devised that would be cheaper than charging the material to the furnaces, and he initiated the investigation of the problem.

The principal difficulty to be met consisted in the fact that the whole arrangement to be used in the treatment of the material must cost but little, since the quantity of flue dust available for treatment was limited and the current production hardly more than 5 tons per day. The other factors of the problem, such as the solubility of the copper, were all in our favor.

Results from Experimental Plant

To get a logical starting point and necessary data for estimates and design of plant, equipment having a capacity of about 1 ton in eight hours was put in operation. This plant consisted of a heap of flue dust, a few barrels filled with carbonate ore and fitted with filter bottoms, a flume 16 in. by 8 in. in cross section and 100 ft. long, a small Pachuca agitator, a settling launder and a series of barrels filled with iron. The plant was operated by means of a stream of water into which a laborer shoveled the flue dust as the water flowed through the launder. After agitation and settlement the solution passed successively through the carbonate ore and precipitation boxes.

The information gathered from a short trial of the experimental plant showed that the flue dust could be rapidly disposed of by a comparatively small plant, without material modification of the general arrangement tried on an experimental scale. The test established also the commercial feasibility of the scheme.

It was determined to be practicable, in view of the rapid sedimentation in the settling launder, to make the process continuous. This, however, would have necessitated the preparation of a much larger oxidized-ore yard, the inconvenience of night work and larger or longer precipitation boxes, all of which would not be warranted by the limiting conditions. Settling capacity would not have been difficult to secure as earthen settling ponds might be used.

Intermittent Process Adopted

An intermittent process was adopted and a plant designed to treat profitably about 25 tons of flue dust and carbonate ore per day. The design embraced about 400 ft. of 9-in. by 9-in. tarred wooden launder, about 500 ft. of 6-in. tarred paper conduit pipes, two earthen settling ponds or settling tanks, a heap of oxidized ore and 300 ft. of 3-ft. by 3-ft. precipitation boxes.

The wooden launder was to be so arranged that its upper lengths could be moved laterally toward the flue-dust piles as clearance was made by shoveling the material into the launder. The design called for the direct treatment of flue dust as drawn from the flue hoppers by placing the settlers sufficiently below the elevation of the hopper bottoms so that the contents of a hopper could be dropped into a launder and sluiced to the settlers. It was shown that in this manner a concentration of the insoluble values could be effected, the soluble salts and acid effectually removed and the concentrated residue easily sluiced where it could drain and later be easily handled.

The estimated cost of production per pound of copper from the flue dust was as follows:

	Cents per pound
Amortization	1.0
Iron for precipitation	2.0
Labor	0.5
Supervision, laboratory and repairs	0.5
Preliminary and experimental work	1.0
Freight, refining and selling	2.5
Total	7.5

The estimated cost of the plant was between $1000 and $1200.

The exigencies of practice suggested various changes of the general plan as laid out, but the only radical innovation consisted in dispensing with the shovelers and

FIG. 1—SLUICING FLUE DUST

simply sluicing the flue dust from the heaps directly into the launders or conveying pipes in imitation of placer work.

Hydraulic Sluicing of Flue Dust

A stream of water from a 2½-in. hose under 60-lb. pressure was directed through a nozzle to the flue-dust pile. The heap was rapidly disintegrated and washed into an earthen basin in which the heavier particles settled. The current carrying the flue dust then flowed through a short, broken, rocky channel to a 9-in. by 9-in. launder, the sections of which were arranged in steps in order to cause a cascading of the mixture and thorough agitation of the flue dust and water, and secondarily to break up cemented lumps of flue dust by the consequent impact. The launder was about 400 ft. long and emptied into the settlers which consisted of two Arizona tanks 28 ft. by 14 ft. by 10 ft. (substituted for the ponds first proposed). The soluble constituents of the flue dust were completely extracted before reaching the end of the launder. The Arizona tanks were usually filled in about three hours, and the sediment allowed to settle out of the solution over night.

In the morning the solution was pumped out of the tanks by means of adjustable air lifts and caused to flow into the carbonate-ore ponds. The solution was robbed of the greater part of its acid content as it gradually percolated through the ore pile to the asphalt floor beneath.

The plant was located close to a spur track, along which the carbonate-ore yard and the precipitation boxes were laid out.

Construction of Carbonate-Ore Ponds

The ore yard was formed by clearing a space of sloping ground about 80 ft. long by 70 ft. wide. The prepared ground was covered with a rough surface of broken brick, over which was spread a very argillaceous slime brought from concentrator. After drying a coat of Portland cement was brushed over the hardened clay. The yard was then completed by melting over it three coats of asphalt. The asphalting was extended almost to the top of the railroad embankment.

On this prepared floor was spread a 6-in. layer of ore, the irregular fragments of which averaged in their smallest dimension about 3 in. On this was piled about 1500 tons of ore, 9.4 per cent of which remained on a ½-in. mesh screen and 53.4 per cent passed through a ten-mesh screen. The ore was dropped over the embankment from self-dumping ore cars, distributed later by means of a steam crane and finished by a scraper to form a flat top surrounded by low walls, thus making a rough basin to retain the acid liquor charged on the ore from the settlers.

The drainage from the ore pile flowed into a small sump and this discharged into the precipitation boxes. The sump was set low enough so that any possible leak through the asphalt floor would flow along the ground through the interstices of the broken brick and finally discharge to the sump.

The carbonate ore was usually leached to a white residue in from five to six weeks. No channeling of any consequence took place, but the walls of the pile were acted on more slowly by the solutions and were usually left in place when the rest of the material was removed. A continuous percolation through the sides occurred, but this showed only in dry weather by the accumulation of crystals of cupric and ferric sulphates on the outer slopes of the walls.

On completion of the leaching and the subsequent washing, the residue was excavated by a steam crane, to the extent of its reach, and dropped on the other side of the railroad track. The remainder of the material was sluiced through gates built into the walls of the pile. The time required to clean the floor of the yard was ordinarily about twenty-four hours. To fill with fresh ore, level and prepare the top of the pile for a pond required from sixteen to twenty-four hours.

Precipitation of Copper from Solution

The strength of the solution draining from the ore pile changed slowly, but varied at different times between 0.5 per cent and 4 per cent, as the copper and acid tenor of the flue dust and wash solutions varied and the copper in the ore pile decreased. The copper in the discharged precipitated solutions remained constant at about 0.01 per cent. The discharge was controlled by leaving iron out of the precipitation launder or by increasing the quantity of iron introduced, and regulating the temperature of the solution by means of steam jets near the head boxes.

A single flume, 3 ft. by 3 ft. in cross section and 300 ft. long, was used for precipitation of copper. At intervals along the flume bulkheads were placed to maintain the solution at or near an average level of 33 in. above the bottom of the flume. The iron with which it was charged was dropped over the embankment of the railroad track from a small flatcar on which the iron had been collected from different parts of the smelter grounds.

An arrangement which saved much time by obviating the removal of the iron, consisted in the insertion of barrel staves spaced along a stringer, placed longitudinally from cross braces on the flume. A longitudinal space 7 in. wide was left along one side of the partition formed, in order to provide an opening for the shovels used in removing the precipitate. The iron was charged into the bellied side of the partition; and the precipitated copper, much of which was pulverulent, was gradually discharged through the interstices of the partition to the small compartment where it accumulated until the box was cleaned. It is obvious that this arrangement could be modified so that the precipitate could be removed from both sides of the flume; and that deflection wings, or the use of air or steam jets, or mechanical stirring would materially accelerate the precipitation of copper by inducing rapid circulation of the copper-bearing liquor through the iron.

General Results

Two men operated the plant. At set intervals during the eight-hour day they sluiced the flue dust into launders; made connections, repairs and extensions of the system; collected cement copper; supplied fresh scrap iron to the boxes where needed; and every second day

FIG. 2—SLUICING FLUE DUST

1—Tarred conduit pipe. 2—Washing flue dust out of broken brick and mortar. 3—Earthen dam.

washed and sluiced out sediment which had settled in the tanks.

The general results obtained may be fairly illustrated by data secured on one experimental batch consisting of 248 tons of flue dust and 250 tons of carbonate ore. The summary is as follows:

1	Total copper in material, pounds	19,073
2	Copper left in residue as sulphide, and soluble copper lost in sediment after washes, pounds	729
3	Copper lost in discharge from precipitation launders, pounds	200
4	Copper lost in leaks from pile, pounds	60
5	Copper lost in leaks in precipitation launders, pounds	78
6	Total copper recovered, pounds	18,006
7	Percentage recovery	94.4

Item 3 was higher than the general average loss at the discharge.

Item 4 was determined by difference, roughly checked by measurements.

Item 5 was deduced by weighing crystals scraped from the boxes and by measuring and estimating as closely as possible the tiny leaks which appeared from time to time.

Summed up the treatment described was a successful solution of a minor smelter problem, in which some of the beneficent elements of fortune were with us. Further than this, the plant lent encouragement and provided means to make experiments on the wet treatment of mill and smelter products and ores—systematic

experiments tried on a sufficiently large scale to provide really useful data applicable in future operations. Altogether the case is cited as one in which the theory and practice of copper hydrometallurgy worked together without dissention.

Ludwig, Nevada.

Industrial Motor Applications

Some Considerations Affecting the Choice of Motor and Auxiliary Equipment in the Metallurgical and Chemical Industries

BY H. B. BARNES

In undertaking the following analysis of some of the considerations entering into the broad field covered by the above title, it is not the intention of the writer to enter into the theoretical side of the problem, but rather to present in a non-technical way such information as will enable the mining or metallurgical engineer to analyze his problems; or to more intelligently review the analysis and conclusions of others as they affect his particular conditions. It is a fact that many of the technical men in charge of present day industries are men who secured their training years ago, and to whom much of the recent development of electrical machinery is unfamiliar. There is also the large class of the younger men, recent graduates of technical schools, who have not yet had an opportunity to gain through experience the familiarity with electrical equipment, and the practical considerations in connection with its use, that are necessary for its intelligent application. To such engineers it is hoped that this article may prove of interest and perhaps of value.

Choice of Systems

The average user of electric power is a consumer only, seldom a producer, and therefore the choice of the system to be used is usually made for him, as he has to use what his local power company will furnish. However, there are many cases, especially when local conditions compel the installation of an isolated plant, where the choice of the distribution system to be used must be carefully considered. Such a choice involves a study of the individual problem which can hardly be expected from one unfamiliar with the considerations involved, and it should properly be placed in the hands of a competent consulting engineer.

For reasons of efficiency, economy in transmission, etc., the use of polyphase alternating current has become well-nigh universal in this country, and practically all electric service companies supply energy in this form. The user's problem thus becomes the selection of alternating-current motors to meet his conditions, or of direct-current motors with proper characteristics, and of such transforming apparatus as may be necessary for converting the purchased energy from alternating into direct current.

In many installations made years ago, direct-current motors are still used in large numbers, but the later equipment and the equipment of nearly all new enterprises is almost invariably designed for alternating current, and for this reason the following article will deal only with alternating-current motors and their applications.

Motor Characteristics

The polyphase induction motor, either two or three-phase, has certain operating characteristics that are seldom clearly understood, either in their relation to the work to be performed or in their relation to each other, and yet it is only by a complete understanding of these characteristics that an intelligent selection can be made to meet certain predetermined conditions.

The familiar induction motor of the so-called "squirrel-cage" type is ideal in its simplicity of construction and operation due to its freedom from brushes, moving wires, and from all wearing parts except the bearings, which are usually made dust-proof and with automatic ring-oilers which require a minimum amount of attention. The construction of this apparently simple squirrel-cage rotor, as the revolving member is termed, has a vital bearing on the service to be rendered by the motor for the following reasons:

1—The starting torque of a squirrel-cage motor, for a given applied voltage is approximately inversely proportional to its rotor resistance.

2—The full-load running efficiency of the same motor is also an inverse function of its rotor resistance.

It is thus obvious that the construction required to produce maximum starting torque is the identical construction that produces the worst running characteristics, so that it becomes necessary to compromise or to eliminate these opposing tendencies. Assuming that a certain rotor resistance gives maximum running efficiency and the best regulation, approximately eight times this resistance is required to produce maximum starting torque in the same motor. This problem has given rise to several different forms of rotor construction. The familiar squirrel-cage rotor with low-resistance end rings is the standard construction for motors designed for starting under relatively light loads or where the load can be thrown on after the motor is up to speed, and this is the type of motor most generally used.

For intermittent operation where high starting torque is required and close speed regulation is not essential, such as in elevator work, the squirrel-cage motor with high-resistance rotor is frequently used on account of the simplicity of its control, and there are conditions, as for instance where long line-shafts have to be started, where slight increases are made in the rotor resistance, the purchaser being willing to sacrifice a few per cent in efficiency to obtain greater starting torque, on the score of greater simplicity and reliability in his motor equipment. This "high-resistance rotor" type of motor has been standardized by several manufacturers and under certain conditions has proved a very satisfactory machine.

For constant-speed work where high starting torque is required, several methods have been developed by different manufacturers for inserting the necessary resistance into the rotor circuits during the starting period, this resistance being short circuited or cut out when the motor is up to speed, thus giving the motor the ideal running characteristics. In every case such a motor is provided with a so-called "phase-wound" rotor, the distinction being made between the form-wound coils and polar arrangement used in this construction, and the straight bars and end rings used in the "squirrel-cage" type. One manufacturer provides a centrifugal device in the body of the rotor which automatically short circuits the rotor winding when the motor approaches full speed; another provides a hand-operated device for cutting out an internal resistance, up to certain motor sizes, while all manufacturers have standardized the so-called "slip-ring" type of motor in which the terminals of the rotor winding are brought to collector rings on the shaft, through which rings any resistance combination desired may be introduced into the rotor circuits by means of external resistors and switching devices.

The so-called "synchronous" motor, which normally operates at all times in exact synchronism with the generator supplying its energy, has a relatively limited application. It is essentially a light-load starting machine, but under certain conditions is extremely val-

uable on account of the corrective characteristics which it exercises on the line and equipment used in conjunction with it. These characteristics are of an extremely technical nature, and as they are of interest chiefly to the company supplying the power, they need hardly be considered here.

There are also several commutator-type motors, both single-phase and polyphase, which have been recently put on the market, which have operating characteristics approximating those of direct-current motors. They have not come into very general use except in the smaller sizes and have only a limited application.

Character of Service

In most commercial power applications the motor service naturally falls into one of the following classes:

1—Constant speed, light starting loads.
2—Constant speed, heavy starting loads.
3—Intermittent service.
4—Variable speed.

The choice of motors for operation in any of these classes depends not only on the service to be rendered and the operating characteristics of the motor, but also on the source of power supply. Obviously a power system having several thousand kilowatts of generating capacity behind it is better able to absorb the disturbances incident to the starting of heavy loads than one of only a few hundred. Therefore the operator of a relatively small isolated plant must consider very carefully the size and type of motors he proposes to install, while the purchaser of power from a large system has few if any such restrictions.

Here again the choice between individual motors and group-drive often influences the decision, as the ability to start loads consisting of large groups of machines may often permit substantial economies through concentration of motive power into larger units.

The operation of rolls, crushers, tube-mills, concentrators and accessory equipment as used in modern milling plants is a specific instance of group-drive practice which may justify a brief digression and more detailed analysis. The ideal arrangement is to so group the machines that operate together, that they may be driven by one motor, or at least may be simultaneously controlled. Recent practice favors individual drive for certain machines, notably tube-mills. This has been directly influenced by the developments in the design and commercial production of the "herring-bone" gear which has made possible gear ratios for such work that were impractical heretofore, and have made possible the direct-geared connection of standard moderate speed motors. Individual drive is not, however, to be universally recommended as an analysis of the operating characteristics of such machines will show.

No matter what the mechanical equipment of a mill may comprise, the motor equipment must be proportioned so that it can successfully start any individual part of the plant under the most unfavorable conditions that may arise in service. As a typical case may be taken a crushing or sampling plant consisting of Blake or Dodge type of crusher, one or more sets of rolls, and auxiliaries. Such a plant should properly be driven by one motor, a conclusion that is almost obvious, as a moment's consideration of the requirements of the individual machines will show. The crusher, for instance, may require only 15 to 25 H. P. to run it, but may easily require 50 to 60 H.P. to start and accelerate it. Likewise the rolls which may ordinarily use 10 to 30 H.P., may, if slightly choked, take two or three times this amount to start. Under such conditions the ability to concentrate the motive power of the entire group upon the one refractory unit is of the greatest advantage, and is usually to be encouraged. When the total capacity of a plant is large and is made up of a number of similar units, as in some of the large reduction plants now running, the trend towards individual drive has been very marked, but it is not to be carried to extremes.

In small plants good practice seldom allows the installation of an individual motor of a size greater than 20 per cent of the generator capacity. Thus in an installation having a generator capacity of 250 H.P. a motor larger than 50 H.P. might be expected to cause objectionable disturbances all over the system due to the heavy currents required by such a motor during starting and acceleration, particularly if the motor is of the squirrel-cage type.

A squirrel-cage motor of almost any standard make may be expected to exert a starting torque of about two and one-half times its rated full-load running torque if full line voltage is applied at the motor terminals. Under these conditions, however, it may draw from the line a momentary current from seven to nine times its normal full-load requirements. As the resulting start under such conditions is so abrupt as to be objectionable and the sudden draft of current is frequently so great as to cause disturbances elsewhere on the system, it is customary, except on motors of 5 H.P. or less, to provide a "compensator" or other starting device which reduces the voltage applied to the motor during the starting period. As the starting torque of an induction motor is proportional to the square of the applied voltage, it can be shown that with a motor having a maximum torque at full voltage of 250 per cent of its normal running torque, such a motor will exert a starting torque of 100 per cent of its rating with 63 per cent of normal voltage applied at its terminals. Under this condition the momentary starting current will be limited to from two to two and one-half times the normal full-load requirement of the motor, an amount which is seldom objectionable on any well-designed distribution system.

The starting characteristics of a motor with a "phase-wound" rotor are very different. The performance curve of a typical motor of this type shows that with full-line voltage applied at the motor terminals it will exert a torque equal to 150 per cent of its rating, with a current requirement of only 150 per cent of its normal full-load amperage. The same motor will exert a maximum torque of 200 per cent to 250 per cent of its rating with a maximum current requirement of not over two and one-half times normal. Thus it will be seen that such a motor can start its rated load with vastly less disturbance to the system than can the squirrel-cage type, and also that it can develop a maximum torque condition with hardly more current than is required by the squirrel-cage type to produce normal torque.

For constant-speed work, therefore, the user must consider the size and the nature of the load and particularly the starting conditions, and also the ability of his supply system to absorb the disturbances caused by starting loads, before he can intelligently determine the type of motor to be used for each specific installation.

Intermittent service has two general classes: (1) such as elevator service where the load factor is extremely low and where the load conditions are fairly constant, and where speed variation is not required, and (2) hoist service where the work may be fairly continuous but varying constantly both as to direction and as to loads handled. Accurate speed-control is also essential and the motor may frequently be called upon to operate at reduced speed for considerable periods.

There is also an additional class of intermittent serv-

ice covering automatically controlled pumps for mine or other service.

The "high-resistance rotor" type of squirrel-cage motor, as stated above, has obtained a wide application in elevator service on account of the extreme simplicity of its control, a simple reversing switch being all that is required. A solenoid-operated mechanical brake is usually used with it, connected in series with the motor, the initial rush of current at starting being unusually effective in securing a prompt release of the brake. This type of motor also possesses electrical braking characteristics which prevent overspeeding in lowering, which will be considered more in detail later.

For hoist service the "phase-wound rotor" with slip rings is used exclusively except in the very largest hoists, where various complex systems involving the use of heavy flywheels and other devices for equalizing the load have been found commercially practicable. The three-phase "slip-ring" motor with either hand- or master-control meets fully all the requirements of the most difficult hoisting problems and such motors up to 750 H.P. are in successful every-day operation. In the smaller sizes, say up to 150 H.P., hand-control is the rule, reversing controllers with from five to as high as fifteen speeds being standard apparatus. Such equipments make possible an accuracy of control that is not approached by any but the largest steam hoists, and there is an assurance as to results from handling such a controller that the operator of a steam throttle never gets.

Another valuable characteristic of the polyphase motor for this work is the resistance offered by the motor, when connected to the line, to any tendency to overspeed it, as mentioned above. In operating a single-drum hoist, or a double-drum when unbalanced, substantial savings can be made by lowering with the motor connected to the line; both through recovery of power by the motor acting as a generator, and also by the reduction of wear on the hoist brakes, as the motor will hold the speed constant while lowering and the brakes need be used only to do the final slowing down and stopping.

For the operation of either centrifugal or plunger pumps, especially where automatic or remote control is to be used, the slip-ring motor will be found especially valuable. Automatic control usually involves the acceleration not only of the pump and its motor, but also of a column of water under conditions where any sudden shocks might be disastrous; and under these conditions the slow and uniform acceleration possible with this type of motor is most desirable. The writer was one of the first to recommend and to install phase-wound motors for this class of service, nearly ten years ago, since which time many important installations have been similarly equipped; although it is well known that for high-speed service, where bypassing or other hand-control is possible, the squirrel-cage motor may be preferable under certain conditions.

Variable Speed

The polyphase induction motor is essentially a constant-speed machine. While certain types having phase-wound rotors may be operated at reduced speeds and give very satisfactory service under such conditions, yet their efficiency at reduced speeds and under load conditions requiring constant torque, such as air-compressor or hoist operation, is so low as to make them commercially impracticable. This is due to the fact that the energy dissipated as heat in the resistance, which must be inserted into the rotor circuits to obtain reduced speeds, represents a large part of the total energy supplied to the motor; and as the mechanical output of the motor at reduced speeds is also lowered while the electrical input remains practically constant for a given torque, obviously the overall efficiency of the combination is low. Under certain conditions of load, as for instance mine-fan operation, where the torque required decreases with a decrease in speed, this type of motor will show a decreased power consumption at reduced speed; but it is still so inefficient that it is seldom if ever used alone for such service. In the large sizes the energy otherwise dissipated in the resistors is sometimes recovered and returned to the line through so-called "regulating sets," but as these auxiliaries are large and expensive in proportion to the economies effected they are not commercially practicable, except as before stated in the larger sizes, say 300 H.P. and above.

Single and polyphase motors of the "repulsion" type have been developed in the smaller sizes which give fair speed-control and regulation over a limited range and with good efficiency. Such a motor has a commutator and brushes, the speed variations being obtained by shifting of the brush holder, or by means of external controlling devices. Due to the construction, complex as compared with the squirrel-cage motor, they are almost invariably heavier and more expensive than the constant-speed types, so that where variable speed is required it is usually cheaper and more satisfactory to obtain it by some mechanical means.

Multi-speed motors. As distinguished from variable-speed motors there is an established type of induction motor which has two, or in some cases three fixed operating speeds at any one of which it will develop its full rated torque, although of course with output reduced in proportion to the speed. In the case of the two-speed motor these are usually full and half speed, which speed change is obtained by means of a simple double-throw switch which changes the number of poles for which the primary winding is connected. Other speed changes and ratios are obtainable in the same way, but the complication involved is so great that this method is seldom used. The two-speed motor with 2:1 ratio, however, is a regularly listed standard motor and is frequently used where half-speed and full torque is desired, as in air-compressor operation.

Other methods of speed control, by the use of two or more motors in various combinations, are possible, but these are special problems.

Converting Apparatus

Although most power requirements can be met by the direct application of alternating-current motors, there are many applications of electric power which compel the use of apparatus for converting alternating into direct current; as, for instance, electrolytic work or the operation of direct-current motors for railway or other variable-speed purposes. In such a case the choice lies usually between motor-generator sets and rotary converters, with a limited use of the mercury arc or other types of so-called "rectifiers."

The motor-generator set, as its name implies, consists of an alternating-current motor driving a direct-current generator, which may, of course, be either belted or direct coupled if both machines have approximately like speeds. Such a combination possesses infinite flexibility, as obviously the motor and the generator may each be designed for the conditions as they exist; for instance, a 10,000-volt motor may be used to drive a low-voltage direct-current generator, while a rotary converter operates with an approximately fixed ratio between the a.c. and d.c. voltages. The motor-generator set has, however, certain disadvantages, among which are larger size and first cost and lower efficiency due to the double conversion of energy from electricity into mechanical power and back again.

The rotary converter, rotary transformer, or synchronous condenser as it is variously called, may be said to consist of a synchronous motor and a direct-current generator in one and the same piece of apparatus. It has a stationary field frame and a revolving armature having a commutator on one end as in an ordinary direct-current generator, and on the other end collector-rings and brushes as in an ordinary synchronous motor of the revolving-armature type. In this machine the alternating current is introduced into the armature winding through the collector rings and is commutated or rectified into a uni-directional or direct current by the revolving commutator, thus being converted without passing through the transformations involved in the motor-generator set. For this reason the overall efficiency of the rotary converter is usually higher than that of the motor-generator set, and due to its more compact construction its cost may be kept low. It has the disadvantage, however, of involving synchronous operation which is seldom clearly understood by the average operator, and also the disadvantage of having a fixed ratio between the voltage of the alternating current supplied, and the voltage of the direct current furnished by it. This ratio approximates 1 to 0.7, with slight variations according to the method of connection used. In the case of a converter delivering 250 volts direct current it would have to be supplied with alternating current at approximately 175 volts. Obviously to furnish a low alternating voltage from a transmission system carrying say 10,000 volts would require additional static transformers for this purpose, and it is the cost of this and other auxiliary equipment that frequently results in the use of the motor-generator set in preference.

Various methods have been introduced to vary the delivered voltage of a rotary converter, the customary ones being to vary the applied a.c. voltage by means of switches or induction regulators; or the use of the so-called "booster" converter, which consists of an additional winding on the converter armature which is influenced by a second or auxiliary field winding. Either of these methods is effective over a limited commercial range, but neither approximates the flexibility of the motor-generator combination.

Starting and Protective Apparatus

Intelligent selection of motor equipment should in every case be accompanied by similar attention to the starting and protective apparatus with which motors are supplied, as too often this essential detail is neglected, with the result that the motor operation is unsatisfactory when in reality the motor itself is in no way at fault. Instances almost without number might be cited to illustrate this point, but one or two selected from personal experience will be fairly representative.

In a mine-pumping installation consisting of plunger pumps driven by slip-ring motors, float-controlled automatic starting apparatus was specified, which was to have the period of acceleration adjustable up to one minute. Through an error, "current limit" control only was furnished, which in this case brought the motors up to speed in three or four seconds. This rapid acceleration was in no way injurious to the motor but had disastrous effects elsewhere, as the water pressure resulting from the inertia of the column of water in the discharge line was so great that one valve-body and two flanged connections were burst during the enforced operation of this equipment. Upon the substitution of a starting device having a fixed time element no further trouble was experienced, as the period of acceleration was lengthened to nearly fifteen seconds and the column of water was put in motion with hardly any perceptible rise in pressure.

In another instance some delicate and complex apparatus which was ideal in its theory was installed in a sampling mill, in a location where it was impossible to entirely protect it from the omnipresent sulphide dust. The result was that within less than a week the equipment was absolutely inoperative, and it was eventually replaced with other apparatus which was both cheaper and better able to stand up under the severe service conditions imposed.

Three-phase squirrel-cage motor starters may be classed under types as "star-delta," "resistance," and "compensator;" and under methods of operation as "hand-operated," "master-control," and "automatic." Each type can, of course, be operated by any method, so it is obvious that there are abundant alternatives to choose from.

The "star-delta" starter is one of the simplest forms and takes its name from the two ways in which the motor coils can be grouped. When the phase circuits of a motor designed for delta-connected operation are connected in star, the resulting combination would require 173 per cent of normal voltage to secure normal operating conditions. As the normal available voltage is only 57 per cent of this amount, the application of this voltage to the star combination is equivalent to a 43 per cent reduction of voltage applied to the delta combination which is the normal operating combination for which the motor was designed. This potential, as was shown when discussing motor starting characteristics, is sufficient to secure satisfactory starting under certain conditions. As it offers, however, only one starting torque, which may be greater or less than is desired in any specific case, it lacks the flexibility of the other systems. It also has the disadvantage of requiring six wires between the motor and the starting switch instead of the three required by other systems.

The "resistance" method of starting consists of merely inserting an ohmic or non-inductive resistance into the primary circuit, which results in lowering the voltage applied to the motor during the starting period. This is a highly inefficient method of starting, as the line current remains very high, the difference between the line voltage and that applied at the motor terminals being absorbed by the resistance, and the energy represented by it being dissipated in the form of heat. The resistance starter has the one advantage of being cheap in the small sizes, and it has secured a limited recognition for this reason.

The "compensator" method of starting is the one most generally used with squirrel-cage motors, and is standardized in various forms by practically every motor builder. It consists of a case containing either two or three auto-transformer or compensating coils, and a switching device by which a reduced potential obtained from the transformer coils may be applied to the motor terminals during the starting period. When the motor has attained full speed a second operation of the device disconnects the transformer coils and connects the motor directly to the line. By arranging for various taps or connections to the coils the starting voltage obtained from them may be conveniently changed to suit the requirements of the individual motor with which the compensator is used.

Starters for phase-wound motors have, of course, but one type, that of varying the rotor resistance. Motors having this resistance carried inside the rotor (the so-called "internal-resistance" type) are of value chiefly for obtaining easy acceleration with a minimum amount of line disturbance, their ability to start heavy loads being limited by the ability of the resistors to dissipate the heat generated during the starting period. A 15 to 30-second period of acceleration for normal load is the rating of one of the standard motors of this type

now on the market, but if either the load or the time factor is likely to be materially exceeded the purchaser should consider the use of the slip-ring motor with external resistors and switching device or controller, as it is usually termed.

Regarding methods of control, regardless of motor types, certain considerations should always be kept in mind. The familiar types of hand-operated starters are too well known to need comment here, but the introduction of large motors has brought with it a condition that has resulted in the development of "master-control" for two reasons: (1) The necessity for means to limit the rate of acceleration, and to prevent motor abuse, and (2) the necessity for means of controlling motors, the starting equipment of which is too large for manual operation, or which may be located at a distance from the operator.

The control developed to meet the first of these was largely due to the introduction of electrical equipment into industrial fields where the operators were either unable or unwilling to use discretion in handling it. Briefly, it consists of automatic switching devices which control the motor in all its functions exactly as its designer intended; the operator in charge having no control over it except to determine when it is to start and stop, and in some cases the direction of its rotation. The operator handles only the master-controller or "master-switch," as it is sometimes called, the controller proper consisting of a panel with the necessary electrically actuated switches and automatic relays on it, which may be located near the motor, or if desired, in a more protected place. The relays referred to prevent too rapid acceleration, and this style of control equipment as a whole has resulted in a remarkable decrease in the maintenance cost of the motors, as the brains of an expert are substituted for those of the average operator who may be and often is entirely ignorant of the equipment placed in his charge.

The second reason cited is also an outcome of the same conditions, as the increasingly large size of motors now frequently installed require starting and control apparatus of a size that is entirely too large to be handled manually, and these motors are also, as a rule, placed some distance from the operator. Another condition frequently arising is the simultaneous control of two or more motors by one operator. This condition is best typified by the "multiple-unit" control developed for railway motor cars, where the motors on all the cars of a train are controlled simultaneously from one point, or as in certain manufacturing establishments where a group of motors in a department are sometimes controlled from one location.

From master-control to automatic-control is only a short step, the substitution of the automatically-operated master or pilot switch for the hand-operated being merely a detail. There are, however, two general types of automatic-control which are seldom clearly understood, viz.: current-limit control and time-element control, and a brief consideration of these may be in order.

Current-limit control, as its name implies, consists of switches and relays so designed as to limit the current passing to a certain predetermined maximum. In itself this is an excellent thing, but it can easily be seen that it involves acceleration at all times at a current rate equal to the maximum that may be required by the motor at full-load full-speed conditions, as it is obvious that unless the relays are so adjusted there may occur conditions of starting load which the motor could not accelerate with less than full-load current, and, of course, the control equipment cannot be expected to differentiate between a light and a heavy starting load condition. This state of affairs may, and usually does, result in light-load starting at an objectionably rapid rate of acceleration, simply because the control equipment must of necessity be left so adjusted that it can take care of the occasional heavy-load starting conditions that may occur. Under such conditions the introduction of a time element into the control system is most desirable, as it can be made to assure an almost uniform starting performance regardless of load conditions.

Assume for instance a 50-h.p. motor driving a crusher, which, when the crusher is empty, has merely to accelerate itself and the crusher flywheels. When the crusher is more or less choked the motor will have to exert additional starting torque, depending upon the amount of choking, up to perhaps two or three times its normal full-load running torque. In such a case the starting equipment would have a time element of say forty seconds, cutting out the starting resistance in steps at fixed intervals regardless of the resulting current conditions. Under such conditions if the crusher were only slightly choked the motor would start it on say the second or third point of the control, and if the crusher were badly choked it might not start until the fourth or fifth of the six or eight steps provided. Overload protection would be required only in case it was impossible to start the crusher, and the resulting motor overloads were to continue for a considerable length of time. Under such conditions an overload circuit breaker having a time element incorporated in it should be installed, which would permit the brief overloads, such as starting peaks, to exist, but which would open instantly in case of dangerous overloads or in case of light overloads continuing for a considerable length of time. Such circuit breakers are standard commercial articles.

Protective Apparatus

In the matter of protective apparatus for alternating-current motors there is not a great deal to be said, the choice between circuit breakers and fuses being usually a matter of local conditions and personal preference. There are, however, two details which are not always given the consideration that they merit, namely, protection in case of interruption of current supply, and protection against single-phase operation in the case of polyphase motors.

The result of applying full voltage to a circuit to which one or more induction motors may be connected is, of course, equivalent to closing switches at the motors themselves. Under this condition, as stated before, the motor, unless provided with automatic starting equipment, will take from seven to nine times its normal full-load running current, which, while it may not injure the motor, will result in an extremely sudden start unless, as is usually the case, the fuse or other protective apparatus acts and disconnects the motor from the line. While the effect on the motor of such treatment may not be injurious, and while the trouble and expense of replacing the protective equipment may be bearable, yet it is easy to see that if all the motors on a system were operated in this way the enormous momentary current necessary to operate all the overload protective devices on the system under such conditions would be so great that no available generating capacity could supply it, and it would be impossible to again get full voltage on the line. For this reason every motor should be supplied with some form of device that will automatically disconnect it from the line in case of an interruption to the energy supply. The majority of motor starters for squirrel-cage motors have this function incorporated in their design, and for phase-wound motor operation there are available automatic switches or circuit breakers which have this "no voltage release" attachment.

When one phase of a polyphase motor circuit is opened while the motor is in operation the motor will continue to run without apparent distress unless heavily loaded. It will, however, have its entire load concentrated on the one phase winding left in service, and this will in most cases constitute an overload on this part of the winding which, if allowed to continue, will eventually burn out and destroy the winding. It is important, therefore, that protective apparatus should be employed which, in the event of the opening of any one phase, will entirely disconnect the motor from the line, thus preventing single-phase operation and consequent damage. Unfortunately this fact is not fully appreciated, with the result that fuses are still largely employed, which of course can, and frequently do, burn out in one phase from some momentary overload condition, leaving the motor to run single-phase until it burns out, or the fact is discovered through its refusal to start subsequently. A three-phase motor running on single-phase emits a characteristic hum or buzz which is entirely different from the sound heard under normal operation, and any engineer or operative in charge of any such motors should familiarize himself with it, as much trouble may often be avoided thereby.

While much of the foregoing may seem elementary to those well acquainted with modern motor equipment and practice, yet it has been the writer's experience that much of it is unfamiliar to many engineers skilled in other lines, and it is hoped that to some of these it may prove of interest and possibly of value.

Denver, Colo.

Melting Points of Chemical Elements and Other Standard Temperatures

The following tables are reproduced from Circular No. 35 (second edition) of the United States Bureau of Standards as they should prove exceedingly handy for use.

The values of the melting points used by the Bureau of Standards as standard temperatures for the calibration of thermometers and pyrometers are indicated in capitals. The other values have been assigned after a careful survey of all the available data.

As nearly as may be, all values, in particular the standard points, have been reduced to a common scale, the thermodynamic scale. For high temperatures, and for use with optical pyrometers, this scale is satisfied very exactly by taking $c_2 = 14{,}500$ in the formula for Wien's law connecting I, monochromatic luminous intensity of wave length λ, and T, absolute temperature: $\log I/I_1 = c_2\lambda \log e(1/T_1 - 1/T)$. For all purposes, except the most accurate investigations, the thermodynamic scale is identical with any of the gas scales.

At high temperatures some of the values are quite uncertain; thus, while the melting point of platinum may be considered accurately known to 5 deg. C., that of tungsten is uncertain by 100 deg. C. or more. Temperatures centigrade are rounded off, and the exact Fahrenheit equivalents are usually given.

The Arizona Copper Co. produced 1600 tons of copper during the month of February, 1915.

The German Kali Syndicate production of potash in 1914 was valued at about $37,128,000. This was a decrease in comparison with 1913 when the value was $45,696,000. But for the war it is estimated that the value for 1914 would have been about $49,980,000.

The importation of chemicals, drugs and dyes into the United States has average $7,700,000 per month during the last five years. In August, 1914, the total fell to $5,622,000 and in September to $5,519,000; but in November the amount had increased to nearly $8,000,000. Imports of sodium cyanide last July amounted to 134,000 pounds. This fell to 84,000 pounds in August, but rose to 2,182,000 pounds in November.

The Formation and Decomposition of Sulphates During Roasting

BY BOYD DUDLEY, JR.

(*Concluded from page* 226)

II. The Effect of Reaction Velocity

The velocity of a reaction occurring between the phases of an heterogeneous system is largely dependent upon the extent and the nature of the separating surface between the reacting phases. It also depends upon other circumstances of a secondary nature, such as the diffusion capacities of the liquid or gaseous reactants, and the velocity of stirring. Furthermore, it is highly probable that at every boundary between two phases equilibrium is established at a practically infinite velocity, as compared with the rates of diffusion.[8] These principles have been tested by various investigations of reaction velocity between solid and liquid phases, and have been found to hold good. While experimental proofs are lacking, there appear no good reasons why the velocities of reactions between solid and gas phases at high temperatures should not be governed by like considerations. Assuming such to be the case and applying these principles to the question of the rate of sulphate formation and decomposition, the following conceptions may be advanced.

Assume a mixture of a metal sulphate, which decomposes directly into oxide, and the corresponding oxide to be placed in a heated space containing a definite partial pressure of sulphur trioxide. The gas film in immediate contact with the solids will at all times contain sulphur trioxide to the amount corresponding to the dissociation tension of the sulphate at the prevailing temperature.

Whether the sulphate is decomposed or the oxide is sulphatized is determined by whether the dissociation tension of the sulphate is greater than or less than the partial pressure of the sulphur trioxide in the gas outside of the contact film. The rate at which the sulphate is decomposed or the oxide sulphatized depends upon the rate at which the sulphur trioxide diffuses through the contact film from the sulphate to the gas outside the film in the former case, or upon its rate of diffusion from the gas to the surface of the oxide in the latter. In either event diffusion is the controlling factor; conditions that accelerate it will increase the reaction velocity, and conditions that retard it will retard the reaction.

The rate of diffusion in any case depends mainly upon three factors, which are, the diffusion co-efficient of the gas, which in general shows rapid increase with increasing temperature, the difference between the dissociation tension of the sulphate and the partial pressure of sulphur trioxide in the gas, and the thickness of the contact film surrounding the solids.

From these facts it appears that, other things being equal, the rate at which a sulphate will be formed or decomposed will increase with increasing temperature, with increasing difference between the dissociation tension of the sulphate and the partial pressure of sulphur trioxide in the gas phase, and with increasing rate of stirring. The effect of stirring is to reduce the thickness of the contact gas film between the solid and the gas phases. It is, of course, understood that the direction of the reaction is determined by the partial pressure of the sulphur trioxide in the gas phase as compared with the dissociation tension of the sulphate at the prevailing temperature.

While the above conceptions probably represent the main features of the question of reaction velocity under the conditions being discussed, in any attempt to apply them to the study of reactions in the roasting furnace the following facts, which have been emphasized before but which are of sufficient importance to be repeated, must be borne clearly in mind. Usually in the roasting furnace an ore bed several inches in depth is treated, and, therefore, the conditions existing in the interstices of the bed at any given point are usually quite different from those existing at the surface of the bed. Consequently it is possible to have particles of a given sulphate undergoing rapid dissociation at a point on the surface of the bed of ore, while at some depth the rate of dissociation of this compound may be insignificant. In fact, due to high sulphur trioxide concentrations in the interstices of the ore bed resulting perhaps from the decomposition of a sulphate that has a high dissociation tension at the prevailing temperature, the oxide of a metal may undergo sulphatization in the deeper portions of the bed at the same time that its sulphate is being decomposed at the top of the bed.

An interesting example of the effect of the difference between the dissociation tension of the sulphate and the partial pressure of sulphur trioxide in the furnace gas upon the rate of dissociation of a sulphate is furnished by following at constant temperature the process of the complete decomposition of a sulphate that produces first a basic sulphate and then the metal oxide. As was mentioned in a preceding paragraph, basic sulphates resulting from the decomposition of the normal compounds

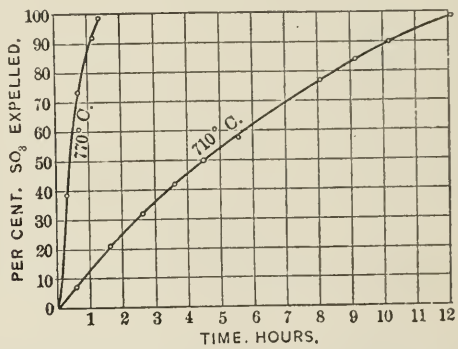

FIG. 5—VELOCITY OF DECOMPOSITION IN A CURRENT OF AIR OF Ni_1SO_4 AT 710 DEG. AND 770 DEG. C.

have in general at given temperatures lower dissociation tensions than have the sulphates from which they are produced.

Heating a thin layer of a sulphate that dissociates directly to oxide at constant temperature in a current of dry air should, in view of the arguments that have been advanced, produce a nearly constant rate of decomposition. The rate will, of course, decrease somewhat as complete decomposition is approached, due to the obstruction of the process of diffusion by the oxide produced.

On the other hand, if a sulphate that dissociates first into a basic compound is heated under similar conditions, the rate of decomposition will remain practically constant only until complete conversion of the normal sulphate into the basic compound has occurred. The basic sulphate, having at the prevailing temperature a lower dissociation tension than the normal compound, will maintain a lesser difference between the sulphur trioxide concentration of the contact film and that of the gas as a whole than did the normal sulphate. Other conditions remaining the same as before, a new and slower rate of diffusion of the sulphur trioxide from the sulphate to the gas will be established, and the rate of decomposition of the compound will be correspondingly reduced. Or rather the changed conditions will establish the rate of decomposition of the basic sulphate at a

[8] Nernst, Theoretical Chemistry, Translation of 6th Ger. Ed., p. 584

lower figure than that of the normal sulphate. These points are nicely illustrated by two typical curves from the experiments of Hofman and Wanjukow.[9]

Fig. 5 shows the rates of decomposition of 0.3 g. of crystalline nickel sulphate at 710 deg. and at 770 deg., after the crystalline salt had been dehydrated. In this case no basic sulphates are produced, the curves being smooth and nearly straight. Fig. 6 shows the rate of decomposition of a like amount of cadmium sulphate at 960 deg. A marked change in the rate of decomposition is observed when about 80 per cent of the sulphur trioxide has been evolved, which indicates the formation of a basic sulphate containing one-fifth as much sulphur trioxide as the normal sulphate. The formula of the basic compound may, therefore, be written $5CdO \cdot SO_3$. By other and independent methods the composition of the salt was determined and found to correspond to this formula. It is evident that by following the rate of decomposition of a sulphate in the manner described it is possible, by this procedure alone, to detect the formation of basic sulphates and to establish the composition of the compounds formed.

In the discussion of the factors that regulate the velocity with which sulphates are formed or decomposed, to simplify matters, only the process of the diffusion of sulphur trioxide from the surface of the sul-

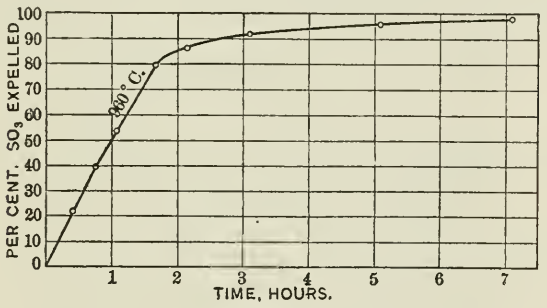

FIG. 6—VELOCITY OF DECOMPOSITION IN A CURRENT OF DRY AIR OF $CdSO_4$ AT 960 DEG. C.

phate undergoing decomposition or to the surface of the oxide undergoing sulphatization was considered. As a matter of fact the dissociation of the sulphur trioxide plays a most important part with reference to the velocity of such reactions.

To illustrate, consider the dissociation of a metal sulphate at constant temperature and under constant conditions of air current, thickness of the layer of sulphate, etc. In most cases the temperature is such that the sulphur trioxide evolved from the sulphate tends to dissociate according to the reaction.

$$2SO_3 = 2SO_2 + O_2.$$

As may be seen from the equation, this dissociation is accompanied by an increase in the gas volume. Accordingly, the process of sulphur trioxide dissociation will assist diffusion in the removal of sulphur trioxide from the film in contact with the sulphate. Likewise the dissociation of sulphur trioxide within the interstices of the bed of material being treated will accelerate the removal of the compound from these spaces.

It follows that the rate of dissociation of a sulphate depends not only upon the factors affecting the diffusion rate of sulphur trioxide, but also upon the rate and the completeness of the dissociation of this compound. By accelerating the rate of dissociation of the sulphur trioxide evolved from a metal sulphate and by increasing the completeness of this dissociation the rate of dissociation of the sulphate should be correspondingly increased. The degree to which sulphur trioxide will dissociate depends mainly upon the temperature, while the rate at which this compound dissociates and comes to equilibrium with its dissociation products is mainly determined by the presence or absence of efficient catalysts.

It has been already explained that contact with such substances as platinized asbestos and similar materials will greatly accelerate the reaction between the sulphur oxides and oxygen, and that certain metal oxides as ferric oxide will exert a similar influence but to a lesser degree. These facts lead naturally to the conclusion that the rate of sulphate decomposition in the roasting furnace will, other things being equal, depend to some degree upon the presence in, or absence from, the roasting ore of catalysts, ferric oxide being probably the most important material in this respect that is of common occurrence under such conditions.

The above remarks may be extended to cover the process of sulphate formation, when the conditions assumed are such as might result in the formation of a sulphate through the oxidation of sulphur dioxide and the union of the sulphur trioxide thus formed with the metal oxide. Inasmuch as this process is simply the reverse of the one that has been discussed above, it is considered unnecessary to describe it in detail.

This theory concerning the influence of admixed materials upon the rate of decomposition of sulphates has been tested by the writer in the following manner.

Aluminium sulphate (nearly anhydrous) contained in a porcelain boat was heated at constant temperature in an electric tube furnace, a current of dry air being meanwhile passed through the tube. The rate of decomposition of the sulphate was determined by removing the boat from the furnace at intervals of one-half hour and weighing. Then at the same temperature a mixture of the sulphate with ferric oxide was treated in a similar manner. As will be shown by the following detailed account of the experiments, the rate of decomposition of the sulphate was in all cases accelerated by mixing it with iron oxide. Analysis of the gases escaping from the furnace tube showed that the acceleration of the sulphate decomposition is attributable to the catalytic effect of the ferric oxide upon the dissociation of sulphur trioxide.

Aluminium sulphate was selected not because of its importance in a metallurgical sense, but because it forms no basic sulphate, and because at the temperatures involved there seemed little likelihood of complications arising due to the direct union of alumina with the ferric oxide. It was desired to show that the action of the ferric oxide in accelerating the dissociation of sulphates does not necessarily depend, as has been stated,[10] upon its union with the metal oxide to form ferrite. It may, and usually does, function simply as a catalyst. Therefore, a sulphate was chosen the oxide of which has not been observed to unite with ferric oxide at the ordinary temperatures of roasting.

Kahlbaum's crystalline aluminium sulphate (Grade I) was partly dehydrated by heating in a porcelain dish over a gas flame. The caked material from this operation was pulverized and subjected to further dehydration in the electric tube furnace. The heating was conducted at a temperature of about 350 deg. Owing to insufficient time being given to this operation the material was not completely dehydrated, the analysis showing

Al_2O_3 ..... 28.41 per cent
SO_3 ..... 66.50 per cent
H_2O ..... 5.09 per cent (by difference).

The presence of this quantity of water was not detrimental, it being expelled during the first few minutes of heating at the temperatures employed in the experiments. The loss in weight during the first half-hour

[9] Loc. Cit.

period of the heating was, therefore, water and sulphur trioxide, the amount of sulphur trioxide being obtained by subtracting 5.09 per cent of the weight of sulphate taken from the total loss in weight.

The ferric oxide was prepared by first dehydrating and then calcining in a muffle furnace Kahlbaum's crystallized ferric nitrate (Grade 1). This material was not analyzed, but was tested by ignition in an open crucible, showing neither loss nor gain in weight.

The arrangement of the apparatus is shown in Fig. 7. In the preliminary experiments the exit end of the furnace tube was left open, but later, when it was desired to determine sulphur dioxide in the gas, the arrangement was as the figure shows.

In the first tests 0.5 g. of the prepared sulphate contained in a porcelain boat was heated in the furnace in a current of dry air at 800 deg. At the end of each

half hour the boat was removed from the furnace and weighed. The loss in weight during the first period was sulphur trioxide and water; during the subsequent periods the losses were sulphur trioxide only. During the periods when the boat was not in the furnace, i. e., during the cooling preparatory to weighing and during weighing, the boat was handled carefully in order not to disturb or stir its contents. Owing to the fact that the depth of the sulphate powder in the boat amounted to about 2 mm., either thorough stirring between each heat or no stirring at all should be employed, if consistent results are expected. A mixture of 0.5 g. of the prepared aluminium sulphate with 0.2 g. of the prepared ferric oxide was subjected to the same treatment. The results obtained are shown in Table VIII.

TABLE VIII—LOSSES OF SULPHUR TRIOXIDE SUSTAINED BY 0.5 G. OF ALUMINIUM SULPHATE WHEN HEATED ALONE AT 800°, AND WHEN HEATED WITH FERRIC OXIDE

ALUMINIUM SULPHATE ALONE		ALUMINIUM SULPHATE+FERRIC OXIDE

169	379	255	564
129	508	214	778
100	608	175	953

The results thus obtained indicate clearly that the rate of dissociation of the sulphate is greater when it is heated with the ferric oxide than when it is heated alone. Close microscopic examination of the mixture at the end of these heatings failed to show any indications of the formation of a compound between the ferric oxide and the other constituents of the mixture.

A second series of tests were performed wherein 0.5 g. of the prepared aluminium sulphate was heated for two and one-half hours at 735 deg. The boat was removed from the furnace at the end of each half hour and weighed. Then, after carefully but thoroughly stirring the sulphate, the boat and its contents were returned to the furnace. After heating in this manner for two and one-half hours or five half-hour periods, 0.2 g. of the ferric oxide was mixed with the material in the boat, and the mixture was subjected to further heating at the same temperature. The results are given in Table IX.

In this case it is seen that the addition of the ferric oxide practically doubled the rate of dissociation of the sulphate. The change in the velocity of decomposition after the addition of the ferric oxide is strikingly shown by plotting to scale the data of Table IX. This has been done in Fig. 8.

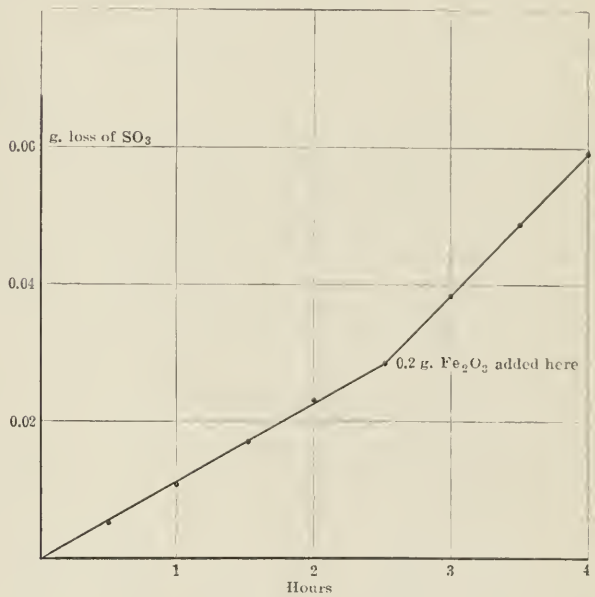

FIG. 8—RATE OF DECOMPOSITION OF $Al_2(SO_4)_3$ (0.5 G.) HEATED IN CURRENT OF DRY AIR AT 735 DEG., FIRST ALONE AND THEN WITH 0.2 G. OF FE_2O_3

In order to establish the fact that the increase in the velocity of dissociation in the presence of ferric oxide is due to the catalytic effect of this compound upon the dissociation of the sulphur trioxide, a third series of tests was made, in which the ratio of sulphur trioxide to sulphur dioxide in the gas evolved from the sulphate was determined. In order for such a determination to be of value it is necessary to catch the gaseous dissociation products of the sulphate at a point near the surface of the decomposing compound, and to convey them out of the heated space as rapidly as possible. Otherwise the slow passage of the gas through the

[10] Mostowitsch, Metallurgie, VIII, 771, 1911.

silica furnace tube is quite likely to produce an alteration in its composition due to reaction between the sulphur oxides and oxygen.

Accordingly, in this series of experiments the air was introduced into the furnace tube as usual, but was removed, together with the gaseous dissociation products of the sulphate, through a silica tube of 1 mm. internal diameter, which was inserted into the furnace tube in the position shown in Fig. 7. From the small silica tube the gas passed through an absorption tube containing a known amount of standard iodine solution, which absorbs surphur dioxide according to the equation

$$SO_2 + I_2 + 2H_2O = H_2SO_4 + 2HI.$$

At the end of the heating period the iodine solution was washed from the absorption tube into a beaker, and the excess or unconsumed iodine was determined by titration with a standard sodium thiosulphate solution, using starch as the indicator.

In this manner the amount of sulphur dioxide in the dissociation products of the sulphate was determined. The total amount of sulphur trioxide evolved from the sulphate during the same period was given by the loss in weight sustained by the boat and its contents. The sulphur trioxide remaining undecomposed in the gas is found by calculating the amount of sulphur trioxide equivalent to the amount of sulphur dioxide found, and then subtracting this quantity from the total amount of sulphur trioxide evolved from the sulphate.

One gram of the prepared aluminium sulphate contained in a porcelain boat was heated in the tube furnace at 800°, the gas being removed and analyzed as above described. At half-hour intervals the boat was removed from the furnace and weighed. The sulphate was then stirred, and the boat was returned to the furnace. The results are given in Table X.

Table X—Rate of Dissociation and Analysis of Gas Evolved, when Aluminium Sulphate (1.0 G.) was Heated in Current of Air at 800°

Total Time of Heating	SO_3 Loss in 0.5 Hour	Cumulative SO_3 Loss	SO_2 Found in Gas	SO_3 Equiv. to SO_2	SO_3 in Gas	Vol. Ratio SO_3 to SO_2
0.5 hr.	0.0484 g.	0.0484 g.	0.0040 g.	0.0050 g.	0.0434 g.	8.7
1.0	435	919	32	40	395	9.9
1.5	432	1351	30	38	394	11
2.0	466	1817	23	29	437	15
2.5	542	2359	47	59	483	8.1
3.0	475	2834	35	44	431	9.9
3.5	415	3249	27	34	381	11
4.0	420	3669	28	35	385	11
4.5	415	4086	26	33	382	12
					Average=	11

The volume ratios of sulphur trioxide to sulphur dioxide in the last column are calculated from the weights of the gases by dividing the gas weights by the molecular weights of the respective gases. Thus,

$$\frac{\text{Volume } SO_3}{\text{Volume } SO_2} = \frac{\text{Weight } SO_3/80}{\text{Weight } SO_2/64} = \frac{\text{Weight } SO_3}{\text{Weight } SO_2} \times 0.8$$

While the ratios of sulphur trioxide to sulphur dioxide as determined during this experiment are not in close agreement, they indicate with all necessary accuracy the conditions existing within the furnace tube at a point close to the decomposing sulphate. In fact, considering the probable error of the determinations of such small amounts of sulphur dioxide, such variations in the ratio are to be expected. The average ratio of eleven volumes of sulphur trioxide to one of sulphur dioxide indicates only a slight dissociation of the sulphur trioxide. Hence the rate of dissociation of the sulphate was in this case mainly dependent upon the rate of diffusion of the sulphur trioxide from the surface of the solid.

A similar test was made at 800° under the same conditions as the preceding, only in this case 1.0 g. of the prepared aluminium sulphate was mixed with 0.2 g. of the ferric oxide. The results are given in Table XI.

Table XI—Rate of Dissociation and Analysis of the Gas Evolved, when 1.0 G. of Aluminium Sulphate was Heated with 0.2 G. of Ferric Oxide at 800°

Total Time of Heating	SO_3 Loss in 0.5 Hour	Cumulative SO_3 Loss	SO_2 Found in Gas	SO_3 Equiv. to SO_3	SO_3 in Gas	Vol. Ratio SO_3 to SO_2
0.5 hr.	0.0841 g.	0.0841 g.	0.0410 g.	0.0513 g.	0.0328 g.	0.64
1.0	858	1699	379	474	384	0.81
1.5	997	2696	449	561	436	0.78
2.0	1015	3711	481	601	414	0.69
2.5	690	4401	331	414	276	0.67
3.0	620	5021	295	369	251	0.68
3.5	475	5496	226	283	192	0.68
4.0	235	5731	109	136	99	0.73
4.5	150	5881	70	88	62	0.71
					Average=	0.71

In this case, as in the preliminary experiments, the rate of dissociation of the sulphate was accelerated by the addition of ferric oxide. The average ratio of sulphur trioxide to sulphur dioxide was found to be 0.71 volumes of the former to 1 of the latter, which indicates much more complete dissociation of the sulphur trioxide than occurred when the aluminium sulphate was heated alone.

A third test was made by heating 1.0 g. of the prepared aluminium sulphate with 0.1 g. of platinized asbestos, containing about 0.025 g. of metallic platinum. The heatings were conducted for 0.5 hr. at 800° in the manner described above. The reason for trying the platinized asbestos was not on account of the possibility of any application it might have to practice, but simply to show that other catalysts will produce effects similar to that of the ferric oxide. Results are given in Table XII.

Table XII—Rate of Dissociation and Analysis of the Gas Evolved, when 1.0 G. of Aluminium Sulphate was Heated with 0.1 G. of Platinized Asbestos at 800°

Total Time of Heating	SO_3 Loss in 0.5 Hour	Cumulative SO_3 Loss	SO_2 Found in Gas	SO_3 Equiv. to SO_2	SO_3 in Gas	Vol. Ratio SO_3 to SO_2
0.5 hr.	0.1006 g.	0.1006 g.	0.0501 g.	0.0626 g.	0.0380 g.	0.61
1.0	940	1946	439	594	391	0.71
1.5	895	2841	384	480	415	0.86
					Average=	0.73

It will be observed that the rate of dissociation of the sulphate is accelerated by the presence of the finely divided platinum, the results from this test being practically the same as those obtained when the sulphate was mixed with ferric oxide. However, it should be noted that the amounts of platinum and of ferric oxide were by no means the same, the quantity of platinum required to produce a given effect being much less than of ferric oxide.

In order to show in graphical form the influence of the catalysts upon the dissociation rate of aluminium sulphate, the data of Tables X, XI and XII have been plotted to scale in Fig. 9.

It is interesting to compare the ratio of sulphur trioxide to sulphur dioxide found in these experiments with that to be found in the equilibrium mixture resulting from the dissociation of sulphur trioxide at atmospheric pressure. In the interstices of the layer of sulphate grains the sulphur trioxide tends to dissociate into sulphur dioxide and oxygen. Hence a comparison of the ratio of these two gases found experimentally with the theoretical ratio will indicate how nearly the conditions in the interstices approached the equilibrium conditions. From Table IV or Fig. 2 it is seen that at atmospheric pressure and 800° (the temperature of the experiments) sulphur trioxide alone will dissociate until its ratio to sulphur dioxide is only 0.433 to 1. From this it may be seen that the ratio of 11 to 1, obtained

when the aluminium sulphate was heated alone, indicates conditions far removed from the equilibrium; while the ratios 0.71 and 0.73 to 1, obtained in the presence of catalysts, indicate conditions near to the equilibrium.

Experiments along this line could be continued indefinitely, using other sulphates and other catalysts, but since the data so secured cannot be applied to roasting on a large scale in a quantitative manner, it is considered sufficient to have established the point in question. The results apparently leave little doubt as to the fact that ferric oxide and other catalysts will accelerate the rate of dissociation of sulphates by catalyzing the dissociation of the sulphur trioxide and thus removing it from the film of gas in contact with the sulphate at a greater rate than it would be removed by diffusion

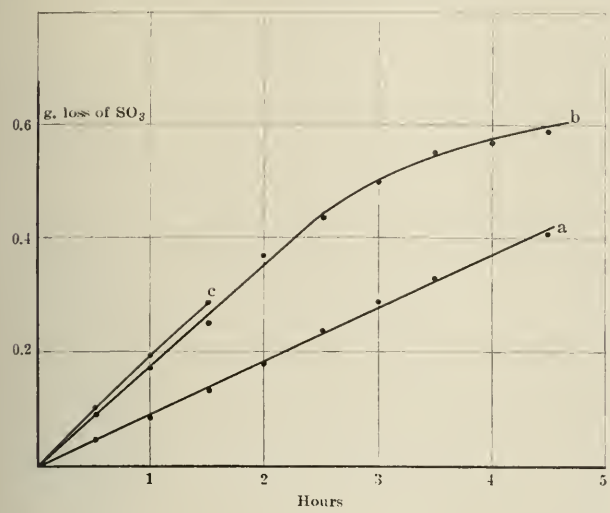

FIG. 9—RATES OF DECOMPOSITION OF $Al_2(SO_4)_3$ (1.0 G.) HEATED IN CURRENT OF DRY AIR AT 800 DEG.

a—sulphate alone; b—1 g. of sulphate with 0.2 g. of Fe_2O_3; c—1 g. of sulphate with platinized asbestos containing 0.025 g. of Pt.

alone. Ferric oxide has been considered and discussed in particular because of its very general occurrence in materials that are subjected to roasting, and because it is known to be one of the most efficient catalysts, with the exception, of course, of finely divided platinum and similar metals. However, cupric oxide is also known to be effective as a catalyst and deserves mention in this connection. Such substances as silica, alumina and probably lime are comparatively poor catalysts.

With the aid of all of the foregoing facts and conceptions it should be possible to trace what may be called the life history of a sulphate or of a number of sulphates in the roasting furnace. While, owing to the complexity of conditions and reactions within the furnace, nothing better than general statements can be made, the picture thus produced may be of some value in making clear the principles that govern the reactions.

As it is frequently conducted the process of roasting is a slow one, the cold, granular material being introduced into the furnace and having its temperature gradually raised by being advanced from the cooler to the hotter portions. In certain processes of blast roasting this procedure is not followed, and consequently this discussion does not necessarily apply to these cases. As the temperature of the ore is increased the water is expelled, and the sulphides are ignited, the ignition temperature varying with different sulphides and depending to some extent upon the grain size.

Of the sulphides commonly present in the furnace pyrite is probably ignited at as low a temperature as any. Hence at comparatively early stages of the roast the oxidation of pyrite is started, with the production of sulphur dioxide and ferric oxide or the magnetic iron oxide. In the interstices of the ore bed sulphur dioxide is produced by the partial union of the oxygen with the sulphides, and here the conditions are favorable to the production of sulphur trioxide. The temperature is comparatively low; sulphur dioxide and oxygen are mixed together in the presence of iron oxide and other catalysts; the formation of sulphur trioxide is a natural consequence of these conditions. At the low temperature prevailing the dissociation tension of ferric sulphate may be less than the partial pressure of sulphur trioxide that has been produced, and a part of the ferric oxide is sulphatized.

Then the reactions occurring in the ore bed are disturbed by the passage of a rabble, which exposes at the surface of the bed many grains that have hitherto been underneath and buries others that have been on the surface. Also the material, as a whole, is advanced toward regions of higher temperature. As a result of the stirring the ferric sulphate that has been brought to the surface, being exposed to direct contact with the furnace gas, may begin to dissociate. Similarly the iron oxide that has been formed at the surface of the ore bed, upon being buried and placed in an atmosphere comparatively rich in sulphur trioxide, may become sulphatized.

With rising temperature other sulphides are ignited, producing metal oxides and sulphur dioxide, from which the corresponding sulphates may result by processes similar to that of the formation of ferric sulphate. In these processes ferric oxide doubtless plays an important part in catalyzing the reaction by which sulphur trioxide is produced.

It has been previously noted that the dissociation tension of ferric sulphate increases more rapidly with temperature than is the case with the other sulphates. Therefore, while the ferric sulphate is readily formed during the earlier stages of the roast, the advancement of the ore to regions of higher temperature will rapidly increase the dissociation tension of this compound The sulphur trioxide tension thus maintained in the interstices of the ore bed will aid in the sulphatization of other oxides.

The action of ferric sulphate in sulphatizing other oxides by its own dissociation is, of course, not peculiar to this compound alone. Other sulphates in their turn will dissociate and assist in the formation of still other compounds of lower dissociation tension.

When mixtures of several oxides are present in the ore bed at one time, the order of sulphate formation will in general be the reverse of the order of magnitude of the dissociation tensions of the corresponding sulphates at the prevailing temperatures, i.e., the sulphate of lowest dissociation tension will form first. However, it cannot be said that the order of sulphate formation in the roasting furnace is strictly in accord with this principle, because to have sulphates formed there must first be oxides, and the ignition temperatures of the sulphides determine to some extent the temperatures at which the various oxides will appear.

An oxide that may combine with sulphur trioxide to form a basic sulphate as well as the normal sulphate will first be converted into the basic compound, which in turn may be converted into the normal compound. This is true because the basic sulphate has in general the lower dissociation tension of the two.

In considering the question of sulphate formation in the roasting furnace the important part played by catalysts, notably ferric oxide, must be remembered. These substances accelerate at low temperatures the oxidation of sulphur dioxide and thus aid in establishing relatively high concentrations of sulphur trioxide within the interstices of the ore bed. It is here, if

anywhere, that favorable sulphatizing conditions are to be found; the surface of the ore bed, being in direct contact with the furnace gases, is not a region in which the formation of sulphates is to be expected, under the ordinary conditions of roasting.

It is not to be inferred from the foregoing that there is a definite order in which the metal sulphates make their appearance in the roasting furnace and that each sulphate must be formed and then decomposed before the next of the series is produced. Nothing could be further from the truth than this idea. Sulphates may begin to form in roasting as soon as their corresponding oxides are produced, provided sulphur dioxide and oxygen are present to produce by their combination the necessary sulphur trioxide. The condition necessary for sulphate formation is that the dissociation tension of the sulphate be less than the existing partial pressure of sulphur trioxide.

This condition is most likely to occur in the deeper portions of the ore bed.

The reverse of this condition will produce the dissociation of the sulphate, and conditions tending to produce dissociation are to be expected at the upper surface of the ore bed.

Bearing in mind the fact that the ore is generally stirred to a greater or less extent, it should be evident that at no time can a single oxide monopolize all of the sulphur trioxide in any part of the furnace, and, therefore, that many sulphates may be formed and decomposed at the same time. This statement includes no consideration of the rate of formation and decomposition of the various sulphates; that is quite another matter and has been discussed at some length in a previous paragraph.

As the ore is advanced in the furnace and its temperature is increased the dissociation tensions of the various sulphates that have been formed increase, and their tendency toward dissociation increases accordingly. The rates of dissociation, when the sulphates are brought to the surface of the ore bed by rabbling, are thus accelerated; and, in addition to this, increasing temperature tends to reduce the partial pressure of sulphur trioxide maintained within the interstices of the ore bed by shifting the equilibrium of the sulphur dioxide, oxygen and sulphur trioxide system. Thus the partial pressure of sulphur trioxide in these spaces may be reduced below the dissociation tensions of many of the sulphates, and at elevated temperatures even in the deeper portions of the ore bed sulphates may undergo decomposition at a fair rate. At this stage the presence of the iron oxide and other catalysts is of great assistance in aiding the dissociation of sulphur trioxide, thus accelerating the dissociation of the sulphates. Therefore, at high temperatures ferric oxide is of assistance in the dissociation of the same sulphates that are formed by its aid at lower temperatures. Since, as has been already pointed out, the basic sulphates have in general lower dissociation tensions than their corresponding normal compounds, the former will persist at higher temperatures and for a greater time than the latter.

Finally for the complete elimination of sulphur it may in some cases be necessary to produce reactions between various gangue constituents and the remaining sulphates or basic sulphates. By this means the sulphur trioxide is liberated and such compounds as silicates and ferrites are formed, with or without complete fusion of the roasted material.

Correction: In the first part of this article, published in the April issue, on page 222, in the seventh line of the first column the word absorption should read adsorption.

Flotation in Gold Metallurgy*

BY W. B. BLYTH

The application of flotation to the concentration of gold ores is only a question of time. Already plants have been erected in this connection, and operated (so it is said) successfully.

In the first place, being a concentration process, it is of value only where the valuable constituents of the ore are in the mineral, or when some refractory mineral is present in an otherwise free-milling ore, and it is desired to remove that mineral subsequent to cyanidation. In this latter connection the flotation process seems to have an extended field of usefulness in the preliminary concentration of cupriferous gold ores. These have been a bugbear to metallurgists for many years—not because the copper interferes with the dissolution of the gold, but because it consumes so much cyanide during the process. A very small percentage of chalcopyrite will render the treatment of a low-grade gold ore unprofitable under existing conditions. The flotation process will remove the copper in the form of a marketable concentrate, and will do it cleanly and at small cost. The remaining pulp will be in a fit state to undergo ordinary cyanide treatment.

It is doubtful if it will ever pay to float mineral from an ore that yields its gold readily in an all-sliming process. It must be remembered in this case that the mineral that is slimed in a circulating cyanide solution during crushing will yield its gold by simple, inexpensive agitation. The coarse mineral can be removed, classified, and slimed in the usual manner, and the slimed product mixed again with the rest of the pulp prior to agitation. If the mineral is floated off, then the same ultimate procedure must be adopted with the floated portion. The additional expense of flotation will be incurred, as against the cost of agitation and filtration of a large proportion of more or less barren tailing. The latter will generally be found cheaper.

When studying the features of roasting refractory floated concentrate prior to cyanidation, it must be remembered that the standard flotation process is particularly efficacious in floating mineral slime. As tables do such excellent and cheap work in separating out the coarse mineral, it may be said that, as regards gold ores, the chief field for flotation lies in the concentration of refractory slimes.

It must be borne in mind that the roasting of slimes from a cyanidation standpoint is a difficult problem, and one that, as far as the writer is aware, has never been solved. The process of drying slimes leaves lumps, and these, however small, will never roast perfectly sweet.

Filter-pressing and air-drying, followed by disintegration of the concentrate prior to roasting, might get over the difficulty. The writer, however, would emphasize that it is a problem in itself, and warns investigators that the mere fact of being able to successfully float the values from a mineralized slime does not indicate that it can be successfully treated unless there is a smelter handy to buy the concentrate.

In many cases in Western Australia the mineral constituents of the ores are so fine, and so intimately mixed with the gangue that the whole ore must be reduced to a colloidal slime before the mineral is liberated. When liberated, the mineral in this class of ore can be readily floated. Kalgoorlie ore, worth 40s. a ton, can be readily reduced to 3s., with the production of from 10 per cent to 15 per cent of concentrate, in this manner. The expense of reducing to colloidal slime, however, is very great, and this, as well as the question of the subsequent roasting prior to cyaniding of the floated slimed concentrates, is not particularly attractive.

*Aust. Inst. Min. Eng., *Bulletin* 16.

The Cyanamid Process*

BY FRANK S. WASHBURN

The fixation of atmospheric nitrogen has had commercial application for the past ten years. During this period different types of processes have been conceived; four, the Serpek, Haber, arc and cyanamid, have seriously attempted commercial exploitation; two, the arc and cyanamid processes, have proved to be commercially practicable in the broad sense. Of these two the latter may justly claim to be of great economic importance to the world because the unit of fixed nitrogen in its first product is capable of being more cheaply produced than by any other present-known process, and because this first product has a direct and valuable use of itself and constitutes the raw material for a varied and important line of derivatives into which, for the most part, it can be cheaply transformed.

The annual productive capacity of the existing plants employing the arc and cyanamid processes is between 90,000 and 100,000 net tons of fixed nitrogen, which, at the normal average value of the product at the factory door, represents $25,000,000. This is divided in the ratio of two-thirds to cyanamid and one-third to the arc process. The American Cyanamid Company's factory at Niagara Falls, Canada, has alone a capacity in fixed nitrogen approximately half as great as the total world's installed capacity by the arc processes.

More than 3000 technical articles dealing with almost every conceivable phase of nitrogen fixation have appeared in different languages. The patents applying to the subject in all its branches number into the thousands. So far as the author of this paper knows, nothing has appeared in the nature of a differentiation of processes based on the economics of the world demand for nitrogen. It is only for a limited developmental period that the theoretical, technical advantages and limitations of related processes constitute a practical basis for hazarding opinions as to their ultimate commercial value. It is also true that until an art has had some years of commercial application it is impossible to analyze and draw sound conclusions from the economics of the situation, the final arbiter in determining the social value of any process.

The art of atmospheric nitrogen fixation is now old enough to enable one to see the economic aspects of the case, and therefore, in casting about to determine what part of this vast subject to deal with in this paper, the author thought it would be of interest and possibly of value to treat herein the broad commercial outlook for the various fixation processes, and in order to limit the matter to conditions more or less well known to all of us, conditions on the North American continent, for the most part, will be the only ones considered.

Two nitrogenous compounds, nitrate of soda and sulphate of ammonia, constitute in value 80 to 85 per cent of the total raw nitrogen compounds produced throughout the world. The value of their combined production in 1913 was between $190,000,000 and $200,000,000. It is estimated that 80 per cent went to agriculture, corresponding to an annual per capita tax on the 600,000,000 inhabitants of the earth of thirty-three cents.

Nitrogen has four main uses: as an agricultural fertilizer, as nitric acid and derivatives therefrom, as ammonia, and in dyes and various other chemical compounds. Measured in the quantity of contained nitrogen, and in view of the restricted opportunities in the United States for immediately developing the chemical and dye industries on a large scale, we need consider as bearing decisively on atmospheric nitrogen fixation processes only the three first-mentioned uses, namely, for crop fertilizer, for nitric acid and its derivatives, and for ammonia as such.

The farmers' purchases in nitrogen used east of the Mississippi River last year approximated $75,000,000. More than 90 per cent of fertilizer nitrogen is in the form of ammonia. The normal annual consumption of nitric acid in the same region is about $7,000,000. The price paid per unit of nitrogen is about the same for each, and the percentage annual increment of consumption is about 10 per cent in each case. However, the importance of the fertilizer field in comparison with the nitric acid field, in their bearing on the fixation of atmospheric nitrogen, is not fully nor even approximately measured by this ratio of ten to one.

The use of nitric acid is along established lines looking comfortably to the future for a steady growth, with no serious limitations hampering modest development and no great unsatisfied human need demanding great development. It is essentially a small business as great industries go. The fertilizer industry has a very different significance. The population of the United States from 1900 to 1910 grew from 76,000,000 to 92,000,000, an increase of 21 per cent. Crop production increased 10 per cent in the same period. Exports of wheat and flour decreased from 31 per cent of their production to 13 per cent. The importation of foodstuffs and live animals practically doubled, while imported manufactured foodstuffs more than doubled. Beef cattle production fell off 32 per cent as the population increased 21 per cent. These figures are strikingly reflected in the increased cost of foodstuffs, which from 1896 to 1912 amounted to 80 per cent in the United States, while the general advancement in the cost of living during this period was 59 per cent in the United States, 40 per cent in England, and 40 to 45 per cent in continental Europe.

These facts point to the necessity of increasing crop yields without additional labor—and that defines fertilizer. European yields per acre cultivated are 50 to 100 per cent greater than American yields. The use of fertilizer in Europe, per acre cultivated, is enormously greater than in America. The average increase in yield in Germany for the past twenty years has been approximately 60 per cent, in the United States 20 per cent. Abroad this increase is attributed to intensive farming, better selection of seed, the rotation of crops and, to the extent of 50 to 70 per cent of the increase, to the use of commercial fertilizers.

The farmers' purchases of fertilizer in the United States last year in nitrogen and phosphorus constituents (later it will be shown why both are here included) was approximately $150,000,000. Were the cultivated lands east of the Mississippi to receive for each of two years out of every three the quantity of fertilizer normally used per acre each year in Germany, the bill would have been approximately $1,600,000,000, or ten times as great as the actual expenditure. The very limited use of fertilizers in the United States does not arise from the possibility that fertilizers do not pay. Indiana experiments, conducted in ten counties, produced an average increase of 11.6 bu. of wheat per acre, valued at $11.60, for an expenditure of $3.67. An instance of a very low return in the use of fertilizers is an unpublished record of thirty-seven experiments in Illinois in 1913, showing an average increase of 5.2 bu. of wheat, valued at double what the fertilizer cost.

The fertilizer industry to-day suffers many handicaps. These originate in part from the farmer's limited capital for properly conducting his business, his lack of knowledge which closes to him what would otherwise

*A paper presented April 23, 1915, at the Atlantic City meeting of the American Electrochemical Society for general discussion, having been previously read at a joint meeting on March 12, in New York City, in a joint meeting of the American Institute of Electrical Engineers and the New York section of the American Electrochemical Society.

be avenues of advancement and prosperity, and in part also from the fact that there is no vital, broadcast propaganda and educational bureau conducted by the fertilizer industry itself.

The greatest handicap is possibly in the material used. The industry is carried on by collecting at a great number of places throughout the agricultural regions east of the Mississippi a great variety of materials, each containing some one of the so-called plant foods, namely, nitrogen, phosphorus and potash, the last representing only about 10 per cent of the total. For the most part these materials are low in fertilizing value, and when mixed in a manner to include the low as well as the high-priced materials, there results of necessity a product of which 85 to 90 per cent is useless dead weight, only the small remainder having fertilizer value. Forty per cent of the annual fertilizer product in value is in the nitrogen constituent drawn from materials that are either by-products or wastes, such as sulphate of ammonia, slaughter-house refuse, fish scrap, vegetable refuse, waste of sugar works and distilleries, hair, leather, wool, hoofs and horns. The phosphoric acid constituent is secured from acid phosphate analyzing from 14 to 16 per cent P_2O_5, and as a general rule constituting one-half of the complete fertilizer mixture. Few of these raw materials in the broad sense are satisfactory. They are borne with because up to the present time there are no others commercially available. They pay the uttermost limit in the way of transportation charges to the point of their preparation, and after being mixed they bear a further great transportation burden to the consumer's railway station. There is a relatively large expense for mixing, storing, drying, bagging and selling. After the farmer has received his goods at the railway station, he must haul over spring roads, often almost impassable, 1,000 pounds of material in order to get 150 pounds of plant food. It is one of the recognized, recurring, contributing causes for small crops, particularly in the South, that the roads are so bad in the spring, due to rains, that farmers cannot haul the necessary amount of fertilizer.

Notwithstanding the consumer pays for nondescript materials, requiring only to be mixed in the crudest manner, a price 60 per cent greater than their spot value, the fertilizer industry as a whole, which prepares and sells the product, is conducted without measurable profit.

Unless revolutionary developments in some vital respect come to the aid of this great industry in the United States, any marked improvement is impracticable. It would appear, for reasons already set forth, that possibly the matter of greatest economic importance in the United States to-day is that conditions shall be brought about by which the farmer will use a vastly greater quantity of fertilizer than is now used. We believe the most important single contribution to this end would be a high-grade chemical salt containing nitrogen and phosphorus, well balanced and in large percentages, and possessing in a high degree the many requisites of a good fertilizer, such as being non-hygroscopic, non-toxic, finely granular in form, non-leachable in the soil and readily convertible by nature's forces into the organism of the plant. The process for the fixation of atmospheric nitrogen that will contribute the nitrogen content to such a fertilizer compound to the greatest net advantage may be justly viewed as the most important, not only to society, but also therefore to those who exploit it.

Discussions of the ultimate commercial superiority of the favorite process and the consequent complete annihilation of every other have been almost interminable. These have proceeded apart from any broad conception of time, place, the demands of mankind or the quantitative application of the product. They generally take the form of rival claims for cheapness in the cost of production, and this without much reference as to whether the unit cost applied to a form of nitrogen for which there was any particular or large demand, and without reference to whether the product was to be produced at a place and in a form enabling it to be transported to the consumer.

The Serpek process was discussed by volunteer adherents without knowledge that per unit of nitrogen fixed the necessary expenditure of heat energy from electricity alone is as great as the total electric energy consumption in cyanamid. Therefore, no suspicion was aroused that possibly nature had not placed the necessary raw material, bauxite, within practicable shipping distance of equally necessary cheap water powers. The limitations of the by-product, upon which the commercial possibilities of the process depend, were not questioned either as to the difficulties in converting it to commercial aluminum or as to the relation of its volume to the market demand for the metal.

The Haber process has been taken by the public for granted as one practicable of universal application because of its large though single use by a great concern of brilliant accomplishments in the commercial chemical world. The public does not know of the pressing problem of disposing of great quantities of sulphuric acid, and the single problem involved of how, under the local conditions, to devise the cheapest possible means of providing the requisite ammonia for using the acid in sulphate of ammonia. The electric energy necessary to the process is generally considered negligible, and yet a proposal to establish a plant close to New York involved, at the necessary power cost in that vicinity, as great an expense for electric power as the total power cost for cyanamid in an available site then under consideration for that process.

Air nitrogen fixation processes divide themselves into two broad classes, namely, those that come in at the nitric acid end, and those that come in at the other extreme, the ammonia end. There is no expectation that the various "arc" processes producing nitric acid will ever have employment in the production of ammonia compounds, for the sufficient reason that there is no prospect of ever being able to commercially convert nitric acid to ammonia. Therefore, the best that can be said of the "arc" processes is that they may be able by reason of having nitric acid as their first product, to occupy exclusively the field for the production of nitric acid. We have already seen that this field is not only relatively but absolutely a limited one for the present, as it is prospectively for the future.

The "ammonia" processes are not ready to admit, however, that there is an insurmountable barrier separating them from the nitric acid field. A tried, thoroughly workable, commercial plant for the oxidation of ammonia into nitric acid is not yet complete and in entirely satisfactory operation, but, on the other hand, the various steps necessary to the operation of such a plant have been separately brought to such stages of development as to leave no doubt in the minds of the experienced men who have worked upon the problem of the ultimate complete commercial practicability of carrying the ammonia processes for the fixation of atmospheric nitrogen through to the nitric acid producing stage.

A powerful factor operating as a disadvantage in the "arc" processes to the manufacture of nitric acid is the extraordinary difficulty of transporting the acid from the remote, cheaply developed water powers, very limited in number, where alone these processes can be employed, to the place of use for the acid, both sea and rail transportation being practically invariably

necessary. This audience does not need to be told how serious a matter is this. The nitrate compounds made from acid produced by the "arc" processes have found no place as a fertilizer in this country. Nitrate of lime, even in the so-called basic form, is too strongly hygroscopic to permit its use alone or as part of a mixture to be used through the ordinary drills by which fertilizer is distributed to the soil in this country. Even if the physical form were entirely satisfactory, it could not satisfactorily have a very large place in fertilizer mixtures in this country because of its being too readily available in the soil and because the valuable form of fertilizer nitrogen is as ammonia and not as nitrate. We have seen furthermore that the fertilizer industry demands something more than a new nitrogenous material, however meritorious it may be, merely as an additional one to the many which now constitute a part of a complete fertilizer mixture.

For a time it was thought that the treatment of phosphate rock by nitric acid might possibly find a large place in the fertilizer world. Two decisively unfavorable and irremedial results have developed from this attempt; first, the product is excessively hygroscopic, the surface when exposed taking up sufficient moisture to reduce the external parts to a molasses-like condition, and second, the content in plant food, approximately 11 per cent nitrogen and 14 per cent phosphoric acid, is markedly lower than that readily securable in the new commercial ammonium phosphate compounds resulting from the combining of ammonia and phosphoric acid. When carried to the monocalcic stage, thereby giving it the desired water solubility, the excess acid is of necessity so great that the crop is burned and destroyed. Much money has been spent on these efforts, which have always resulted in failure.

This brings us now to the consideration of the practicability of an ammonia phosphoric acid compound for agricultural use. The mono-ammonium phosphate, containing theoretically 14.6 per cent of ammonia and 61.3 per cent of phosphoric acid (P_2O_5) and the di-ammonium phosphate, containing theoretically 21.8 per cent of ammonia and 53.4 per cent of phosphoric acid, have been recognized by the scientific world for many years as fertilizers of extraordinary value, being in effect perfect materials, as they possess every qualification of a good fertilizer. The manufactured product made in this country has not developed any limitation. Under some circumstances, at least, the results in crop increase are greater per unit of ammonia and phosphoric acid than is securable from any other fertilizer or fertilizer compound, and the question has arisen whether this salt may not produce its result partially from the exercise of the same natural laws that apply to the action of manganese sulphate, for instance, in which there is a crop increase that cannot be attributed to the taking up by the plant of anything contained in the fertilizer. The effect may some day be safely attributed to the inducement that the salt has given to increased activity of the chlorophyl and thereby increased power of assimilation on the part of the plant.

The commercial ammonium phosphate product may be readily produced at will with varying proportions of ammonia and phosphoric acid, ranging from 13 and 47 to 21 and 46 per cent respectively. Thus it is that the plant food constituents of this single material, varying between 60 and 67 per cent, occupy the entire range of the usually desired relationship between ammonia and phosphoric acid. The phosphoric acid content of the commercial acid phosphate now used in agriculture, a product which, roughly speaking, results from pouring a ton of 52 deg. sulphuric acid on a ton of rock containing 30 to 32 per cent P_2O_5, contains about 14 to 16 per cent P_2O_5. In value it constitutes about one-half the farmer's fertilizer bill in the United States each year. Whatever advantages a new kind of phosphoric-acid-containing material may have, it should be capable of being produced at a cost no greater than the per cent unit cost of phosphoric acid in acid phosphate.

Two methods of manufacturing ammonium phosphate compounds have been developed. One of these is in the proved commercial stage and can produce as cheaply, at least, as by acid phosphate. The other is in the advanced developmental stage and promises still cheaper production costs. The first is applicable wherever cheap sulphuric acid may be had, and the second, which employs the electric furnace in driving off phosphorus from the phosphate rock, is applicable only where there is cheap water power available.

When the problem is referred to the actual conditions existing on the North American continent, the most available process known for providing agriculture in a broad way with the ammonia constituent of an ammonium phosphate compound is the "cyanamid" process. Searching investigation and analysis, for four years, of prospective cyanamid manufacturing sites, covering the United States and Canada, has developed a state of facts establishing the practicability of placing ammonia at the disposal of agriculture and the arts in practically every place of large use in the United States, and cheaper and simpler than could be accomplished in any other way. This may be done by shipment of cyanamid from a central point of manufacture to these various localities and its conversion there into ammonia.

These natural tendencies toward the "cyanamid" process as the principal source for nitrogen supply might be turned aside, however, unless that material and its important derivatives, notably ammonia, could be produced and delivered to the consumer cheaper than by other means and through the employment of capital in such a manner as would induce the investment of money in the undertaking. This brings us then to a consideration of the costs of production applied to a distinctive set of conditions which correspond not only with all the important conditions surrounding the demand for and use of the product but also those which characterize an actual place of production and its geographical relation to the consumer.

There is properly a hesitancy on the part of any business enterprise to disclose actual costs. Such information is frequently made wrong use of, and the risk involved in making it public is wholly out of proportion to the gain. At the same time the author realizes that without volunteering exact statements of comparative cost figures, open to confirmation or refutation, as the case may be, it is difficult to carry conviction to the hearer that one's conclusions are sound. The founders of the American Cyanamid Company have not from the beginning been wedded to any particular process for the fixation of atmospheric nitrogen. The aim and policy have been to conduct the company's activities and research work toward the end of developing a great nitrogen industry. It has investigated many processes with the conviction that it could not hope to have permanent and ultimate success except through the application of the best. Its research work in entirely new fields, and in the regular manufacture of its product, has been practically continuous from the day it first began commercial operations in 1910. It is therefore natural that those connected with the company should feel confident of their judgment on many matters bearing upon the relative merits and limitations of various nitrogen fixation processes.

Therefore, while it may be impolitic to disclose actually attained minimum costs it may be possible to establish particular facts and comparisons which will by

their logic carry conviction as to the order of compared processes so far as production costs are concerned, without, however, expressing the exact differences in costs. For instance, by the "arc" process the factory cost of nitrogen in commercial nitric acid, excluding all power costs (derived by applying actual working records to a particular manufacturing site where all conditions are of the most favorable nature) is greater than the total cost of nitrogen in "cyanamid," including power at $10 per continuous horsepower per annum (at a site where raw materials and labor are relatively high). Furthermore, taking that particular "arc" process which is the lowest in power consumption, the power cost alone, at eight to ten dollars per continuous horsepower per annum in weak nitric acid is greater than the total cost of "cyanamid," including power at the same cost per horsepower per annum (and at a site where raw materials and labor are high). These are actual comparisons and lead conclusively to some irrefutable deductions: first, that the "cyanamid" process can fix nitrogen cheaper than the cheapest of the "arc" processes, even although a charge of ten dollars per continuous horsepower per annum is made against "cyanamid" and the power is given free to the "arc" process; second, if the cheapest of the "arc" processes, so far as power consumption is concerned, is charged only with power at the rate of eight to ten dollars per continuous horsepower per annum and the process is presented without cost or charge of any sort with all labor, raw materials and supplies, its unit of nitrogen would cost more than the total cost of the unit of nitrogen by the "cyanamid" process. It also follows from these conditions that the total cost of the unit of nitrogen in commercial nitric acid made by the "arc" process cannot by any chance be less than double the total cost of the unit of nitrogen in cyanamid made by the "cyanamid" process. We have seen that the really great application of nitrogen is at the ammonia end and these comparisons are impressive in showing not only that there is no hope of the "arc" process working into ammonia production but also, and what is of more importance, that the "cyanamid" process has to its credit a wide margin of saving in cost to span the gulf between "cyanamid" and nitric acid.

The first step in the derivation of nitric acid from cyanamid is to convert the latter into dry ammonia gas. Such conversion is now conducted in so many places and on so large a scale that the actual cost of the operation, including all losses, is no longer a matter of speculation or approximation. The efficiency has been raised in actual practice to over 99 per cent and the cost, while not negligible, is so low as to add only a small percentage to the ordinary cost of the unit of nitrogen in "cyanamid." Therefore, the facts just set forth as to the cost of the unit of nitrogen in "arc" process nitric acid, compared with the cost of the unit of nitrogen in cyanamid, apply as well to the cost of the unit of nitrogen in pure ammonia gas. Roughly speaking, therefore, there is to the credit of the ammonia, available for oxidizing it to weak nitric acid, fully one-half the cost of weak nitric acid derived by the "arc" process. As a matter of fact the indications are that this span will be bridged by the absorption of not more than one-half this difference, making weak nitric acid by the "cyanamid" process cost approximately three-quarters of the "arc" process. As power is brought below ten dollars per continuous horse-power per annum, production costs by the "arc" processes approach more nearly to costs by the "cyanamid" process. It is possible to make the general statement that the costs per unit of nitrogen in weak nitric acid may be taken as the same for both processes where power costs about $4 per continuous horse-power year.

Comparison of the costs of ammonia gas by the "cyanamid" process and the "Haber" process show, broadly speaking, that the Haber process in its most favorable environment involves a cost nearly double that of the "cyanamid" process under favorable conditions practicable of attainment.

It must not be understood that the "cyanamid" process has exhausted the possibilities of further economies in manufacture. As examples, in one new factory study in which the requisite coke is to be made by local by-product ovens, the operations so balance that the fuel gas derived is the quantity required, and as the tar and ammonia products pay for the coking, the coke is had at the price of coal. Where ammonia is derived at the cyanamid factory the sludge from the autoclaves composed of calcium carbonate and carbon may be turned back through the carbid furnaces and maintained in the cycle practically indefinitely as a carrier of nitrogen.

However, the whole story is not involved in a study of production costs, for there are other factors which may have a deciding voice, and of these we may mention as important the amount of the necessary investment for a given output, the salvage in the case of ultimate abandonment, the ratio of interest charge to the out-of-pocket expense, bearing in mind that the latter may be very much reduced by improved operating means while the former is fixed for all time. Taking the necessary investment in the "arc" process per unit of nitrogen in weak nitric acid as a basis, and assuming power to be placed upon the switchboard at an investment cost of $50 to $75 per horse-power, the corresponding investment in the "cyanamid" process for a unit of nitrogen in weak nitric acid would be about one-half, and as cyanamid or ammonia gas about one-third. It is believed that the Haber process in the United States on the same basis would involve an investment of about two-thirds to three-fourths of the "arc" process. In the contemplation of any enterprise requiring large fixed capital there is a reasonable amount of capital beyond which objections to an increased amount are not to be measured by applying the interest and amortization rate to the estimated costs of production. Converting a vast amount of gold in the bank into bricks and mortar, special machinery and appurtenances, particularly in the application of a new and special art is a serious risk for which there is no exact measure, but which in contemplating the risk should weigh heavily as a guide to judgment.

In the case of ammonia production by the "cyanamid" process the fixed investment may be as low as one and one-half times the annual value of the product and in the case of the Haber process three times. In the case of nitric acid by the "cyanamid" process the investment may be as low as one and one-fourth times the annual value of the product and in the case of the "arc" process with a power investment of $75 per continuous horse-power the fixed investment would be between three and four times the market value of the annual product.

The majority of manufacturing concerns in the United States vary in fixed investment from one to one and one-half times the value of the annual product and the inherent risk in industrial enterprises, for reasonably assured profits demand, for the most part, very special conditions where this proportion is exceeded. Even that class of investments considered most stable as to reliability, permanency and growth, namely, public utility corporations, do not exceed $4 to $6 investment per dollar gross revenue. We are therefore met in the case of the Haber and arc processes with the necessity for making an investment which, in the judgment and practice of the industrial world, is wholly out

of proportion to the market value of the annual product, while in the case of cyanamid the requirements are within the limits of ordinary commercial practice.

These considerations serve to emphasize the difficulties in commercially advancing any new enterprise. The younger technical men do not encounter these difficulties and therefore do not give them due weight. There is extraordinary difficulty, particularly in the United States, in financing a new chemical enterprise, particularly if it involves a large preliminary expenditure in research and developmental work. The banker's attitude, and properly so, is to compare assets and liabilities. Buildings, equipment and manufacturing sites are acceptable assets notwithstanding that in many companies if the business itself were abandoned there would be little or no value in the physical properties. Knowledge, processes, and ideas are not impressive assets. They are considered in large part to have been something secured at great cost, but, even with good patent protection, practically available for the use of prospective competitors without cost to them. In some other countries such enterprises are viewed quite differently, notably in Germany, where ideas are the foundation of great and profitable enterprises and where by law and practice they are better protected for the exclusive use of those who have developed them than in this country.

The promise, or even the assurance of reasonable profit, is seldom a sufficient inducement to the investor to undertake a pioneer enterprise. The competitive element which dominates almost every other activity is lost sight of by the amateur promoter. He forgets that to the mind of the prospective investor he is in the sharpest kind of competition with those presenting other types and kinds of enterprises demanding capital. His project must grip the imagination with peculiar attractiveness as well as impress the practical sense of those to whom it is brought as not only being prospectively profitable but also assuredly safe with a minimum prospect of loss and a maximum prospect of profit. Of the many subordinate advantages there may be specifically mentioned an early dividend paying period, a ready market for the securities, their acceptance as good collateral, and a ground-floor prospect in future extensions. In the end it must outweigh, in some cases, literally scores of other projects all claiming equal if not superior merit in every particular. There is another consideration of kindred merit which will be impressive if one considers that in a thing so extensively engaged in as trade in securities, one of the very largest activities in which mankind interests itself, there must grow up inevitably certain more or less arbitrary rules, practices and points of view. These all turn naturally upon the usual thing, and the usual thing is the established industry, or at least an enterprise engaged in an established industry. Therefore, the new thing has a slow and difficult road to travel and its difficulties are more than in direct proportion to the amount of capital demanded. Those fixation processes which employ and own their own water powers make a plea to capital that others cannot make, for the reason that it can generally be shown that should unexpected competitive developments in the remote future drive the undertaking to an unreasonably low return upon the investment, the rental value of the water powers for other purposes will probably insure the continuance of a satisfactory return upon the total investment.

Even if it were granted that the "cyanamid" process is prospectively to play the leading rôle in the fixation of atmospheric nitrogen so far as the most important use of nitrogen is concerned, namely, in agricultural fertilizers, and even if it were further granted that it is the logical source of nitric acid, the question may still be an important one as to whether the raw product of this process may be looked to as the source of a long and important line of nitrogen derivatives. The fact is that there is an almost interminable line of derivatives which can be produced from cyanamid with the greatest technical success and assurance and their manufacture has proved to be in some cases commercially feasible. The direct and valuable application of the raw product, cyanamid, is unique in air nitrogen fixation processes. The proof of this value lies in the fact that fully 80 per cent of the entire annual product of normally $15,000,000 value is sold as the raw product.

The principal derivative at the present time is ammonia, which has earlier herein been referred to. None is being made in America at this time outside of the Cyanamid company's research laboratory, but abroad various plants are producing some 15 tons of gas per day, part of which goes into high-grade sulphate for fertilizer use and part into anhydrous ammonia. There is also installed and about ready for operation a large Norwegian plant erected for the Birkeland and Eyde interests for transforming some 60 tons of cyanamid per day into ammonia, which will be absorbed in nitric acid for the production of ammonium nitrate. The transformation takes place according to the following reaction:

$$CaCN_2 + 3H_2O = CaCO_3 + 2NH_3$$

This decomposition is accomplished by the use of water and high-pressure steam in autoclaves, and large-scale working plants show an efficiency of over ninety-nine per cent nitrogen transformation. The ammonia gas is delivered from the autoclaves mixed with steam and absorbed directly in sulphuric acid without removal of the steam, or passed through a very small ammonia column equipped with condensers and coolers for the removal of the steam, thereby yielding a very high-grade pure ammonia gas. In case it is desired to make anhydrous ammonia it is simply necessary to intensify this drying action and compress the gas; considerable quantities of this ammonia are sold in France in the anhydrous state. The cost of the transformation is almost negligible, as the units have very large capacity and require very little attention.

Cyanamid in the presence of water tends to transform itself slowly to dicyandiamid, and this latter to urea. Methods have been recently evolved which make practicable these transformations either to urea or dicyandiamid with approximately 90 per cent efficiency and obtain chemically pure salts as the end product. Dicyandiamid, formula H_2CN_2, contains 66.6 per cent nitrogen, or probably the highest concentration of any staple nitrogen compound. It has been proposed for use in explosives, acting as a deterrent, also for use in the dye industry. Its greatest future possibly lies in the ease with which acids transform it into the guanidines, which should find large uses in the explosive industry. The material has been proposed for use as a fertilizer because of its high nitrogen content, but it is probable that its slow decomposition in the soil will never warrant its use for this purpose.

The United States is importing about $50,000 worth of high-grade urea annually for the celluloid industry alone, and could this material be cheaply produced there is no doubt but that it would find an even greater use in the explosive industry. Considerable quantities of this material have been produced in the research laboratory, which has been tried by the celluloid manufacturers with perfect success. It is now practicable to replace the importations of this expensive salt.

In the field of organic derivatives of cyanamid there is practically no end to the series that have developed abroad. The latest addition to this group has been

creatin, which seems to be getting somewhere close to synthetic foods.

The calcium in the calcium cyanamid can be replaced by the heavy metals, and recent experimenting with some very interesting compounds, such as lead cyanamid and copper cyanamid, promise valuable results.

When certain grades of cyanamid are melted with common salt the free graphite in the original material is combined with the calcium cyanamid, forming cyanide. A transformation of better than 90 per cent nitrogen efficiency is obtained and the resulting product contains approximately 25 per cent KCN equivalent. This material, which can be prepared so as to deliver it into the hands of the consumer at about two-thirds the present price of high-grade cyanides, requires solution in water and filtration. Both operations are easy, and the filtrate can be used in the place of cyanide for the extraction of precious metals. Large scale experiments have been tried out in various cyanide works throughout the world, and in every case it has proved to be identical in behavior with regular cyanide, showing the same extraction efficiencies. The lower price at which this material can be delivered to the consumer more than takes care of the very simple extra dissolving and filtering operations incident to its use, and there should be, therefore, a very large field for this material, supplanting the more expensive, high-grade cyanides.

Naturally, when the transformation to cyanide is so simple it is also possible to manufacture ferrocyanide, and enter into the case-hardening field and other uses for this material. As a matter of fact, cyanamid itself can be very simply compounded into a case hardener which is the equal of any of the present materials on the market and superior to most of them. The German cyanamid makers have, since the beginning of the war, been swamped with orders for this case-hardening material, sold under the name of "ferrodur."

Reference has been made heretofore in this paper in a general way to nitric acid production from ammonia. There has been developed recently a new process of re-oxidizing ammonia to nitric acid at high efficiency. It is believed to do away with all of the limitations of the Ostwald process and, if so, the industry will be in a position to meet nitric acid demands by way of cyanamid at a cost under conditions existing in the United States below anything any other process can offer. The gases leaving the oxidizing chambers are many times more concentrated than those from the "arc" process furnaces and, therefore, condensation is greatly simplified and recovery much increased. The units can be made large or small and their cost is rather low, so that small nitric acid plants can be installed at almost any place in the country within shipping range of the cyanamid plant, it being autoclaved into ammonia and converted into nitric acid at the point of use.

Quite recently the American Cyanamid Company has been using the "cyanamid" process as a means of producing argon gas in quantities, producing the nitrogen by means of the copper process and later eliminating the nitrogen by continued re-absorption in the cyanamid ovens, leaving argon as the final gas. Thousands of feet of this gas, highly concentrated, is being sold to the lamp industry, chiefly for American use, but in part to consumers abroad.

Atlantic City Meeting of the American Electrochemical Society

The twenty-seventh general meeting of the American Electrochemical Society was held in Atlantic City, N. J., on Thursday and Friday, April 22 and 23, and was concluded in Philadelphia on Saturday, April 24. Since Atlantic City has no local members, the attendance was somewhat less than usual (the number of those who registered being 130), nor was there any official smoker or banquet, but the meeting will be remembered as the one which among the many lively meetings of this society, has produced the most lively and extended discussions, and in the crisp spring air the Atlantic City board walk was enjoyed at its best in spite of an occasional little shower during sessions. When a session closed the sky would clear up.

The hotel headquarters were at the Chalfonte, where all sessions were held.

Thursday Session.—Business Meeting

The annual business meeting was called to order by President Lidbury on Thursday afternoon. The secretary of the society, Dr. Joseph W. Richards, read the annual report of the Board of Directors. The membership at the end of 1914 was 1377 and twenty-nine new members have been elected since the first of the year. Reports of the different committees were then presented and the report of the tellers of election was announced as follows:

Mr. Lawrence Addicks, of Douglas, Ariz., is the new president. Messrs. L. E. Saunders, John A. Mathews and L. Kahlenberg were elected vice-presidents. Messrs. L. D. Vorce, William Acheson Smith and William H. Walker were elected managers. Mr. P. G. Salom was re-elected treasurer, and Dr. Joseph W. Richards of Lehigh University, South Bethlehem, Pa., was re-elected secretary.

Mr. Lawrence Addicks, the new president, was born in Philadelphia, Pa., on March 3, 1878. He was educated at the University of Pennsylvania and at the Massachusetts Institute of Technology from which he graduated in 1899 in both the mechanical and electrical courses. He went to New Mexico, where he was employed in a copper mine, but returned East in 1900 to become assistant to the superintendent at the Raritan Copper Works. In 1905 he became chief engineer and a few months later superintendent of the U. S. Metals Refining Company of Chrome, N. J. He was the superintendent of this copper refinery for nine years. In 1914 he became connected with Phelps, Dodge & Company to conduct the large-scale leaching tests on low-grade copper ore at Douglas, Ariz. Mr. Addicks is recognized as one of the highest authorities on electrolytic copper refining and has presented numerous papers before the American Electrochemical Society, the American Institute of Mining Engineers, the American Institute of Electrical Engineers and other technical and engineering societies.

Presidential Address

The retiring president, F. A. Lidbury, works manager of the Oldbury Electrochemical Company, Niagara Falls, then presented his very able and interesting presidential address on the American Electrochemical Society in Its External Relations, which is published in full on page 277, of this issue.

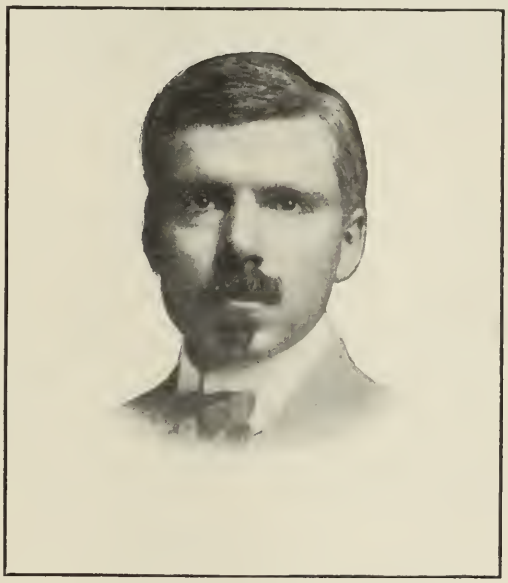
Fibrox

A paper by Dr. **E. W. Weintraub**, of the General Electric Company, Lynn, Mass., deals with the preparation and properties of fibrox, which is the name given by the author to a fibrous material of the composition of silicon oxycarbide. The name is to suggest the remarkable structure of the material. The author first reviews former work done on amorphous silicon oxycarbides by various investigators from Schuetzenberger to Tone and then describes the manufacture as follows:

A muffle (or pot) of material capable of withstanding a temperature of 1400 deg. to 1500 deg. C., having its bottom covered with a layer of silicon pieces, is heated in a gas furnace to the temperature of incipient melting of silicon. A muffle of Dixon graphite clay-lined has proved to be suitable. The ends of the muffle protruding outside the furnace are luted on to the muffle in a gas-tight manner. It is essential that a catalytic agent be used. One such agent is calcium fluoride.

After a run of a few hours the muffle is found filled completely with fibrox, which is removed and the operation repeated. It is only necessary from time to time to break up the slag which forms on the surface of the silicon and to add some fresh fluorspar or other catalyzer.

It is obvious from the process described that fibrox is a product of slow and quiet growth, and from its composition it must be formed when silicon vapors and carbon dioxide or carbon monoxide react. The silicon vapors come from the silicon. The carbon dioxide comes from the combustion gases of the furnace. One has, therefore, to picture to himself the oxide of carbon slowly diffusing through the pores of the vessel and reacting with the silicon vapors. This slow interpenetration of the reacting gases through a permeable wall is an important feature of the process and is essential if the finest structure is to be developed.



LAWRENCE ADDICKS, PRESIDENT
AMERICAN ELECTROCHEMICAL SOCIETY

The fluorspar or other catalyzer used has most probably the function of keeping the slag (silica?) in a sufficiently soft condition to allow the silicon to "seep" through it and expose a clean surface from which the silicon vapors can freely escape.

The most remarkable thing about fibrox is its physical structure. It is a soft, resilient, fibrous material; after general compression it returns to its original shape; it can be cut into plates, sheets, and rings which are self-supporting. The material is an agglomeration of exceedingly fine fibers much thinner than fine hair. The diameter of the fibers is in average about 0.6 micron, or about the wave length of yellow light. Some fibers are undoubtedly smaller and probably approach 0.3 micron.

The apparent density of the material, while varying with the circumstances, is usually between 0.0025 and 0.0030. In other words, it weighs only about 2½ to 3 grams per liter. The real density of the material varies with its composition. When the composition corresponds nearly to the theoretical silicon oxycarbide SiCO (about 21 per cent. of carbon), the real density is 1.84. As the carbon content diminishes the real density increases up to about 2.2 or nearly that of silicon. From the real and apparent density, the actual volume occupied by air is figured out to be over 99.5 per cent. and in the best cases equal to 99.9 per cent. and that of the solid material is only between 0.5 and 0.1 per cent.

For the temperature interval of 100 deg. to 15 deg. a long-fiber dark-green sample of fibrox compressed to a density of 0.767 lb. per cubic foot or 12.3 grams per liter has a resistivity in degrees per watt, per inch cube, $R' = 1675$, or per cm. cube $R = 4200$. A comparison with other materials will be instructive. For wool at a somewhat higher density of 0.955 and the same temperature interval R' (in. cube) = 802 (R/cm. cube = 2000) and at a density of 3.4, $R' = 110$ (R cm. cube = 2700). Wool has to be compressed to a density of 12 pounds per cubic foot or more than 15 times that of fibrox to get the same value of heat resistivity. Eiderdown reaches a value equal to that of fibrox at a density of 5, or more than 6.5 times the density of fibrox. Among the inorganic heat insulators, monox has a density of 6.18, $R' = 1000$ ($R = 2500$) and "Elephant Ear" at a density of 8.4, $R' = 1100$ ($R = 2700$). It will be seen that by its value of heat resistivity fibrox stands in a class by itself. The heat insulating values decrease with higher temperatures. While fibrox is the best heat insulator, it is a relatively good electrical conductor with a conductivity comparable to that of electrolytic solutions. This is most remarkable.

Dr. Weintraub exhibited samples of this most interesting new heat-insulating material. While nothing definite yet can be said concerning the price at which it will be sold, it seems certain that the price will not be prohibitive, as it may be possible to sell the cubic foot at 50 cents, when fibrox is placed on the market.

In the extended discussion which followed Mr. Tone spoke of his own work in this line and said that his silicon oxycarbide differed from fibrox in degree, but not in kind, and Mr. Arthur spoke of similar work done at the Schenectady laboratory of the General Electric Company. Mr. Northrup referred to filtering possibilities and Messrs. Baekeland, Hitchcock, Franklin, Taylor, Mott, Hering, Richards, Frary continued the discussion. While Dr. Weintraub makes fibrox in a gas-fired furnace, Mr. Saunders expressed the opinion that fibrox could be made in an electric furnace.

Thermal Conductivity of Refractories

A paper by Professor **Boyd Dudley, Jr.**, of the Pennsylvania State College, deals with "the methods and results of an investigation designed to develop a practical and reasonably accurate means of determining the thermal conductivity of regular kinds of brick, under conditions approaching those of practice and without the necessity of preparing special shapes or samples of the materials being tested." The author

first gives a classification and review of the various methods which have been devised to measure the heat conductivity of refractories and then describes his own method.

This method of determining thermal conductivities consists of using the brick under test in the construction of one single wall of a specially constructed coke-fired furnace, and measuring the rate of heat flow through a certain area of the test wall by means of a water jacket applied to the cold side. Temperature measurements are made at various points in the brick, and from the data thus secured the conductivity of the material constituting the wall is calculated. The advantages of the method are these: Special shapes or test pieces of the refractory are not needed, the tests being made on samples of commercial brick. The conductivity is readily calculated from the observed data without recourse to complicated factors involving the shape of the conducting body. Variation of the conductivity with temperature is made apparent by graphic representation of the temperature gradient through the brick.

The furnace consists of three permanent walls, one side and two ends, provided with a permanent roof and stack connection. These three walls are constructed of fire brick and tile, and are each 9 inches thick. The roof of the furnace and stack connection are supported from the end walls on iron bars placed as shown. The fourth wall (the front side of the furnace) is independent of the other parts of the furnace and is built of the brick to be tested. The fuel used is sized by-product coke, which is charged through the fire door at the top of the back side of the furnace. The grate consists of four iron bars. Air enters under the grate, and additional air is drawn through openings in the back side of the furnace. These openings may be closed or left open as is necessary; it is found that by regulating the amount of air entering the furnace at the various points it is possible to secure rapid combustion of the coke, from the top of the bed of fuel to the grate, a depth of about 26 inches. In this manner a sufficiently large area of the test wall is heated to a uniform temperature to render permissable the use of a calorimeter 1 foot square.

Concerning the details of the arrangement and especially the construction of the calorimeter with which the rate of heat flow through the wall is measured, the reader is referred to the complete paper to be published in the Transactions of the Society.

The method was applied by the author to tests of four types of refractories. The kinds of brick tested were first-quality fire-clay brick, silica brick with clay bond, silica brick with lime bond and magnesite brick. All were manufactured by the Harbison-Walker Refractories Co., Pittsburgh, Pa.

Details of the composition of the different bricks are given in Table I.

Table I.—Analysis of Brick

Per Cent	Woodland	Quartzite	Star Silica	Magnesite
SiO_2	52.93	73.91	95.85	2.50
Al_2O_3	42.69	22.87	0.88	0.50
Fe_2O_3	1.98	1.48	0.79	7.00
CaO	0.33	0.29	1.80	2.75
MgO	0.38	0.31	0.14	86.50
Alkalies	1.55	1.20	0.39	....
Loss on ignition	....	....	....	0.10
Apparent density	1.91	1.91	1.56	2.46

The results of the measurements of heat conductivities are given in Table II.

Table II.—Heat Conductivities of Brick

Material	Test No.	Exp. Temp. Range	Mean k Over Exp. Range	Calc. k at 100°	Calc. k at 1000°
Woodland	1	120 to 965	0.00676	0.00532	0.00816
Woodland	2	100 to 1025	0.00666	0.00438	0.00880
Woodland	3	400 to 995	0.00704	0.00332	0.00886
Quartzite	1	100 to 935	0.00679	0.00504	0.00880
Quartzite	2	100 to 960	0.00670	0.00521	0.00836
Star silica	1	100 to 910	0.00794	0.00561	0.0108
Magnesite	1	445 to 830	0.0343	.....	0.0343

The third column gives the temperature range in deg. C. for each test. The fourth column gives the mean conductivity k for this temperature range in gram calories per second per inch cube per deg. C. Columns 5 and 6 give calculated values of the heat conductivities k at 100 deg. and 1000 deg. C. respectively.

While the calculated conductivities are in some cases not in close agreement, in general they are consistent in indicating the relative conductivities of the various materials. Taking the averages of the figures applying to each material the conductivities at 100 deg. and 1000 deg. C. are given in Table III in gram calories per second per inch cube per deg. C.

Table III.

Material	Average k at 100 deg.	Average k at 1000 deg.
Woodland	0.0043	0.0086
Quartzite	0.0051	0.0086
Star silica	0.0056	0.0108

For magnesite brick it was found that between 445 deg. and 830 deg. C. the conductivity of the magnesite brick was practically constant, the value being 0.0343 gram calories per second per inch cube per deg. C. For this reason magnesite brick is not included in the above Table III.

It is estimated that the precision of the figures representing mean conductivities is within 5 per cent. The precision of the average figures representing the conductivities at definite temperatures is less, but it is difficult to estimate.

In the absence of Professor Dudley, his paper was presented by Dr. Richards. It was discussed at some length by Messrs. Hering, Schluederberg, Hitchcock, Addicks, Chapin, Northrup, Frary, and Richards. Dr. Hering pointed out that Dudley's method of measurement gives directly the heat conductivity of the solid material and eliminates the surface resistance to flow of heat. This additional resistance may become important in practice. Mr. Hitchcock replied that the thermal resistance of the solid material is really what is wanted by the practical man; he plotted curves to show that the additional surface resistance is relatively insignificant. Dr. Northrup emphasized the altruistic character of such heat-conductivity experiments with their immense technical difficulties and the enormous expense of time they require.

Reaction Between Graphite and Magnesia

A paper by Professor **O. L. Kowalke** and Mr. **D. S. Grenfell**, of the University of Wisconsin, gave an account of measurements of the temperature of reaction between Acheson graphite and magnesia.

Three different methods were used: In the first method, weighed samples of the two materials—magnesia and graphite—were heated in contact with each other for half an hour at various temperatures and the loss in weight determined.

The second method was based on the fact that the reaction is endothermic. When the substances attain the reaction temperature, heat will be absorbed from the surroundings and the temperature falls, which becomes manifest in the pyrometric curves.

The third method employed a vacuum furnace; the beginning of the reaction would be detected by an increase in pressure.

The second method gave the best results. The pyrometric curves indicate that the reaction commences slowly at about 1950 deg. C. and becomes very violent at temperatures above 2030 deg. C.

The paper which, in the absence of the author had been presented by Professor Frary, was discussed by

PHOTOGRAPH TAKEN AT ATLANTIC CITY MEETING OF AMERICAN ELECTROCHEMICAL SOCIETY

Messrs. Bennett, Northrup, Hinckley, Whitney, Richards, Mott, Hitchcock, Frary, Saunders and FitzGerald. The latter thought that such reaction temperatures are rather indefinite.

Analogies Between Electricity and Mechanics

In the evening of Thursday, Professor W. S. Franklin of Lehigh University, presented a most interesting experimental lecture on "some mechanical analogies in electricity." The principal object was to show some exact analogies between rather difficult yet fundamental conceptions in alternating-current engineering and well-known mechanical conceptions. Professor Franklin showed especially the analogy between induction in electromagnetism and inertia in mechanics and the analogy between a condenser in electromagnetism and and an elastic medium in mechanics.

Professor Franklin's experiments were striking and the audience was still more impressed by the decidedly original viewpoint of the lecturer, which may be indicated by his quotation, made in concluding the lecture, from his recent little textbook "Elementary Electricity and Magnetism" (Macmillan Co., 1914, page 56):

"Electricity or energy; which? When water is pumped through a pipe it is usually the amount-of-water-delivered-in-a-given-time that is important. The amount of power represented by the stream of water is of no great importance. It is the water itself that is useful, and the power expended in driving the pump is merely enough to carry the water where it is needed. But one might conceivably use a pump to drive water through a circuit of pipe for the sake of the heating effect of the moving water in the pipe or to drive a water motor placed anywhere in the circuit of pipe. In such a case one would be interested primarily in the amount of power represented by the stream of water because the desired effect (heating or motor driving) would depend upon the amount of power.

"So it is in the case of the electric current. It is not 'electricity' (whatever that is) that one uses, it is work or energy; and the important thing about an electric generator (a battery or dynamo) is the amount of power represented by the electric current delivered by the machine. This may be illustrated most pointedly as follows: A wheel drives another wheel by a belt. A person knowing nothing at all about machinery and especially a person having no available words to use in describing such an arrangement, might look at the continuous stream of leather given off the first wheel and decide to call this wheel a leather generator! Everyone knows, however, that a driving wheel does not generate leather; it gives off energy work and the work is transmitted to the driven wheel by the belt. It seems very ridiculous to speak of a belt-wheel as a generator of leather, and indeed it is equally absurd to speak of a battery or dynamo as a generator of electricity. One must be careful not to take electrical terms and phrases too literally.

"To speak of a dynamo as an electric generator is, however, not seriously objectionable, but to speak of 'electricity' as a motive power indicates a very serious misunderstanding. When it is proposed to drive a machine by a leather belt it is always understood that something must drive the belt, but when it is proposed to drive a machine by 'electricity' it is not always understood that something must drive the 'electricity'. Electricity as applied in the arts is merely a go-between like a leather belt, and no one ever thinks of leather as a motive power!"

Friday Morning Session.

The Friday morning session was opened by the presentation of two papers by Dr. W. D. Bancroft, of Cornell University, on colloidal chemistry. In Professor Bancroft's absence the first paper was presented by Dr. Whitney, the second by Professor Frary.

Coagulation of Albumin by Electrolytes

A paper by Professor **Wilder D. Bancroft**, of Cornell University, reaches the following conclusions:

So far as the data go the coagulation of albumin by salts can be accounted for more satisfactorily on the assumption that we are dealing primarily with

adsorption rather than on the assumption that we are dealing primarily with an amphoteric electrolyte.

Slightly acid or slightly alkaline solutions of albumin are least stable when the dispersed phase is electrically neutral.

Since the sign of the electrical charge depends on the preferential adsorption of cation or anion, the nature of both anions and cations is important.

When albumin is charged positively, the most strongly adsorbed anion will be most effective in causing precipitation and the most strongly adsorbed cation in preventing precipitation.

When albumin is charged negatively, the most strongly adsorbed cation will be most effective in causing precipitation and the most strongly adsorbed anion in preventing precipitation.

If one adds to negatively charged albumin a salt consisting of a readily adsorbed cation and a slightly adsorbed anion, we shall get precipitation at low concentration and no precipitation at higher concentration; but in this latter case the albumin will be charged positively.

While the reversibility of precipitation depends in part on the ease with which the precipitating agent can be washed out, it seems probable in the case of albumin that the physical properties of the precipitate are important as determining coalescence and agglomeration. There are no data on this point.

In the case of electrolyte-free albumin one must apparently assume that the stability of the solution is due to the peptonizing action of water in the absence of electrolytes.

The coagulation of albumin by electrolysis is a typical and general case, whereas the coagulation of gold sols and ferric oxide sols are special cases.

Neutralization of Adsorbed Ions

A paper by Professor **Wilder D. Bancroft,** of Cornell University, reaches the following conclusions:

The neutralization of an adsorbed ion is due to specific adsorption. The concentration of a given electrolyte necessary to neutralize the charge on a given colloid will therefore depend on the nature of the cation, the anion and the colloid.

It is inaccurate to say that the cation is negligible in the precipitation of a positive colloid and the anion in the precipitation of a negative colloid, though this statement is often approximately true.

Univalent ions are not all adsorbed alike; nor are bivalent ions or trivalent ions. The order to adsorption is specific with each colloid and is not determined exclusively—and perhaps not at all—by the migration velocity or solution pressure of the ion.

Since the adsorption is specific, Schulze's law is only an approximation. Certain univalent ions are adsorbed by certain colloids more than certain bivalent or trivalent ions. In many cases there is, however, a marked tendency to increased adsorption with increasing valence.

Mixtures of two sols will not precipitate each other unless adsorption takes place.

Since adsorption is specific, the order of precipitation of a negative sol by a number of positive sols will not necessarily be the same for any two negative sols.

It is not accurate to say that two sols having the same sign have no effect one upon the other. Adsorption may and often does take place.

Hydrous chromic oxide, which is peptonized by caustic potash may act as a protecting colloid for hydrous ferric oxide, which is not peptonized by caustic potash.

Since an adsorbed ion does not necessarily give the reactions of a free ion, electrometric measurements may and do lead to false conclusions when applied to colloidal solutions.

It is probable that sodium palmitate solutions are hydrolyzed to a very much greater extent than appears from electrometric measurements.

If two colloidal sols did not adsorb each other appreciably and if one adsorbed the cation of a given electrolyte very markedly, while the other adsorbed the anion of the same electrolyte very markedly, the addition of a small amount of the electrolyte to a mixture of the two colloids would produce a solution which would conduct electricity without their being any appreciable amount of substance in true solution.

In sodium palmitate solutions, it seems probable that the hydroxyl ions set free by hydrolysis are adsorbed practically completely by the colloidal soap.

Addition of a colloid to a solution will increase or decrease the conductivity if the adsorbed ion has a greater or smaller migration velocity than the ion adsorbed. In so far as both ions are adsorbed the conductivity will decrease.

When adsorption by a colloid causes hydrolysis the conductivity will depend also on the nature of the products of hydrolysis.

The two papers elicited a very interesting discussion on colloidal chemistry in general in which Messrs. Whitney, Cox, Lidbury, Franklin, Jacobs, Mott, Frary and Taylor participated. One one side Dr. Whitney emphasized the enormous present importance of the development of colloidal chemistry where new and important results are constantly obtained, especially in the explanation of biological phenomena, for instance, the action of the heart, and President Lidbury urged that while in the past biologists had almost monopolized the field of colloidal chemistry, electrochemists should now

make this field their own. On the other hand, Professor Frary, in presenting Dr. Bancroft's second paper, showed how in various instances the point of view of the "old chemistry" was able to explain matters quite as successfully as the colloidal chemist's viewpoint. The whole discussion not only contributed to a more general understanding of such conceptions as adsorption, as distinguished from absorption, but undoubtedly created a broader interest in colloidal chemistry.

Thermo-Couples

A paper by Mr. **T. S. Fuller,** of the Research Laboratory of the General Electric Company, Schenectady, N. Y., gave the results of the measurement of "the thermo emf of certain iron alloys." The methods employed were described and the results given in tables and diagrams. The results for iron-nickel, iron-chromium, iron-cobalt, iron-nickel-chromium and iron-nickel-manganese are given in Tables I, II, III, IV and V.

TABLE V—THERMO EMF OF IRON-NICKEL-MANGANESE ALLOYS. (AGAINST COPPER. 0 TO 100 DEG.)

5.	88.5	0.11	6.2	0.061	0.065	— 1.60

The paper was discussed by Messrs. Fink, Mott, Gillett, Jacob, Whitney, Richards, Hinckley, Ruder, and Fuller. The hope was expressed that these measurements would be extended to higher temperatures.

LeClanche Cells

A paper by Professor **M. deKay Thompson** and **Ernest C. Crocker** of the Massachusetts Institute of Technology deals with the depolarization in LeClanche cells.

In the LeClanche cell the positive electrode consists of carbon in contact with manganese dioxide. The dioxide acts as the depolarizer, but does not depolarize completely, as is shown by the gradual decrease in the current and voltage on closed circuit. LeClanche recommended that the manganese dioxide should be mixed with carbon and that both should be coarse in size. LeClanche cells, in various forms, are extensively used at the present time, especially as dry cells. About fifty million a year are manufactured in the United States alone. Wet cells are also made in smaller quantities.

In view of the considerable difference in sizes of the depolarizer particles, used in different makes of LeClanche cells now in commercial use, the authors made a study of the comparative efficiency of depolarizing mixtures of carbon and manganese dioxide, when the sizes of the particles and the relative amounts of the substances present in the mixture were varied. The chief result of their investigation is that the carbon and pyrolusite particles should have the same size, and this should be such as to allow the particles to pass through openings 1/10 inch (0.25 cm.) square and not to pass through openings 1/120 inch (0.02 cm.) square.

The purity of the pyrolusite affects the depolarization materially. The mixture of carbon and pyrolusite should contain 55 to 60 per cent pyrolusite.

In addition, the authors investigated the cause of polarization in LeClanche cells. It is assumed to be due to the decomposition of the anmmonium radical and its subsequent splitting up, represented in the equation $2NH_4 = 2NH_3 + H_2$. The polarization may, therefore be due either to hydrogen or to ammonia. The investigation shows that the polarization by hydrogen is completely prevented by the manganese dioxide. The remaining depolarization in the LeClanche cell is due to ammonia. This may be largely overcome by the addition of zinc chloride to the solution.

Communicated discussions by Professor Burgess and Dr. Cheney were read and Messrs. Richards, Frary, Whitney, Hitchcock and Franklin participated orally in the discussion. It was pointed out that pyrolusite is a rather variable mineral. Further attention was called to the fact that university professors have to undertake such work, because the commercial companies which have all this information in their files would not publish it.

Copper Leaching

The concluding number on the program of the Friday morning session was a general discussion of leaching of low-grade copper ores with subsequent electrolytic precipitation. This had been the subject of an extended discussion on Jan. 6, 1915, at a joint meeting of the New York sections of the American Electrochemical Society and the American Institute of Mining Engineers. In view of the representative character of the engineers who took part in that discussion, it was of unusual value, being a condensed statement based on wide experience. At Atlantic City a review of the chief results of this discussion was given by Mr. Addicks. We will first give a rather full account of the original New York City discussions and follow this by an account of the additional discussion at Atlantic City.

Discussion in New York

Dr. L. D. Ricketts opened the discussion, expressing his deep interest in the subject and in the value of free discussion by men having special qualifications to consider different phases of the work. He outlined the problem existing at the New Cornelia property at Ajo., Arizona, where there is about 40,000,000 tons of ore containing 1½ per cent copper; 12,000,000 tons is oxidized, 24,000,000 tons sulphide, and about 4,000,000 tons is a mixture of the two classes. Other large tonnages of oxidized ore of low grades were mentioned showing the importance of their treatment.

In our issue for September, 1914, page 591, we presented an abstract of Mr. Stuart Croasdale's paper read at the Salt Lake meeting of the A. I. M. E., giving the results of his experiments on the New Cornelia ore. This ore has a matrix of granite with a large percentage of secondary quartz replacing felspar. There is little calcium present in soluble form, and the oxidized seems adapted to a leaching process.

"Preliminary laboratory tests showed that the ore crushed with the production of remarkably little slime and that the copper will dissolve in dilute sulphuric acid quite freely when the crushed ore contains fragments no larger than 6-mm. cubes. Tests also showed that a little cuprite is present, which is only partly soluble in sulphuric acid. There are also other soluble salts, notably salts of iron and aluminum. It was decided to investigate a leaching process for the oxidized ore, and since the ore made but little fines and could be leached with comparatively coarse crushing, we decided that we would try to leach in tanks by percolation. The amount of silver in the ore is small. Salt is apparently expensive, and it was decided that, other things being equal, the use of chlorine compounds as solvents was not desirable.

"Mr. Croasdale demonstrated that the ore crushed to an 8-mm. cube, or smaller, would yield over 80 per cent of its copper when treated with a dilute solution of sulphuric acid. He demonstrated that slime

presented no difficulty if the ore was distributed in the tanks uniformly, and that by finer crushing 85 per cent of the copper could be obtained in solution if treated for a sufficient length of time with an acid solution. He demonstrated not only that the ore was permeable uniformly, but that with comparatively small tanks the height was not a matter of great consequence, and he was easily able to use a column 12 ft. in height, and could probably use one much higher. Later on we found upward percolation preferable.

"Mr. Wedge showed us that with care in calcining the sulphide fines for reverberatory furnaces at the Calumet & Arizona smelter at Douglas, sulphuric acid of 55° to 60° B. could be manufactured with a low operating cost, and a construction cost of not to exceed $3,000 per ton of daily capacity. The point of manufacture is about 300 miles, more or less, according to the route, from the mine. Mr. Wedge also undertook a study of sulphating and chloridizing roasts. His requirement were that the ore be crushed to pass a 1½-mm. screen. He showed that if the sulphide ore could be mined in parallel with the oxidized ore, and in proportion to their respective tonnages, there would be sufficient sulphur for his purposes and that a very high extraction could be obtained. He also showed that sufficient advantage could not be had in using salt to offset its cost and the difficulties that might arise later. Mr. Wedge also showed that a small amount of heavy sulphides from the Bisbee mines crushed and mixed with the oxide ore would give a very high percentage of extraction after the mixture had been subjected to a sulphating roast. He also introduced the idea that a preliminary water leach would give a perfectly pure sulphate solution from which the copper could be recovered electrolytically and that the acid thus regenerated would be sufficient to complete the leach."

Reference was made to the experimental work of Mr. Laist, at Anaconda, where is was found that by calcining sulphide or mixed ores a high percentage of copper could be extracted by leaching. Temperature control was shown to be vastly important, by both Messrs. Wedge and Laist. Mr. Ricketts made reference also to the McKay process, using a sulphatizing roast to render copper soluble; also the slater and Midland processes, which depend on the use of complex chlorides and hypochlorous compounds to attack copper compounds not affected by sulphuric acid.

"At the beginning of our investigation we seriously considered what I called the 'brutal method' of leaching, namely, the manufacture of sulphuric acid, the solution of the copper from the ore with such acid, and the precipitation of the copper by metallic iron, with the resultant complete, or nearly complete, destruction of both acid and iron and the production of an impure cement copper that will have to go through the process of smelting and refining. The results of Mr. Croasdale's tests and Mr. Wedge's cost figures indicated that such a course was commercial, and we concluded that the 1½ per cent Ajo ore, with no overburden, mined by steam shovel and crushed coarse, would yield a profit on a 12c. copper market if a cheap grade of Alabama pig iron were used.

"But it occurred to me, as it had occurred to many engineers, that oxide of iron could be reduced to metallic iron without fusion, and if so we might bring Bisbee sulphides to the mine, calcine them for the manufacture of sulphuric acid and then metallize the available iron in the impure calcine, already containing values requiring recovery, and use this for a precipitant."

The experiment of metallizing was tried in a small Wedge furnace, but was a failure because in keeping the charge hot the CO_2 formed was sufficient to retard and reverse the action of CO in reduction. Experiments in revolving cylinders, using illuminating gas and fuel oil in a continuous process, also were a failure. Mr. Laist, however, had demonstrated that sponge iron could be made in a revolving drum by an intermittent process. Mr. Ricketts became convinced that the use of iron, with destruction of both iron and acid, was preposterous, and decided to investigate electrolytic processes of deposition, and later the precipitation of copper by sulphurous acid gas.

PRECIPITATION BY SULPHUROUS ACID GAS

"In the precipitation of copper by sulphurous acid gas, temperature and consequent pressure must be considered. If the copper is precipitated in metallic form this temperature and pressure are very high, but if a sub-chloride of copper would satisfy us, the temperature and pressure may be moderate. In both of these processes, the reactions we are familiar with in the formation of sulphurous acid by treating copper turnings with concentrated sulphuric acid are reversed by heat. For the production of metallic copper the action depends upon getting sulphurous acid dissolved in the sulphate solution in sufficient amount to precipitate the copper and then heating the mixture under proper control to about 150° C. The question of the use of an abnormally rich gas is involved. Under proper regulation pure copper is produced, which only needs melting for the market, and a large excess of sulphuric acid is formed. Mr. Van Arsdale has done valuable original work on this process, followed by the work of Weidlein and others in its commercial development. Laist has studied precipitating sub-chloride of copper. A soluble chloride is added to the sulphate solution of copper and the proper amount of sulphurous acid is added. Moderate heat under pressure—90° C. of heat—precipitated almost all the copper as sub-chloride. The subsequent process of obtaining the copper without volatilization and the recovery of the chlorine offered difficulties. It is with no disparagement of the process that we have abandoned it in our case. To me and my friends the electrolytic method seemed best adapted to our condition and the simplest and more certain of commercial application.

INVESTIGATION OF ELECTROLYTIC METHODS

"Of course, the first difficulty was the solution of other oxides than copper and the danger of some loss of acid thereby, and, what was more important, the susceptibility of some of these dissolved neutral salts to oxidation by nascent oxygen to the production of acid salts, which in turn will dissolve copper from the cathode. It seems that such salts are most valuable as depolarizers, but must be held under control."

Mr. F. L. Antisell and Messrs. Pope and Hahn were employed to make a series of tests and experiments covering the difficulties offered by iron and aluminum.

"Both Mr. Antisell and Messrs. Pope and Hahn began their experiments upon a laboratory scale at the Raritan Copper Works. Messrs. Pope and Hahn found the leaching could be so conducted that the rate of increase of iron and alumina was slow. They therefore decided to leach in a certain way and to treat a certain high iron and aluminum neutral solution with copper oxides by agitating, heating, and injecting air. This is a rejuvenation of the old Hoffman process applied to a new purpose. The iron and aluminum sulphates in such foul solution, together with arsenic and other impurities, are precipitated as insoluble oxides and the acid previously combined with these

salts is taken over by the copper oxide and forms sulphate of copper. The clarified solution, with these impurities removed, is then mixed with the balance of the solution, thus keeping an iron content of, say, less than ¾ per cent.

"Mr. Antisell began his experiments by using a patent anode. This anode was a narrow, rectangular wooden or lead frame with thin wooden sheets as diaphragms, forming a long and deep but very narrow box. It was packed with a clean coke in lumps crushed to pass a 1-in. ring, and contact was given by carbon rods imbedded in the coke. A solution of sulphate of iron and aluminum in great excess was made up and sulphuric acid added. This was used as a solvent for the copper. After the solution came from the ore it was at first passed to an absorption tower, where sulphurous acid gas was absorbed, and then it passed to the electrolytic tank.

Promising results were obtained in the laboratory, and later tests were made with full sized anodes at Douglas. Excellent results were obtained there also, but difficulty was had with the complete absorption of sulphurous acid. An extraction of 80 per cent was obtained, and 2 lb. copper was recovered per kilowatt-hour. Nearly the theoretical amount of sulphuric acid was produced from the SO_2 gas.

"Mr. Greenway discovered that if a certain copper solution containing salts of triad elements is treated in a simple way, the iron or aluminum triad salts may be removed. Dyad salts are not affected. He was led to the belief that such oxides thus precipitated were in large part insoluble in dilute acid and that therefore he had a very simple method of removing iron and aluminum from the solution. Against my prediction, laboratory tests seemed to show his contention was correct. Mr. Greenway erected a small plant of his own, and a Pope and Hahn plant was installed and the use of sulphurous acid was temporarily discontinued. As for the Greenway process, I am not yet at liberty to discuss it further. But I may say over 100 charges were run with this process. The iron content in the solution was kept down to less than 1 per cent, and we obtained an average of slightly over 1 lb. of copper per kilowatt-hour, but the extraction was low. We then extended the time of the leach and obtained a higher extraction, and finally we began to crush the ore, which at that time had been crushed only to ½-in. ring, finer, and found that if crushed to pass ¼-in. mesh percolation was not retarded and an extraction of over 80 per cent was practicable. The iron has reached as high as 1.2 per cent, but we are still getting a pound of copper per kilowatt-hour from the electrolytic tanks.

"These experiments have been so successful that we are proceeding with the erection of a 40-ton plant, where tanks will be used that will hold 60 tons, if necessary, and will be abundantly large to permit of a study of the comparatively even distribution of crushed ore, and we shall proceed with these most interesting experiments, using first, as we have in the smaller tanks, the Greenway process. In the meantime, the 1-ton plant will be liberated and we will immediately proceed with the continuance of a modified form of the Antisell system of leaching. He finds that with the construction of better absorption towers we can absorb the necessary amount of SO_2 gas, and he has demonstrated that with the use of SO_2 gas, using dyad iron as a depolarizer and triad iron as an oxidizer, he can manufacture sulphuric acid. We can, if successful, obtain 1½ lb., and possibly more, of copper per kilowatt-hour, and at the same time manufacture sufficient acid to replace wastage. The electrolytic copper in all cases has been fully up to the trade standards.

CONCLUSIONS

"My deductions from a study of the work of the able engineers engaged in these extensive operations are as follows:

1. Dilute sulphuric acid will give a very high extraction on oxidized ores of the Ajo type. Time is a more important element in extraction than strength of acid. A maximum size of 6-mm. cube is required. Such ore crushed to the maximum size permits percolation and the production of a clear solution because the slime content in the ore so crushed is very small.

2. Where such ore is mined at a cost of between 25c. and 50c. a ton, it is commercial on a 12c. market, even if leached with sulphuric acid and the copper precipitated with pig iron to the waste of the acid and iron and the production of an impure cement copper that requires further treatment. Metallized iron from calcines can be made and will prove a little cheaper than pig iron if it is marginal.

3. An electrolytic method for the recovery of pure copper from sulphate solutions is far preferable and will produce cheap copper. In all cases a low current density is required. Hard-lead anodes or composite anodes of hard lead and coke of uniform thickness will be used.

4. Such electrolytic method, with control of the amount of iron and aluminum in the electrolyte, and without the use of sulphurous acid gas, is practicable. An acid loss of about 1.5 lb. per pound of copper will be sustained. Chamber acid will be required.

5. I believe there is a decided probability that the cheapest and best method will be the electrolytic deposition from sulphate solutions without iron control, and the use of the requisite quantity of sulphurous acid. The sulphurous acid will be absorbed without the tank house and in quantity that will not cause annoyance. Iron and aluminum will act both as depolarizers and catalytes. This process promises a high yield of cathode copper per unit of power and the manufacture of sufficient sulphuric acid to replace the waste.

6. While these remarks apply to the Ajo oxidized ore and ores physically and chemically similar, they need not apply to ores of a different composition. Mixed oxide and sulphide ores, be the sulphide chalcocite or chalcopyrite and bornite; ores containing great quantities of clay, or presenting other difficulties, have to be considered separately, and there is beyond question a great field for other processes and for other methods, both for obtaining the copper in solution and obtaining the copper from the solution."

Mr. Utley Wedge called attention to the necessity for making provision for the treatment of the sulphide ore of the New Cornelia, of which there is twice the tonnage that exists of oxidized ore. In his opinion a combination treatment can be evolved that will take care of both types of ore.

"Let the sulphide ore and the ore which is found between the mass of carbonate and the mass of sulphide ore, which partakes of the character of both, be ground to 20 or 30 mesh and furnaced at a temperature not much above a red heat, and the material can at once be leached with as good percentages of recovery as have been secured in the case of the carbonate ore. The copper solutions secured can be electrolyzed, and sufficient sulphuric acid can be produced from the electrolysis for use in leaching all or a portion of the carbonate ore, which methods can be identical with the methods described in the paper.

"I am of the opinion that sulphatizing roasting of

the sulphide ore in the orebody of the New Cornelia Copper Co., coupled with the acid leaching of all or a portion of the carbonate orebody with sulphuric acid by the methods indicated in the paper, will give the lowest possible cost of operation and will give the highest possible recovery of values of any method known to the metallurgical art. This combination of methods would obviate the necessity of construction of a sulphuric acid plant; in the place of this plant there would be constructed a furnace plant for giving the required roast to the sulphide ore. At the start, with only carbonate ore accessible, enough of the carbonate ore could be roasted mixed with small percentages of iron pyrite from neighboring camps to sulphatize the carbonate of copper."

Mr. E. A. Cappelen Smith outlined again the work at Chuquicamata. This has already been published in detail in this journal, May, 1914, page 291. The leaching plant is practically finished, but delay has been occasioned in the completion of the power plant, which is being made in Germany.

Mr. George W. Van Arsdale spoke briefly on the work at Douglas, Arizona, the method used consisting in sulphatizing-roasting, leaching and electrolysis of sulphate solutions, using depolarization.

"The results of our roasting experiments were as follows: We roasted three principal classes of material, in which the average insoluble copper in the calcines was 0.11, 0.16, and 0.41. The water-soluble copper showed 70 per cent of the copper contents, 40 per cent, and 51 per cent, respectively, and the total extraction was 92.9, 88.0, and 70 per cent. One of the principal results of these experiments was to show us that for this class of roasting it was necessary to have more or less fine crushing as a preliminary.

"The results of our preliminary electrolytic experiments were fairly satisfactory. We obtained a total amount of copper precipitated of something over 2 tons at an average figure for power of about 1.6 lb. of copper per kilowatt-hour. We produced acid per kilowatt-hour equivalent to about 5.1 lb. The ampere efficiency was low. This, however, was due to several reasons not directly connected with the process. We had a large number of short-circuits and other troubles, but we felt quite sure at the end of these preliminary experiments that we should get about 2 lb. of copper per kilowatt-hour. We had, however, a certain number of uncertainties and some anomalous results, so we started some further experiments on details of solution and other matters.

"The further experiments resulted in the following general conclusions:

"First, that it was not necessary to have such a large amount of SO_2 in solution as we had previously thought, and that in addition, much better results could be obtained by using SO_2 together with iron, rather than either one alone. In other words, the function of the SO_2 was not only to act as a depolarizer, but also to act chemically in keeping the iron reduced. We also found there was a certain favorable effect from a high aluminum content. The temperature increase is favorable in the same way as in copper refining. With iron salts present there is a decreased ampere efficiency with increased temperature. This was counteracted by SO_2 and by increased current density.

"As a result of these further experiments, we laid down the conditions of high ferrous sulphate in solution, high alumina, a temperature of about 115° to 130° F., current density of about 15 amperes per square inch, and sufficient sulphur dioxide present to reduce the voltage, and maintained sufficiently to keep the iron in the ferrous condition, and under these conditions I expect it will be possible to get a yield of from 2 to 2.5 lb. of copper per kw-hour.

"As to 'foul solutions,' which has heretofore seemed to be the principal bugbear in electrolysis, as long as the iron can be kept in the ferrous state, which can be done by SO_2, it is fairly safe to say that, up to certain limits, better results will be obtained from so-called foul solutions than from pure copper sulphate solution.

"We are now about to start a 75-ton plant, in which we expect to apply the information which we have gained to the treatment of one class of ore, and the result of the work which will be done in that plant will no doubt be published later."

Dr. Raymond F. Bacon, director of the Mellon Institute of Industrial Research, presented the following on methods of precipitation. "Our work on electrolytic processes has been along two lines. First, to ascertain the optimum conditions for the electrolytic precipitation of copper from sulphate solutions obtained by the leaching of oxidized copper ores. In this phase of the work I may say that we finally obtained conditions under which we ran a solution over the ore through the precipitating tanks and then over the ore again, 20 cycles being completed, without any purification of the solution. There was precipitated on the average in these 20 cycles 1.86 lb. of copper per kilowatt-hour and the current efficiency on the twentieth cycle was fully as good as that on the first cycle. Our second line of work on electrolytic processes has been an attempt to find efficient and cheap depolarizers, so as to increase the amount of copper precipitated by a definite amount of electrical energy. We have found one very cheap substance which for short runs gave us 4 lb. copper per kilowatt-hour.

"In regard to the sulphur dioxide process, we have been actuated by this thought—it is necessary in most ores to have quite an excess of acid to take care of mechanical losses and to take care of alkaline substances in the ore. One way of doing this is along the line which has been spoken of, by using the sulphur dioxide in an electrolytic cell. We, also, have used sulphur dioxide in an electrolytic cell, but all of our work has tended to show that the efficiency of sulphur dioxide as an anode depolarizer in a sulphate solution is rather low. Because of this low efficiency, our calculations showed us that it is cheaper to precipitate directly with the sulphur dioxide under pressure than to use the sulphur dioxide as an aid to electrical precipitation; that is, the heat required for direct precipitation with sulphur dioxide will be cheaper in most localities than the electrical energy required either for straight electrical precipitation or for the combination in which sulphur dioxide assists the current. We all appreciate the advantage which any electrolytic process has of giving directly cathodes of electrolytic copper.

DISADVANTAGES OF ELECTROLYTIC PRECIPITATION

"On the other hand, it has seemed to us that for most localities and most conditions the disadvantages of electrolytic processes, as at present developed, outweigh this advantage. Some of the disadvantages of electrolytic processes are these: The fouling of solutions immediately and seriously cuts down the current efficiency. Changes in the character of the ore, particularly as regards soluble impurities, are always to be expected in large orebodies. The electrolytic process is very sensitive to changes thus brought about in the electrolyte. The installation and upkeep costs of the electrolytic precipitation process are very high and to obtain efficiency requires constant

supervision by high-priced men. One rather fundamental objection to electrolytic processes has not been discussed here to-night. In electrolytic processes, at least of the type which have been spoken of to-night, the copper content of the electrolyte can be reduced in the precipitation cells no lower than 1.5 per cent copper. That means that it is not easy to so conduct a cycle of leaching, precipitation, etc., that all of the water-soluble copper shall be removed from the ore and the volume of the solution in the cycle shall be kept constant.

"It is obvious that in any process in which there is practically complete precipitation of the copper, as in Weidlein's sulphur dioxide process, this washing difficulty does not arise. In place of losing soluble copper in the ore, one there loses a corresponding amount of sulphuric acid; and in Weidlein's process sufficient sulphuric acid is constantly being formed, so that this loss can be taken care of. As to the element of danger in processes in which a solution is heated under pressure, I would call your attention to the fact that there are thousands of boilers operating continuously in the United States under pressures considerably in excess of those used in the Weidlein process. We built in Nevada a 40-ton plant and we have had certain mechanical difficulties, as we expected to have. These difficulties we are meeting by the installation of a continuous process of precipitation. The advantages of continuous precipitation will be evident to all mill men. Our expectation that the cost of heat in this process of precipitating pure copper is less than the cost of electricity for electrical precipitation has been borne out. Of course, I recognize that there are localities where electrical power is so cheap that an electrolytic precipitation process should be the one to be considered, but I believe that for most localities in the western United States some of these other processes are more favorable as regards cost. In the Weidlein process, a very large excess of acid is constantly regenerated and all who have had experience in the leaching of ores know how desirable this is. In that connection I will say that we have developed a system of handling sulphur dioxide and a method of concentrating it from dilute flue gases. We believe we have made noteworthy progress in that direction, but I am not prepared at this time to go any further into that. In a short time we will be able to say a little more on the subject."

Mr. Frederick J. Pope described the experiments of A. W. Hahn and himself in controlling the effect of iron salts in solution. As between allowing them to remain in the electrolyte and there controlling their action, or removing them altogether, they decided on some process of removal.

"In considering how to remove iron from the electrolyte, we were reminded of the work which had been done by Hoffman at Argentine, where he precipitated iron from bluestone solution. Hoffman accomplished this by heating the solution in a suitable tank, agitating with air, and adding copper in an oxidized form. I think he used a roasted lead-copper matte. This work of Hoffman's gave us our idea for the removal of iron from the solution.

"For the copper oxide necessary in this work we have used high-grade copper carbonate ore, oxide formed by the roasting of cement copper, roasted high-grade sulphide ore, also roasted copper sulphide concentrates. In order to obtain a satisfactory reaction between the copper oxide and the iron, etc., in the solution, it is imperative to have the oxide material very finely divided. The roasted concentrates we used were ground in a small Abbé mill.

"From the Ajo carbonate ore we removed a little more than 2 lb. of iron per ton of ore treated. In order to keep the iron in the solution below the percentage deleterious to electrical efficiency, it was necessary to treat approximately one-quarter of the solution. We found that by manipulating the solution going on and off the ore in a certain way we could concentrate a large proportion of the iron in a certain part of the solution.

"In purifying, the solution was first heated to 195° to 200° F. When this temperature was attained agitation with air was begun and the finely ground oxide material was gradually added. Maintenance of a temperature of about 195° F. and agitation with air was continued for 3.5 hr. During the first hour all the ferric iron was precipitated. The removal of the ferrous iron was slower and we found that it was not advisable to endeavor to precipitate it all. In 3.5 hr. we easily precipitated 90 per cent of the total iron and at the same time removed 65 to 75 per cent of the alumina, 50 per cent of the manganese, and all of the arsenic, antimony, and bismuth which might be present.

"After the above operation the pulp was passed through a Schreiber wooden filter press. The solution came out beautifully clear and was sent to the high-acid electrolytic circulation system. We anticipated that with the precipitate produced we might have trouble with the filter cake; that it would be slimy and difficult to handle. We did not find it so. The cakes were 2 in. thick, firm, washed well, and the amount of copper in the form of unused oxide they contained was well within commercial limits.

"The only loss of acid is that entrained in the tailing, but this is easily counterbalanced by a proper control of roasting operations. Lead anodes were used, containing 4 per cent antimony, and the cost was estimated to be 0.2c. per ton of ore treated, with lead at 8c. per pound."

Mr. J. Parke Channing.—"The problem presented in the Miami district is a little different from that in the districts referred to in the discussion of this evening, inasmuch as the ore to be treated there is one which is a mixed chalcocite and carbonate. The gangue is particularly free from any impurities that go into solution, but the fact that both chalcocite and carbonate are present makes it a rather difficult problem. The particular ore deposit upon which we worked was that of the New Keystone, but the same class of ore existed in the Miami, and also on the Inspiration. The problem therefore presented to us was either a straight leaching one, which would have to be proceeded with by complete dead roasting, or else it would be a mixed process, water concentration followed by leaching, or possibly leaching followed by water concentration; and then finally, if flotation came in, we might have to make three bites of the cherry—that is, use water concentration, flotation, and leaching. You can readily see there would be a great many combinations and whether it would be desirable to leach first, then water concentrate, and then float, or whether it might be desirable to make the sequence different, we do not know. This Keystone ore averages about 2¼ per cent copper, of which anywhere from 30 to 40 per cent is oxidized. After making a number of concentration tests we decided upon attempting a dead roast; in other words, converting all to the copper into a soluble form and leaching it."

Mr. R. C. Canby—"The only thing I can think of which has not been mentioned is the circulation of the electrolyte. In our electrolytic work I designed the cells so that the solution, instead of flowing

lengthwise against the flat surfaces of the anodes and cathodes, flowed crosswise of the cell. In that way, in the use of sulphurous acid gas, I had hoped, by having a rapid circulation, to use a much smaller quantity of both copper and the depolarizing element in the electrolyte, with a correspondingly stronger current, and also to be able to precipitate the copper without heating the electrolyte. I was able to use a current density as high as 10 or 12 amperes per square foot with the temperature of the electrolyte about 18° to 20° C., and get a very satisfactory coherent deposit. I think that was the only novelty in the electrolytic work.

"The problem in roasting was to use our 14° Baumé fuel oil, to be burned at a temperature of 2000°, and yet keep our ore bed at not to exceed 800° to 1000° C. I accomplished this by using a furnace similar to that used for the Huntington and Heberlein process at El Paso, and at three other American smelting plants, the hearth revolving past the flame, so that I was able to roast the ore without at any time bringing the temperature of the roasting above the desired 1000° C., whereas the fuel was being burned at about 2000°, or a little over. The furnace was entirely of reinforced concrete construction and stood well."

Mr. Richard Lamb described his work in connection with a leaching and electrolytic copper plant at High Hill, Va., for the Virginia Copper Co., treating bornite and chalcocite ores. The ore contained 3 per cent copper, 1½ per cent sulphur, 89 per cent silica, 0.75 per cent lime, 1.5 per cent iron, 3 per cent magnesia and 0.35 per cent alumina. The ore was roasted in an Edwards furnace at a temperature of about 900° F. in order to convert iron to the form of sesquioxide, and leave the copper as oxide and sulphate. The roasted ore was treated in a leaching barrel with sulphurous acid of 10° Baumé for about 3 hr. The copper solution thus formed was filtered and electrolyzed, the sulphurous acid being changed to sulphuric. The voltage in each tank was 1.8, and a current density of 3 amperes per sq. ft. was used. The electrolyte was permitted to run from ¼ to ½ per cent copper when used for further leaching. The output was 30.6 lb. copper per hp.-day of 24 hours. With steam power costing $48 per hp.-year, the cost for electrolytic treatment was about ½c. per pound of copper produced. Total cost of producing copper was estimated at about 6.9c. per pound.

Discussion at Atlantic City

Mr. Lawrence Addicks, after having summed up the discussion which had been held in New York City, added some remarks of his own. Three essentially different problems should be distinguished. First, for sulphide ores roasting and leaching is now not very promising, on account of the tremendous quite recent developments in flotation. Second, for oxide ores, where conditions are favorable, leaching has come to stay. Third, mixed sulphides and oxides represent an entirely open problem and it is impossible to say which process will fit. The presence of silver and gold complicates the problem. As to precipitation, there is now an increasing tendency towards electrolysis. Scrap iron as precipitant is practically impossible, because there is not enough scrap iron available. Mr. Van Arsdale and the speaker found that carbon anodes can be used (which have heretofore been thought to be unsuitable in sulphate solutions); they used Acheson graphite electrodes. Compared with electrolytic copper refining, the bearing of all important factors is reversed in copper leaching.

While iron and aluminium had heretofore been considered the most detrimental impurities, they had now learned how to turn their presence to advantage and use the iron for depolarizer and let the aluminium sulphate grow and form a natural diaphragm which prevents the action of ferric sulphate on the copper cathodes. With a pressure of 0.7 to 0.8 volt they get 2 or 3 lb. per kw-hr.

Mr. G. W. Van Arsdale emphasized the two most important results of his leaching experiments: first, that graphite anodes can be used in sulphate solutions, and second, that it is possible to get along very well with foul solutions. Mr. Van Arsdale also discussed some interesting chemical reactions which they ran across in their experiments.

Mr. John V. N. Dorr showed in an interesting way how his well known machines, originally invented and designed for cyanide practice, are now being successfully used to solve certain mechanical problems in the three operations of copper leaching: dissolution; separation of dissolved copper from ore pulp, and precipitation.

Professors Frary and Richards also participated briefly in the discussion.

Friday Afternoon Session

After the discussion on copper leaching had been concluded Professor Frary presented his paper on the electrolytic production of magnesium.

Electrolytic Preparation of Magnesium

A paper by Professor **Francis C. Frary** and **Harry C. Berman,** of the University of Minnesota, gives an account of an experimental investigation undertaken to find the cause and cure of the difficulties met with in the electrolysis of molten magnesium potassium chloride. Early in their work the authors noticed that after electrolyzing magnesium potassium chloride for an hour in a large graphite crucible the electrolyte on cooling contained numerous dark spots. It was found that this was the suboxide of magnesium and the cause of its formation was further investigated with the following results.

Magnesium sub-oxide is formed during the electrolysis of magesium potassium chloride if magnesium oxide is present. A high temperature facilitates its formation. It is dark colored, heavier than either metallic magnesium or the double salt, decomposes water vigorously, is oxidized (if finely ground) in the air, and is apparently re-oxidized at the anode in the bath.

Magnesium sub-oxide cannot be formed by the reaction of magnesium (metal) on the oxide in the presence of the molten double salt at a bright red heat, and is apparently only formed under such conditions as exist in the electrolytic reduction of MgO.

Magnesium sub-oxide does not react upon a solution of anhydrous nickel chloride in absolute alcohol, while metallic magnesium does.

There is no evidence of the formation of a "metal fog" during the electrolysis, even at a bright red heat, and the dark appearance of the electrolyte under these conditions is due to the presence of the sub-oxide.

Magnesium oxide dissolved or suspended in molten magnesium potassium chloride does not react with dry hydrogen chloride, differing in this respect from lime. As the magnesium oxide cannot be removed from the electrolyte, its formation must be prevented during both the preparation of the electrolyte and the actual electrolysis.

Professor Frary's paper was discussed by Messrs. Lidbury, Richards, Taylor, Vorce and Bennett. Mr. Lidbury suggested that the black mass might have been something like a potassium-magnesium alloy and

refused to accept a new suboxide until it has been isolated and analyzed. Professor Frary summed up his reasons which led him to conclude that the lead mass cannot be anything else but magnesium suboxide.

Calorizing Metals

A paper by Mr. **W. E. Ruder,** of the Research Laboratory of the General Electric Company, Schenectady, N. Y., discussed the application of the "calorizing" process to various metals. The calorizing process consists in producing a rich aluminium alloy upon the surface of the metal to be protected and has already been the subject of a descriptive article in our vol. XII, page 730 (November, 1914).

The pieces which are to be calorized are packed in a mixture containing powdered aluminium. This mixture is made up of alumina and powdered aluminium with the addition of about 1 per cent of ammonium chloride. The aluminium varies from 5 per cent to 50 per cent by weight, depending upon the service to which the piece is to be put. For copper and brass parts the mixture is kept low in aluminium and the temperature of firing held at about 700° C.-800° C. For steel and iron, richer mixtures are used and the temperature of firing is increased to 900-950° C. These mixtures are used repeatedly with the addition of sufficient aluminium and ammonium chloride to make up for the loss at each firing.

Perhaps the most important application of this process is the treatment of iron to withstand high temperatures. While the pieces are kept at a high temperature, as in service, the originally narrow band of aluminium alloy on the surface widens as the aluminium diffuses into the iron.

This diffusion gradually lowers the amount of aluminium in the outside coating, especially if the piece be of heavy section. There is, however, a coating of Al_2O_3 all over the outside which still protects the pieces from oxidation, but if this is broken it cannot renew itself and deterioration sets in. This usually starts in spots.

This spotting, however, occurs only at temperatures above 1050 to 1100 deg. C. and may be prevented by using a small section so that the alloy when completely diffused still remains high in aluminium.

Calorized cast iron parts do not stand up quite as well at high temperatures as calorized wrought iron or steel parts, because of the large amount of gases they contain and also because of their tendency to swell. At 800-900° C., however, it stands up very well. Wires and thin ribbons can only be given a light coating if they are to be kept pliable, because the surface alloy is very brittle and unless very thin will check off.

This process is finding considerable application in furnace parts, pyrometer tubes, annealing boxes, combustion tubes, etc. The original dimensions are somewhat increased by calorizing, especially on the edges. On flat surfaces, however, there is only a very slight increase (0.002-0.004 inch = 0.05 to 0.1 mm.).

Copper parts are equally well protected by calorizing. The result in this case is to produce a coating of aluminium bronze very rich in aluminium. This coating protects the copper from oxidation right up to its melting point.

Nickel may also be calorized. Calorized nickel is particularly good to use in wire form because the coating, unlike that on iron, is not brittle. Thin ribbons for resistance furnaces, etc., when calorized remain quite pliable. Iron ribbon, on the other hand, becomes very brittle and must be shaped before calorizing or else shaped hot afterwards. Calorized nickel gauze is found to be very durable for combustion screens, etc., as it does not burn and remains pliable in heat.

In conclusion Mr. Ruder stated that calorizing protects metals from oxidation indefinitely at temperatures below 1000° C. Above this temperature it still increases the life of metal parts several fold. It is to be noted, however, that it forms no protection against ordinary atmospheric corrosion, except in the case of copper. The aluminium bronze formed in this case is also protective against corrosion.

The paper was discussed by Messrs. Addicks, Hinckley, FitzGerald, Mott, Richards and Vorce.

Fixation of Atmospheric Nitrogen

The conclusion of the Friday session formed a symposium on the fixation of atmospheric nitrogen. Two papers by Mr. Summers and Mr. Washburn respectively, were first presented which had already been read at a joint meeting of the New York section of the American Electrochemical Society and of the American Institute of Electrical Engineers.

The paper by Mr. **Leland L. Summers** giving a general review of the whole situation of fixation of atmospheric nitrogen, was abstracted at length in our April issue, page 241. At Atlantic City Mr. Summers himself gave an abstract of his paper.

The paper by Mr. **F. S. Washburn** on the cyanamide process is published in full in the present issue, page 309. At Atlantic City the paper was presented in abstract by Dr. Fink in the author's absence.

A "polemical note" on commercial nitrogen fixation, by Mr. **S. Peacock,** was then read. "The fertilizer industry of the United States uses annually somewhat more than 100,000 tons of combined nitrogen, computed as ammonia, and the annual increase averages about 8 per cent. The combined nitrogen recovered in the United States from the distillation of coal for various purposes may be stated as approximately 70,000 tons per year, with an annual increase of about 15 per cent; and this increase must be assumed to be practical for several years to come.

"As encouragement to commercial nitrogen fixation, it may be stated that many organic nitrogenous substances heretofore used in fertilizers are finding other and more remunerative uses; and with each year a stronger demand is made on sources of supply which must favorably affect nitrogen fixation. A serious limiting factor is the cost. To illustrate: to grow one bushel of wheat requires nearly four pounds of nitrogen, which at present prices on the farm somewhat exceed 60 cents in cost. It is evident that the cost is practically prohibitive.

"Agricultural nitrogen hunger has been a practical fact for generations, not because ample nitrogen could not be obtained, but because it cost too much. Practically, farmers resort to a form of nitrogen fixation by growing leguminous crops in rotation and otherwise, but unfortunately legume nitrogen is scarcely less costly than the commercial product. Commercially, the promblem is clear and explicit; either the price of farm products must be materially increased, or the cost of combined nitrogen must be lessened. The former may or may not indicate a confession of incompetency on the part of industrial chemists; it is the problem we have to consider.

"As a commercial undertaking, nitrogen fixation must remain substantially dormant so long as the ammonia produced as a by-product of coal distillation remains of such relative amount that it is capable of controlling the rewards of capital invested in nitrogen fixation. It may be accepted as a fact that no nitrogen fixation method has as yet been publicly proposed which can produce combined nitrogen as cheaply as coke by-product ammonia. However, many very prom-

ising processes have been suggested, and it is to be hoped that some one or more will prove successful. The paramount objective must be a producing cost at the factory not in excess of 4 cents per pound of ammonia; such process will lessen the cost of bread and greatly expand the consumption of fertilizer nitrogen.

"It is doubtful if any process simply effecting nitrogen fixation will attain the necessary efficiency; it is probably essential to work out a combination process which not only fixes nitrogen, but also accomplishes one or more additional useful reactions. An illustration of such process is the complementary formation of calcium carbonitride and phosphorus nitride, using a mixture of phosphate rock and carbon, with but one heat effect.

"With the low cost ammonia, oxidation processes will follow, solving the problem of cheap nitric nitrogen and such compounds as ammonium nitrate. The weak point of American industries generally is the enormous proportion of costs permitted to selling and distribution. Therefore, the concentration of associated values in final end products is an important factor. Thus, ammonium nitrate or ammonium phosphate are more economical than ammonium sulphate, calcium phosphate or sodium nitrate, as the latter carry constituents useless or worse than useless for industrial purposes.

"As the fertilizer industry must be regarded as the chief support of nitrogen fixation, the end products must be suitable for fertilizer needs. This implies a product constant in composition, soluble in water, not deliquescent, and one whose component parts do not readily assume undesirable forms, such as a gaseous or insoluble form. It is essential also that, when mixed with other fertilizer materials, such, for instance, as potassium salts, no reactions may occur tending to make the mixture hard and lumpy, or in any way lessen its dry granular state; otherwise the material cannot be used in distributing machines, and thereby becomes practically worthless.

"It may be assumed as a governing principle that a commercially successful nitrogen fixation process must give as an end product potassium nitrate, or ammonium nitrate, or primary ammonium phosphate; and, that the factory cost must not materially exceed 5 cents per pound of combined nitrogen figured as ammonia. It is true that the present price is several times that; but, having in mind the competitive power of by-product ammonia and the vast prospective increase in the production of same, capital is not justified in supporting a nitrogen project under other conditions.

"The host of synthetic ammonia processes, of which that of Dr. Haber is the best known example, can never become commercially important, though they may have a moderate local application.

"From the point of view of a somewhat intimate acquaintance with all the nitrogen fixation processes publicly known at this time, there is nothing in the above conclusions which should in the least discourage American technologists."

A very interesting and lively general discussion followed:

Mr. Summers would not agree with Mr. Washburn's claim that the cyanamid process was *the* solution of the atmospheric nitrogen fixation problem; on the contrary, he thought the tendency of nitrogen men in this country was toward direct combustion processes. He certainly did not think that the cyanamid process was the last word.

Dr. Bennett had sent communicated discussions both of Mr. Summers' and Mr. Washburn's paper. He thought no process was at present commercial and that byproduct coke-oven ammonia would fix the cost of ammonia and determine the success or lack of success of fixation process. While the cyanamid process was the cheapest fixation process, yet ammonia from cyanamid could not compete with byproduct coke-oven ammonia.

Mr. Mott gave and discussed a mathematical equation for the efficiency of arc processes for nitrogen fixation.

Dr. Fink thought all processes should be encouraged. Dr. Richards said that the Cyanamid Company expected rapid developments in the whole field, with many changes from present practice in the near future.

Mr. J. E. Johnson, Jr., gave figures on byproduct coke-oven ammonia and suggested that in arc fixation processes an atmosphere enriched in oxygen should be used.

Mr. Summers agreed this would be theoretically better, but the dissociation which, on cooling, followed the formation of nitrogen oxides made the success illusory. It is not possible now to utilize fully the temperature of the arc, because the gas products are not quickly enough removed. There is phosphate rock in enormous quantities in this country. But the commercial trouble in this country is the expense of distribution methods; the distances are too great, or what amounts to the same thing, the freight rates are too high. Phosphate rock is sent to Europe and brought back in form of fertilizer. Of course, improvements will take place. Mr. Summers, in concluding, remarked that the Birkeland-Eyde process was the only process which had made nitric acid in Europe on a really large commercial scale and that the success of the Ostwald process, in conjunction with cyanamid, on a large scale, was still questionable.

Dr. Backeland spoke of the development of the fertilizer industry as a problem of opportunity. Belgium up to now has been using more nitrogen fertilizers than Germany and has produced yields greater than anywhere in Europe. But Belgium was compelled to do so; it was a process of gradual logical development. The rents for land in Belgium were very high (compared with this country), as the laws were made by the land owners. On the other hand the wages for farm workers (families with women and children) were low. Their salvation was the use of fertilizers and they used plenty of it to pay the landlord. As a result of the co-operation of Belgian farmers, fertilizers cannot be obtained anywhere in the world at as low a price as in Belgium. And this is the reason of Belgium's agricultural success; but the whole development took time. In time conditions in this country, favoring a greater use of fertilizers, will become more like those in Europe.

Professor Franklin referred to the spontaneous combination of oxygen with iron in presence of water, and thought that a nitride process based on the spontaneous combination of nitrogen with some metal in presence of liquid ammonia might be promising.

Dr. Whitney did not agree with Mr. Peacock's remarks on the Haber process.

The further discussion dealt largely with the question as to what will determine the price of ammonia. Besides byproduct coke-oven ammonia other sources of ammonia were discussed. The production of ammonia from Mond gas producers which, as Dr. Richards stated, is in successful operation in England, is not in use at all in this country. Dr. Baekeland called attention to peat as a source of ammonia.

Saturday Morning Session

On Saturday morning an early train was taken for Philadelphia, where the concluding sessions of the con-

vention were held at the University of Pennsylvania.

The morning session was held jointly with the Illuminating Engineering Society.

The first speaker, Dr. H. E. Ives, was introduced by the chairman, Mr. Addicks, as the personal representative of the fire-fly.

The Illuminating Engineer and Ideal Light

Dr. **Herbert E. Ives,** of the United Gas Improvement Co., Philadelphia, Pa., emphasized four important points in modern artificial illuminating practice:

(1) Lack of thorough understanding between the engineer who produces the light and the engineer who exploits this light.

(2) In spite of great improvements made in artificial illumination the intrinsic brilliancy of modern lamps is by far too intense for our eyes.

(3) The color of modern illuminants is very often not satisfactory.

(4) In the best modern illuminants the light obtained per unit power is strikingly low.

The distinctive function of the illuminating engineer is the utilization of light sources in the most efficient manner. Dr. Ives suggested that the illuminating engineer rewrite his specifications. He must tell the light producing engineer exactly what is required as a final product. Anyone can admire the dazzling intensity of the arc lamp, but it took a real student of the essentials of light production like Langley to realize that the common fire-fly is a much more wonderful light source.

Commenting upon the intrinsic brilliancy of modern light sources Dr. Ives pointed out that the tungsten vacuum filament is 300 times as bright as the brightest object by day, namely, a white surface in the sun. The nitrogen-filled tungsten lamp is 1000 times as bright and it becomes necessary to employ reflecting and diffusing media. What we require is a surface source of an intrinsic brilliancy of not over 1/1000 candle power per square centimeter. A true luminous paint which could be easily excited at will would meet this idea. A low intrinsic brilliancy is in great demand. What is really wanted is not a brilliant point, but a surface of low intrinsic brilliancy, like the surface of a window square.

The efficiencies of modern illuminants are surprisingly low. If we figure from coal 1 per cent is the best figure obtainable today. Light is actually only a small byproduct. The total luminous efficiency of a 4-watt carbon lamp is 0.42 per cent, that of the yellow flame arc 7 per cent. These figures are based on 50 cp per watt as the mechanical equivalent of light.

Flaming Arc Carbons

The paper on this subject by Dr. **William C. Moore,** which was then called up for discussion, has already been printed in full in our January issue (vol. 13, p. 52, 1915), since it had been originally presented before the New York Section of the Society.

The paper, which, in the absence of the author, had been read by Mr. Mott, was discussed at considerable length by Messrs. Barrows, Franklin, Hering, Darrah, Miller, Fink, Moon, and Richards. Dr. Fink suggested the possibilities of using flame-arc carbons in electric furnace work and Mr. Mott agreed that the flame-arc characteristics distinctly indicates such possibilities, as the voltage-current curve of the flaming arc starts at lower voltages and rises less steeply than the curve of the ordinary arc.

Lighting of Electrolytic Tank Rooms

A paper by Mr. **R. E. Harrington,** of the Edison Lamp Works, General Electric Co., Schenectady, N. Y., discussed lighting of electrolytic tank rooms by means of tungsten lamps. Correct lighting increases safety and production, two factors of vital importance. This correct lighting may be secured by the proper selection of lamps and reflectors, the porcelain enamel reflector being given the preference. Of the various methods of lighting commonly employed the system of general illumination is most universally adaptable, although localized general lighting should be used where tanks are covered by hoods. Considering the question from a cost standpoint, experience has shown that in many cases the cost of proper lighting with the modern lamps is often less than improper lighting with the older types of lamps. In addition the advantages previously mentioned are obtained.

The paper was discussed by Messrs. Lidbury, Addicks, Stephens, Barrows, Franklin, Mott, Harrington, and Hogaboom. The question of the illumination of plating shops elicited quite an extended discussion of the best methods for producing artificial daylight for the correct matching of colors.

Saturday Afternoon Session

A complimentary luncheon at Houston Hall, tendered by the University of Pennsylvania to the Society and its friends, was greatly enjoyed. The afternoon session, held like the morning session at the Harrison Chemical Laboratory, was held jointly with the American Electroplaters' Society.

Electroanalysis

The session was introduced by an immensely interesting informal address of Dr. **Edgar F. Smith,** provost of the University of Pennsylvania. Dr. Smith said that it was for the fourth time that the American Electrochemical Society held a meeting at his laboratory and that there were good reasons why the society should feel at home in the congenial atmosphere of the University of Pennsylvania, where Robert Hare had worked on calcium to improve Davy's work and where Wolcott Gibbs had been a pupil of Robert Hare and had received the inspiration which led him to suggest the use of the mercury cathode in electroanalysis.

Dr. Smith then reviewed the very extended work of many years, carried out by him and his co-workers on electroanalysis. This sketch was as interesting in its chemical details as it was as a human document. He started his work on electroanalysis in 1878, but it took a long time to get converts. But by and by he and his case won out.

The latest achievement, described at the conclusion of the lecture, is a new method worked out by Dr. Smith and his assistant, Dr. Lukens, for the quantitative separation of cobalt and nickel. It is based on the observation that with a moderate current density nickel will not be precipitated from nickel ammonium fluoride, while the cobalt is precipitated. With a higher current density the nickel is precipitated as metal on the cathode and the cobalt as dioxide on the anode.

The lecture was illustrated by experiments, among which Dr. Lukens exhibited a simple method for agitating the electrolyte.

Cleaning and Plating in the Same Solution

A paper by Dr. **Oliver P. Watts,** of the University of Wisconsin, discussed the possibility of using the same solution for both preliminary cleaning and for plating proper. The author's experiments related especially to copper plating in connection with Lovering's solution, but some experiments were also made on brass plating and nickel plating.

The paper which, in the absence of the author, had been read by Professor Frary, was discussed by Messrs. Schluederberg, Addicks, Bennett, Hogaboom, Proctor, Benoliel and Frary.

Electrolytic Lead Deposits

A paper by Professor **Frank C. Mathers** and **Asa McKinney**, of Indiana University, points out that the electrolysis of solutions of lead nitrate ordinarily produces a mass of loose crystals upon the cathode. The authors have, however, succceeded in obtaining as smooth coherent lead deposits from lead nitrtate solutions as from any other lead bath.

The best composition of the bath is: 10 per cent lead nitrate, 2.5 to 5 per cent acetic acid and 1 per cent of the residue from the commercial extraction of Curacao aloes in the manufacture of aloin. Crude aloes may be used in the place of the aloes residue, but the deposits are not as good. The aloes or the residue should be dissolved by warming in the acetic acid before adding the lead nitrate solution. The bath should not be filtered before using. A current density of 0.4 amp. per sq. dec. (3.7 amp. per sq. ft.) may be used.

Free acetic acid is necessary in the bath to avoid the formation of basic salts. Free nitric acid in place of the free acetic acid greatly hastens the deterioration of the baths, and the greater the concentration of the acid the quicker the deterioration of the baths.

A number of addition agents were tried, but none approached the residue from Curacao aloes in efficacy. The aqueous extract of poplar wood, which gave excellent deposits in acetate baths, was not satisfactory in these nitrate solutions.

The baths have a life of only six or seven weeks, after which the deposits become spongy and non-arherent; consequently it seem unlikely that this nitrate bath can have any practical use. No way was found to overcome this deterioration of the baths.

A rough but not spongy deposit shows the exhaustion of some constituent of the bath. Warming the bath for a few minutes will bring more of the aloes residue into solution and correct any trouble due to lack of addition agent. Sometimes more acetic acid must be added to replace that which has been used in chemically dissolving the lead.

The paper which, in the absence of the author, had been read by Dr. Richards, was discussed by Messrs. Bancroft (who strongly suggested the application of broad fundamental principles to addition agent experiments), Lidbury, Bennett, and Addicks.

Electroplating with Cobalt

An elaborate paper, by Professor **Herbert T. Kalmus**, Mr. **C. H. Harper**, and Mr. **W. L. Lavell**, of Queen's University, described extended cobalt plating experiments made both in the laboratory and plating shops. The following general conclusions were reached from commercial tests:

Several cobalt solutions were found to be suitable for electroplating with cobalt under the conditions of commercial practice. Best among these are the following:

Solution I B:

Cobalt-ammonium sulphate, $CoSO_4.(NH_4)_2SO_4.6H_2O$, 200 grams to the liter of water, which is equivalent of 145 grams of anhydrous cobalt-ammonium sulphate, $CoSO_4.(NH_4)_2SO_4$, to the liter of water. Sp. gr. = 1.053 at 15° C.

Solution XIII B:

Cobalt sulphate $CoSO_4$	312 grams
Sodium chloride NaCl	19.6 "
Boric acid	nearly to saturation
Water	1000 c.c.

Sp. Gr. = 1.25 at 15° C.

Cobalt plates from these solutions, on brass, iron, steel, copper, tin, German silver, lead and Britannia metal articles, of different shapes and sizes, deposited under conditions identical with those met with in general nickel plating practice, are firm, adherent, hard and uniform. They may readily be buffed to a satisfactorily finished surface, having a beautiful luster, which, although brilliantly white, possesses a slightly bluish cast.

The electrical conductivity of these solutions is considerably higher than that of the standard commercial nickel solutions, so that other things being equal, they may be operated at a lower voltage for a given speed of plating.

Solution 1 B is capable of cobalt plating on the various sizes and shapes of objects met with in commercial practice at a speed at least four times that of the fastest satisfactory nickel solutions.

Solution XIII B is capable of cobalt plating on the various sizes and shapes of objects met with in commercial practice at a speed at least fifteen times as great as that of the fastest satisfactory nickel solutions.

Plates from both of these solutions on various stock pieces satisfactorily withstood the various bending, hammering and burnishing tests to which commercial nickel work is ordinarily submitted.

These two very rapid cobalt solutions are remarkable for their satisfactory throwing power. That is, they readily and satisfactorily deposit the cobalt in the indentations of the work.

These two rapid solutions operate at these high speeds in a perfectly still solution without agitation of any kind.

These solutions are both cleaner, that is freer from creeping salts and precipitated matter, than the standard commercial nickel baths.

The cobalt deposited at this rapid speed is very much harder than the nickel deposited in any commercial nickel bath. Consequently a lesser weight of this hard cobalt deposit will offer the same protective coat as a greater weight of the softer nickel deposit. Considering solution XIII B, operating at 150 amperes per square foot, on automobile parts, brass stampings, etc., a sufficient weight of cobalt to stand the usual commercial tests, including buffing and finishing, is deposited in one minute. With the best nickel baths it takes one hour at about 10 amperes per square foot to deposit a plate equally satisfactory. Therefore, the actual weight of metal on the cobalt plate must be approximately one-quarter that of nickel.

For many purposes, under the condition of these rapid plating solutions, one-quarter the weight of cobalt, as compared with nickel, is required to do the same protective work. Consequently, if nickel is worth 50 cents a pound, in the anode form, cobalt could be worth nearly $2 a pound, in the same form, to be on the same basis, weight for weight of metal. In addition there are other advantages of cobalt in saving of labor, time, overhead, etc.

A smaller plating room would handle a given amount of work per day with cobalt than with nickel.

With these very rapid plating solutions, by the use of mechanical devices to handle the work, the time required for plating, as well as the labor costs, may be tremendously reduced. Solution I B, and particularly Solution XIII B, are so rapid as to be revolutionary in this respect.

Obviously the cost of supplies, repairs, etc., would

be less with cobalt-plating than with nickel-plating, as the size of the plant for a required amount of work is less.

The voltage required for extremely rapid cobalt plating is greater than that for most nickel-plating baths; it is not so great but that the machines at present in use may in general be operated. For the same speed of plating the cobalt solution requires much the lower voltage.

For a given amount of work the power consumption for this rapid cobalt work is less than that for nickel. This is obvious, because the total amount of metal deposited in the case of cobalt is very much less, whereas the voltage at which it is deposited is not correspondingly greater.

Ornamental work on brass, copper, tin or German silver would require only a one-minute deposit. Even wares exposed to severe atmospheric influences, or friction, could be admirably coated with cobalt in bath XIII B in 15 minutes. The tremendous possibilities of this solution are not to be completely realized unless mechanical devices are applied to reduce hand labor to a considerable extent.

Thick deposits from these solutions are vastly superior to any that we have seen produced from nickel solutions. The tendency to distort thin cathodes is less pronounced, while electrotypes and electro-dies have been given a superior thick deposit in a most satisfactory manner. The lines were hard, sharp and tough and the surface smooth. Nickel does not equal cobalt for excellence of massive plates.

Many of these tests were passed upon by uninterested skilled mechanics at the plant of the Russell Motor Car Company, who invariably reported in favor of the cobalt as above.

Both baths I B and XIII B are substantially self-sustaining once they are put into operating condition, and the amount of ageing required to do this is very much less for them than that for the present commercial nickel baths.

The paper which, in the absence of the authors, had been presented by Dr. W. Lash Miller, was discussed by Messrs. Bennett, Fink, Watts, Proctor, Hogaboom, Blum, Chapin, Lidbury, Lukins, and Richards. While most of the electroplaters present thought that cobalt plating could not become practical on a large scale until the price would be down to that of nickel, others expressed the opinion that if the electroplaters would go on with cobalt and create a demand the price would go down.

After a hearty vote of thanks the meeting adjourned. The next meeting will be held in San Francisco on September 16, 17, 18, 1915, and it is proposed to hold joint sessions with the American Institute of Mining Engineers and the American Institute of Electrical Engineers.

The following is an alphabetical list of those who registered at the meeting:

Mr. and Mrs. Lawrence Addicks, Douglas, Ariz.; Wm. H. Adolph, Philadelphia, Pa.; T. R. Alexander, Jr., Philadelphia, Pa.; Walter Arthur, Philadelphia, Pa.; L. H. Baekeland, Yonkers, N. Y.; Samuel Barr, Philadelphia, Pa.; G. S. Barrows, Philadelphia, Pa.; E. H. Bedell, New York City; Wm. J. Bell, Philadelphia, Pa.; S. D. Benoliel, Philadelphia, Pa.; E. Blough, Pittsburgh, Pa.; Wm. Blum, Washington, D. C.; Marston T. Bogart, New York City; A. F. Borbeck, Philadelphia, Pa.; P. A. Borek, New York City; Mr. and Mrs. de Courey Browne, New York; A. S. Callen, Philadelphia, Pa.; H. C. Chapin, Cleveland, O.; Mr. and Mrs. H. B. Coho, Mt. Vernon, N. Y.; Jacob Y. M. Connell, Darby, Pa.; V. F. Cooper, Buffalo, N. Y.; Wm. A. Cowan, New York City; S. F. Cox, Princeton, N. J.; Mr. and Mrs. J. S. Crider, Cleveland, Ohio; R. A. Crider, Cleveland, Ohio; T. E. Crossman, New York City; Mr. and Mrs. W. R. Cymor, Cleveland, Ohio; N. E. Dabolt, Mt. Vernon, N. Y.; C. Dittman, New York City; Jos. L. Dixon, Philadelphia, Pa.; John V. N. Doer, Denver, Colo.; John H. Dorricoth, Philadelphia, Pa.; Miss Emlen, East Orange, N. J.; G. S. Ettla, Philadelphia, Pa.; J. Wm. Fehnel, Bethlehem, Pa.; C. G. Fink, East Orange, N. J.; Mr. and Mrs. F. A. J. Fitz Gerald, Niagara Falls, N. Y.; H. S. Flanegan, Mt. Vernon, N. Y.; W. S. Franklin, Bethlehem, Pa.; Francis C. Frary, Minneapolis, Minn.; F. S. Fuller, Schenectady, N. Y.; A. E. Gibbs, Buckingham Que.; Miss Mabel E. Gibbs, Buckingham, Que.; Mrs. W. T. Gibbs, Buckingham, Que.; H. W. Gillett, Ithaca, N. Y.; J. S. Glaze, Niagara Falls, N. Y.; Jac. S. Goldbaum, Norwood, Pa.; Jas. J. Guetz, Philadelphia, Pa.; R. E. Harrington, Newark, N. J.; August Heck, Philadelphia, Pa.; E. G. Henderson, Windsor, Ont.; Carl Hering, Philadelphia, Pa.; Edwin V. Hicks, Philadelphia, Pa.; J. Bennett Hill, Philadelphia, Pa.; A. G. Hinckley, Niagara Falls, N. Y.; H. K. Hitchcock, Pittsburgh, Pa.; Geo. B. Hogaboom, New Britain, Conn.; C. A. Holkesvig, Gibbsboro, N. J.; A. H. Hooker, Niagara Falls, N. Y.; Mr. and Mrs. W. F. Hubley, East Orange, N. J.; G. A. Hulett, Princeton, N. J.; O. Hutchins, Niagara Falls, N. Y.; Herbert E. Ives, Philadelphia, Pa.; J. E. Johnson, Jr., New York City; Roy Kegeneis, Philadelphia, Pa.; Mr. and Mrs. H. W. Kellogg, Niagara Falls, N. Y.; C. E. S. Kimer, Pittsburgh, Pa.; H. F. Kleinfeldt, New York City; Wilson Kutz, Philadelphia, Pa.; Edw. W. Lawler, Bayonne, N. J.; F. A. Lidbury, Niagara Falls, N. Y.; Charles F. Lindsay, Bridgeport, Conn.; Mr. and Mrs. L. M. Miller, Schenectady, N. Y.; W. Lash Miller, Toronto, Can.; H. S. Miner, Gloucester, N. J.; Wm. Roy Mott, Cleveland, Ohio; J. M. Muir, New York; John H. Müller, Philadelphia, Pa.; E. F. Northrup, Princeton, N. J.; N. Petinot, New York; Wm. Petinot, New York; Chas. H. Proctor, Arlington, N. J.; Jos. W. Richards, South Bethlehem, Pa.; E. G. Rippel, Buffalo, N. Y.; Howard S. Roberts (2nd), Philadelphia, Pa.; E. F. Roeber, New York City; F. W. Roller, New York; S. E. Ruder, Schenectady, N. Y.; L. E. Saunders, Niagara Falls, N. Y.; Carl G. Schlueederberg, Pittsburgh, Pa.; Irvin Scioba, Philadelphia, Pa.; Mr. and Mrs. E. M. Sergeant, Niagara Falls, N. Y.; F. T. Setchfield, Salt Lake City, Utah; John M. Shrigley, Williamson School, Pa.; W. Acheson Smith, Niagara Falls, N. Y.; Walter F. Smith, Philadelphia, Pa.; W. M. Snow, La Salle, Ill.; L. L. Summers, Chicago, Ill.; O. R. Sweeney, Philadelphia, Pa.; Walter T. Taggart, Philadelphia, Pa.; Eben T. Takamine, New York City; Johich Takamine, New York City; H. S. Taylor, Princeton, N. J.; F. J. Tone, Niagara Falls, N. Y.; Phil. Uhl, Philadelphia, Pa.; G. D. Van Arsdale, New York City; Mr. and Mrs. L. D. Vorce, Detroit, Mich.; D. E. Weintraub, Lynn, Mass.; T. A. Witherspoon, Washington, D. C.; W. R. Whitney, Schenectady, N. Y.; Hiram S. Wilkins, Philadelphia, Pa.; A. M. Williamson, Niagara Falls, N. Y.; C. A. Winder, Niagara Falls, N. Y.; Chas. Wirt, Philadelphia, Pa.; F. C. Woodside, Pittsfield, Mass.; Mr. and Mrs. J. A. Yunck, South Orange, N. J.

Metallurgical and Chemical Engineering in Great Britain

(By Our London Correspondent)

The British Aniline Dye Industry

The Prospectus of British Dyes Limited

On March 6 the prospectus of British Dyes Ltd. was issued to the public. The authorized share capital is £2,000,000 debentures (for which public subscription was invited) and £1,500,000 4 per cent mortgage debentures to be advanced by the Government. The prospectus follows closely upon the lines of the Government announcement in the House of Commons on the subject, to which I referred to in my last letter. The following points only need mention: (a) the articles of association provide powers for the appointment of committees, including an advisory committee "of persons conversant with the science and practise of dying to advise the directors." (b) If the provisional agreements as to the acquisition of existing dye producing concerns are carried out, their present chemists and staff are to be retained as far as may be expedient. (c) Priority of supply of the company's product is reserved for shareholders subject to their signing a five years' agreement "to take their supplies from the company in all cases where the company is able to provide the same . . . of good quality and suitable for the consumers' business, and prices are reasonable." The dividends payable on the ordinary share capital are to be limited to 6 per cent until the debenture capital is extinguished. There are two Government nominees on the Board of Directors, Sir Frank Adams and Sir Gilbert Claughton. The remaining seven directors are representatives of the industry concerned.

British Dyes Limited—Its Critics

Naturally criticism has not been stinted, and it has been leveled from many points. On the one hand comes the demand for a protective tariff to foster the new industry. On the other hand doubts are raised as to our capabilities to develop the industry on an adequate scale in a worryingly brief space of time.

Still, when all is said and done the scheme is one of many which has received the best measure of support. Sir William Ramsay has come into the field with a criticism directed at the compositon of the board of

directors and speaks strongly on the absence of the scientific element on the board. To a very large extent this is inevitable. In a new industry of this character we have yet to evolve the equivalent of the kings of our iron and steel industry of the past like Sir Lowthian Bell or Sir Henry Bessemer, or to mention one name only, Sir Robert Hadfield, of to-day.

In far too many fields here we recruit commercial men and financiers for the boards of directors, and eschew the scientist and man of practical and technical experience. The result of this segregation has been woeful. The scientist and man of practical and technical experience is too often a child in matters financial and commercial. The financier, on the other hand, lacks to an even greater degree that technical knowledge and the scientifically imaginative foresight which has done so much in other countries. With all our inherent ingrained conservatism, one cannot but believe that the new type will be evolved and that speedily. A certain racial adaptiveness will be moulded by the forces making for industrial and economic evolution which will give us the new type. Not, of course, so quickly as we need or as we desire. The trend towards it has been evident for some time, and during which there has been a marked tendency to take the scientist from the microscope and the laboratory and give him control of works and processes and a voice in shaping the administrative and commercial policy of his firm. The critics came dangerously near to wrecking the whole scheme. Important sections of the industry held aloof. The subscriptions initially received were disappointing. A public meeting of subscribers was called and as a result sufficient blocks of shares were taken up to permit of the company proceeding to allotment. The matter is now on the knees of the gods. We must wait and see what follows.

Market Prices, March, 1915

	£	s.	d.
Aluminium ingots, ton lots	85	0	0
Alum, lump, loose, ton	£5, 5 & 5	10	0
Antimony, black sulphide powder, ton	45	0	0
Borax, Brit. refined crystal, cwt	20 & 1	1	0
Copper sulphate, ton	29	0	0
Caustic soda, 70 per cent ton	10	2	6
Ebonite rod, lb	..	3	0
Hydrochloric acid, cwt	..	4	6
India-rubber, Para fine lb	..	2	5½
Mica in original cases, medium	..	3/ to 5	0
Quicksilver (Spanish), bottle	12	0	0
Sal-ammoniac, ton	49	0	0
Sulphate of ammonia, ton	14	0	0
Sulphur recovered, ton	8	0	0
Shellac, cwt.	3	5	0
Platinum, oz., nominal	9	5	0
Zinc, cwt., suplhate	..	8	0

Copper opened £64.12.6 and fell away till the 3rd, £63.2.6. On the 4th it revived to £63.15.0 and continued stronger to £67 on the 20th. A temporary drop due to stoppage of exports then took place, but the price quickly recovered to £68.7.6 on the 22nd and £69 on the 24th, since easing a little to £68.5 on the 24th and closes £69.2.6.

Tin opened £183, fell off to £180 on the 3rd, and then rose till £190 was reached on the 9th, and the same price after a slight decline ruled on the 12th and 15th. The price then dropped, being £171.10 on the 22nd and £169 on the 24th, and touching £165.15 on the 26th. It recovered to £171 on the 29th and closes £171.5.0.

Haematite opened 82/6 and remained this price till the 17th, when it marked 85/- and rose to 87/6 on the 22nd. Settlement, 95/-.

Scotch Pig was 63/- on the 1st and rather weaker till the 5th, when it touched 62/10½, 63/6 being reached on the 8th, and prices then became stronger to 64/10½ on the 12th and 67/4½ on the 16th, culminating in 69/1½ on the 18th. There was then a temporary decline, but recovery was made on the 22nd, and 69/6 reached on the 24th. Settlement, 75/4½.

Cleveland opened 57/1½ and declined till the 3rd 56/6, it then improved till the 9th 58/-, and dropped on the 10th to 57/0½. Recovering, it reached 63/1½ on the 18th and after a slight dip resumed this price, rising subsequently to 65/- (26th) and 67/5 by the 30th and closes 67/3.

English Lead opened £20.15 and was £21 on the 5th and £24 on the 17th, at which price it remains steady and closes.

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Recovery of Mercury from Amalgamation Residues of Cobalt-Silver Ores.—In the amalgamation of high-grade silver ores and concentrates in strong cyanide solution, as practiced in the Cobalt district, Ontario, Canada, considerable mercury remains in the residues and becomes a source of serious loss. A method of recovering this mercury has been devised by Mr. E. B. Thornhill, of Cobalt, Ontario, and is in use at the Buffalo mill at Cobalt. In the April *Bulletin* of the Canadian Mining Institute Mr. Thornhill describes his process and gives some results of operation. His patent was reviewed in this journal, January, 1915, page 63.

After amalgamation mercury exists in the residues mainly as a mercuric sulphide and partly as elemental mercury. The process consists in leaching the mercuric sulphide from the residues by means of a caustic alkaline sulphide solution, and precipitating the mercury from solution by metallic aluminum. The reactions are thus represented:

$$HgS + Na_2S = HgS.Na_2S$$

$$3HGs.Na_2S + 8NaOH + 2Al = 3Hg + 6Na_2S + 2NaAlO_2 + 4H_2O$$

In operation, the residue in the pregnant cyanide solution is filtered on a Moore vacuum filter, and the cake thus formed is washed with water to remove silver solution. The filter basket is then immersed in a tank containing the sodium sulphide solution, and this solution is slowly drawn through the cake until the effluent shows only a trace of mercury. Usually one ton of solution is used per ton of residue. The filtrate is then agitated with metallic aluminum to precipitate mercury; the precipitate allowed to settle and the clear solution decanted. The precipitate is washed with water and dried, after which the fluid mercury is separated by raking the precipitate with a hoe. The remaining powdered material is retorted and the mercury condensed in the usual manner.

The strength of the solvent used in the filtering process is important. It has been found that a solution of 4 per cent sodium sulphide and 1 per cent sodium hydroxide gives best results. If weaker solution is used the quantity of solution must be proportionately increased, with the resulting necessity of handling the increased quantity of filtrate. Commercial sodium sulphide costs $1.25 per cwt. in barrels, f.o.b. Toronto.

The precipitant used is a waste product from aluminum casting foundries. It is 75 per cent pure, the impurities consisting of copper, silica, wood, waste, grease, etc. The grease is burned off before using the aluminum. About ¼ lb. of the metal is used per pound of mercury precipitated.

Sodium aluminate does not increase in solution, some is removed as hydroxide with the mercury, some as calcium aluminate on the filter cake. By this precipitation of aluminium, caustic soda is regenerated, so that the consumption of this substance is reduced to one-tenth of a pound per pound of mercury recovered. Sodium sulphide also is regenerated, but there is a

mechanical loss of about 20 per cent in leaching, as no wash water is used.

From May, 1914, to date, 37,650 lb. mercury has been recovered at a cost of about 13c. per pound for labor and chemicals. The mercury recovered is of exceptional purity, the only determinable impurity being silver in the quantity of about ¼ oz. silver per ton.

Cyaniding at the Bullfinch Proprietary, Western Australia.—In the monthly *Journal* of the Chamber of Mines of Western Australia, for December, 1914, and January, 1915, Messrs. A. L. HAY and R. B. WILLIAMSON give many details regarding the mill and operations of the Bullfinch Proprietary Company. The ore is a mixture of both oxidized and sulphide material in about equal proportions. The metallic minerals are gold, galena, pyrite, marcasite and pyrrhotite. The galena is silver-bearing. Some native silver occurs in the oxidized ore. A flow-sheet of operations is shown in the accompanying Fig. 1. In brief, the treatment consists in breaking in a Symons gyratory; crushing by

1200-lb. stamps; hydraulic classification, with tube-milling of the oversize; pan-amalgamation of the tube-mill discharge; thickening and agitation of the classifier undersize; filtration by vacuum in a Ridgway filter; and precipitation in zinc boxes.

With stamps dropping 7 in. at the rate of 106 per minute, and crushing through 8-mesh screen on three batteries and a 4-mesh on one, the stamp duty is 11.06 tons in 24 hours. The grading is as follows:

Mesh	Per Cent
+ 10	5.55
+ 20	16.25
+ 40	14.80
+ 60	10.20
+ 80	3.35
+ 150	7.25
+ 200	2.95
— 200	39.65
	100.00

A 50-hp motor runs the batteries which consume 66 hp, the motor showing no difficulty in handling this overload.

A tailing-wheel elevates the crushed product to the hydraulic classifiers. The wheel is 40 ft. in diameter and has 112 buckets each of 720 cu. in. capacity. The peripheral speed of the wheel is 400 ft. per minute. Rope drive is used, and a manila rope 6 in. in circumference lasts 60 days. Power consumption is 7.3 hp, the wheel lifting about 2500 tons of ore and solution per day.

Tube mills are lined with corrugated chilled-iron liners which last 380 days. Plain end liners last 120 days. The tubes are belt-driven by a 40-hp motor; power consumption varies from 36 to 45 hp. Consumption of pebbles is 2.5 lb. per ton of ore crushed at the stamps. Following are gradings of tube-mill feed and discharge:

Feed to Tube Mills		Discharge from Tube Mills	
Mesh	Per Cent	Mesh	Per Cent
+ 20	15.15	+ 20	.10
+ 40	15.70	+ 40	.60
+ 60	20.85	+ 60	9.69
+ 150	37.35	+ 150	47.98
— 150	10.95	— 150	41.63
	100		100

During the above grading tests the tubes handled each 102 tons of sp. gr. 1.74. Power taken was 41.7 hp.

Amalgamation follows tube milling, being performed in grinding pans, the overflow of which is returned to the tailing wheel. Cast-iron shoes and dies are used, the former lasting three months and the latter six. About 150 lb. of mercury per month is added to the pans, and 31.2 per cent of the total value of the ore is recovered in this operation. Mercury loss is 0.005 lb. per ton of ore milled. Pans are cleaned up once a month. Power consumption for two pans is 12.5 hp.

The overflow from the conical classifiers is thickened to 1.5 sp. gr. This pulp is agitated in mechanical agitators, 18 ft. diameter and 8 ft. deep, made of ¼-in. steel plate The stirring arms make 10.5 r.p.m. Power required is 1.6 hp for each agitator. Cyanide is added at the agitators, and 5 lb. lead acetate per charge to precipitate soluble sulphides. Charges are 44 tons of pulp. Time of agitation is 10 hours. The agitated pulp is air-lifted to a tank feeding the loading vats of a Ridgway filter.

The filters are of the movable type, each having two vats, one for pulp and one for wash solution. Time of cycle of operations is:

	Min.	Sec.
Cake formation	20	0
Transport from pulp to wash tank	1	13
Washing	35	0
Transport from wash tank, discharging, thence to pulp tank	2	12
Total	58	25

Extraction is 93.34 per cent.

The five agitators, three filters, three vacuum pumps, residue pump and one 3-in. centrifugal pump are driven by a 70-hp motor by means of ropes. Average horsepower consumed is 38.

In precipitation the zinc consumption is 0.22 lb. per ton of ore, and 1.3 tons of solution is precipitated per ton of ore treated. Precipitation boxes are cleaned once a month; the precipitate is treated with acid. Consumption of sulphuric acid is 0.113 lb. per ton of ore treated. The gold-zinc slime is roasted in muffles, fluxed and melted. Bullion is 908 fine, of which 755 is gold, 133 silver, and the balance copper, lead, etc. Bullion from amalgamation is 715 fine in gold, 230 in silver and 55 base.

The cost of treating 37,976 tons of ore, including proportion of general expense and realization charges, is as follows:

Process	Cost per Ton s.	d.
Rock breaking and conveying	0	4.21
Milling	1	10.58
Fine grinding and amalgamation	1	4.04
Settling and agitation	0	11.32
Filtration	0	11.2
Precipitation and smelting	0	4.49
Disposal of residue	1	3.05
Total	7	0.89

The cost of electrical power, including repairs and renewals:

Particulars	Cost per Hp per 24 Hours s.	d.
Labor	0	5.49
Stores	0	10.92
Total	1	4.41

Water costs 7s. per 1,000 gallons, and firewood, chiefly salmon gum, morrel, and gimlet, costs 7s. 6d. per ton.

Concentration

Butchart Riffle System.—Fig. 2 shows the plan of a deck of a concentrating table of the Wilfley type fitted with riffles of the Butchart system developed at Morenci, Ariz. The riffles are the subject of a paper presented at the February, 1915, meeting of the A. I. M. E. at

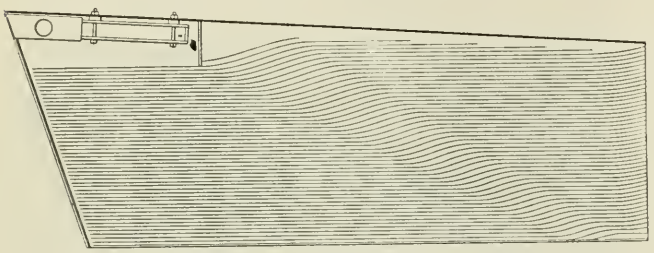

FIG. 2—BUTCHART SYSTEM OF RIFFLING

New York, by Mr. David Cole. The following comparison of the old and new systems of riffling is made.

"The old system accomplished stratification satisfactorily but has insufficient means for separating the strata. The new system not only stratifies the minerals but is provided with ample means for segregating and separating them. The old system has a single cleaning channel, or zone, consisting of the diagonal depression adjacent to and parallel with the successively advancing ends of the riffles, and this is easily overloaded in a way to defeat in large measure the object desired. The new system has as many individual cleaning channels as there are riffles upon the table, and these are not easily overloaded because they are filled in succession and back each other up.

"The old system is not adapted to the handling of very coarse table feeds, stopping for good work at about 2½ mm size, while the new system handles very large tonnages of what have hitherto been jig sizes, with a much simpler arrangement of machinery and with greatly improved general results.

"The new system eliminates the necessity of hydraulic classification beyond the desliming stage. Desliming or classification of any kind is not required on coarse feed because the table rejection is usually dewatered and reground for future treatment, and when either primary or reground material is to be handled it is necessary only to remove thoroughly the slime either in spitzslutte or drag classifiers. When classification is carried further than this too much of the fine sand is eliminated, with detrimental effect upon the work of the new table.

"The new system requires less water than the old. The water consumption of the new system is from 250 to 275 gal. per ton of feed; therefore, when these tables displace jigs the water consumption is reduced from 50 to 75 per cent, and when used instead of the old system it is reduced approximately 50 per cent.

"With these advantages the new system is very important in wet concentration, particularly where the ratio of concentration to be practiced is medium or low, and when used in conjunction with a successful flotation treatment of colloid overflows it makes possible the construction of a most desirable wet concentrating plant, adapted to large tonnages in relatively small space, and for a minimum capital expenditure per ton treated."

Mr. Cole's paper also contains some results of operation, and analyzes in detail the method of operation of both old and new systems of riffling.

Chemical Engineering

Commercial Glucose.—In *Science Conspectus* of the Mass. Inst. of Techn. (Vol. V, 1915, No. 1) George W. Rolfe discusses commercial glucose and its uses, "a much misunderstood and maligned product, necessary for certain food staples and a good substitute for more expensive ingredients." The basic process by which commercial glucose is made, is on the lines of Kirchhoff's old experiment (boiling starch with dilute sulphuric acid and neutralizing with chalk), but the methods are quite different. The "starch milk," a suspension of the granules in water, is pumped into large pressure boilers of gun metal and is cooked for about ten minutes with a few tenths of a per cent of hydrochloric acid under a pressure of about 50 lb. of steam. In percentages of total sugars and dextrines, the product contains 45 per cent maltose, 20 dextrose, and 35 dextrin. This composition has been found to be the most desirable for imparting to the product the properties most suited for a syrup which can be refined readily, and at the same time contain enough colloidal material (dextrin) to prevent its crystallizing at any concentration. This colloidal matter also renders the syrup capable of dissolving considerable amounts of cane sugar without crystallization. The rest of the dissolved substance of commercial glucose consists of 0.3 to 0.5 per cent of mineral matter. There is also about 0.08 per cent of nitrogen corresponding to five or six times its weight of organic substances from the gluten left in the starch. The glucose process does not end with the acid treatment of the starch and the neutralizing, as at this stage the dilute syrup is far from pure, containing oily matters from the corn, some undecomposed gluten and other impurities mostly in suspension. This liquor before it is concentrated to a syrup of about 80 per cent solids, undergoes a refining with boneblack closely resembling that of cane sugar, the apparatus being practically identical—filtering through bags and boneblack filters—but in the case of glucose all impurities affecting the quality of the syrup have to be removed or destroyed as there is no purification by crystallization. The following table, taken from an advertising circular of a manufacturer, shows in a concise way how the different parts of the corn kernel are utilized.

Parts of Corn Kernel	Composition	Products
1—Germ	Oil and Oil Cake	Corn Oil, Corn Oil Cake, Corn Oil Meal.
2—Endosperm (Body of the Corn)	Starch	Dry Starches, Dextrines, and by conversion, Corn Syrup [glucose] and Sugars.
	Gluten	
3—Hull	Bran	Gluten Feed.
4—Water added for steeping	Soluble Substances of Corn	

The oil is used principally for soap and for making vulcanized products used for rubber substitute. The oil-cake and meal from the cake are used as cattle feed. The gluten and bran from the starch, mixed with the soluble matters extracted by the water used to soften ("steep") the grain before grinding is made into "gluten feed" also for cattle. All these are valuable by-products for which there is a good market. The

starch in a moist state, known as "mill starch," is the raw material for making the various goods which are sold under the names of "glucose" ("corn syrup"); "corn sugar" ("grape sugar"), the latter a hard product which is largely composed of dextrose, but never known in trade as "commercial glucose" and little used as a food product; "dextrins," true adhesives which are usually made by roasting starch and entirely different in characteristics from the dextrin ingredient of commercial glucose; besides numerous "dry starches" used by laundries, confectioners, and in many other industries as well as for household purposes.

Glucose is now used in a legitimate manner to mix with cane-sugar syrup in the proportion of 85 per cent of glucose to 15 per cent of syrup, a little salt and sometimes vanillin being added to improve the flavor. The cane-sugar syrup is usually refinery molasses ("barrel syrup"), which imparts the principal flavor. These mixed syrups are sold openly as glucose or "corn syrups." Commercial glucose is used in large quantities in the manufacture of cheap jams and preserves. Apple cores and skins from fruit in its preparation for evaporation or preserving are the basis for most cheap jellies; the pecten substance and juice being extracted by the usual processes of jelly making and mixed with glucose and sugar forms a jelly material to which other fruit juices are added. The law requires such jellies to be plainly described on the label. By far the largest amount of glucose is consumed in the manufacture of candy, the peculiar properties of this syrup making it especially valuable in this industry, as has been explained. The requisite for most candy is that it should not "grain" (crystallize), and glucose, owing to its colloidal nature, is the most effective and wholesome substance to prevent this. Glucose is extensively used in industries not making food products. It is used in cheap soaps, for "filling" leather and tanning extracts, and as many of its uses in such industries are apparently for adulteration such practices have no doubt added to its reputation as the "champion adulterant."

Powdered Coal Plant at Anaconda

The use of powdered coal as fuel, restricted for so many years to Portland cement practice, is now spreading rapidly in metallurgical, chemical and industrial works. A description of a typical and commercially successful powdered-coal plant should, therefore, be of timely interest.

In our March issue (pages 181 to 185) we gave an account of the two admirable papers, presented by Mr. David H. Browne and Mr. Louis V. Bender before the American Institute of Mining Engineers on coal-dust-fired reverberatories at Copper Cliff and Anaconda.

From Mr. Bender's paper we take the following description of the powdered-coal plant at Anaconda and have added some notes and illustrations of the principal apparatus used.

At Anaconda the equipment is larger than is required for one furnace, but was installed with the idea in mind of finally equipping the entire reverberatory plant for coal-dust firing.

"The coal from the storage bin is fed into a 30 x 30-in. Jeffrey single-roll coal crusher, where it is reduced to 1 in. maximum size.

"The coal is then taken by a belt conveyor to the foot of an elevator passing over a Ding magnetic pulley, which removes any pieces of iron, bolts, etc.

"The coal is then elevated and fed by gravity into a 40 ft. x 6 ft. Ruggles-Coles drier. The drier consists of two cylinders, the one within the other. Blades of angle iron are fastened to the inner side of the outer cylinder and the outer side of the inner cylinder, so arranged that as the drier revolves the material fed into the space between the cylinders is lifted and dropped on to the inner cylinder and at the same time carried to the discharge end of the drier. The outer cylinder at the discharge end extends beyond the inner cylinder and has a revolving head riveted to it; on the inside of the head are buckets which lift the coal and deliver it out through the central casting. It takes a particle about 30 min. to pass from feed end to discharge end of the drier. At the feed end the inner cylinder is extended beyond the outer cylinder and, passing through a stationary head, is connected with the fire box.

"The gases are drawn from the fire box by means of a 72-in. Sturtevant fan, forward through the inner cylinder and back through the annular space between the cylinders to the stack. This exhaust fan is placed on top of the fire box and is connected to the drier by means of a 30-in. sheet-iron pipe. The fire box is fed with lump coal. The capacity of a drier depends upon the moisture in the coal and the speed of the fan. With Diamondville coal, we dry 18 tons per hour. During the month of September, 1914, we used 30 tons of coal to dry 1,984.77 tons of coal.

"From the drier the coal is elevated, conveyed by a screw conveyor, and discharged into a steel bin placed above the pulverizer, which is in a separate building from the drier. It is not well to have the pulverizer in the same building with the drier, for the reason that if an accident should occur, causing the coal to overflow, it might be drawn into the fire chamber of the drier and cause a fire, with possible injury to employees.

"The Raymond five-roller mill is used. It has an average hourly capacity of 4½ tons. At the top of the main shaft is a rigidly attached spider which rotates with the shaft and to the arm of which the five rollers are pivotally suspended by trunnions carried in bearings in the roller housing. Both upper and lower bearings of the roller journal are provided with long, removable, phosphor-bronze bushings. The rollers are made of cast iron with chilled faces. The grinding is accomplished by the force of centrifugal motion throwing the rollers outward against the steel bull ring. A plow is located ahead of each roller and constantly throws a stream of material between the face of the roller and the ring die.

"A fan is connected to this mill from which air is admitted underneath the grinding surface. The material is taken away by the air current as quickly as it is reduced by the rolls and blown into a 'cyclone dust collector' placed 20 ft. above the pulverizer. The mill is thus kept free of fine material. The collector is of galvanized steel, cone shaped, and has a return-air pipe leading from it to the housing around the base of the mill. A surplus-air pipe from this return-air pipe relieves the back pressure and is an outlet for any surplus air that may enter with the feed. An auxiliary collector is placed to receive the dust escaping through this surplus-air pipe.

"The finished product is discharged through a spout at the bottom of the dust collector, and is taken by a screw conveyor to a bin placed near to and above the furnace.

"The coal from the bin is introduced into the furnace by means of an air current delivered through five 'burners.' The air current is produced by a No. 11 Buffalo fan at a pressure of 10 oz., and, by means of a pipe carrying a nozzle, is introduced into a 6-in. pipe leading into the end of the furnace. The coal dust, fed from the bin by a screw conveyor, drops upon this

nozzle, which acts as a spreader, and is mixed with the air and taken into the furnace. A secondary air supply is obtained through the port holes through which the burners are projected into the furnace. These port holes are each 12 in. in diameter, which leaves an annular space 3 in. wide around each of the 6-in. pipes. By means of suitable dampers encircling the burners, this secondary air can be regulated. Another source of secondary air is through four openings between and above the burner ports, the size of the openings being regulated by putting in or taking out brick. The amount of coal fed is determined by the speed of the screw, which is easily regulated by a Reeves variable speed regulator. The entire grinding, conveying and bin system, from the drier to the burners, is air tight, as far as practicable, with the result that the entire plant is extremely clean and free from dust."

As to the excellent results obtained with this process of firing, the reader is referred to the further extracts from Mr. Bender's paper on page 184 of our March issue. In the present article we will give some further information on the apparatus used.

* * *

First, as to the **burners**, they are a special design gotten out by Mr. N. L. Warford of the Anaconda Copper Mining Co.

In Fig. 1, which shows the Warford pulverized-coal burner, A is the screw conveyor housing, B the mixing chamber housing, C the blast air nozzle, D the drive-

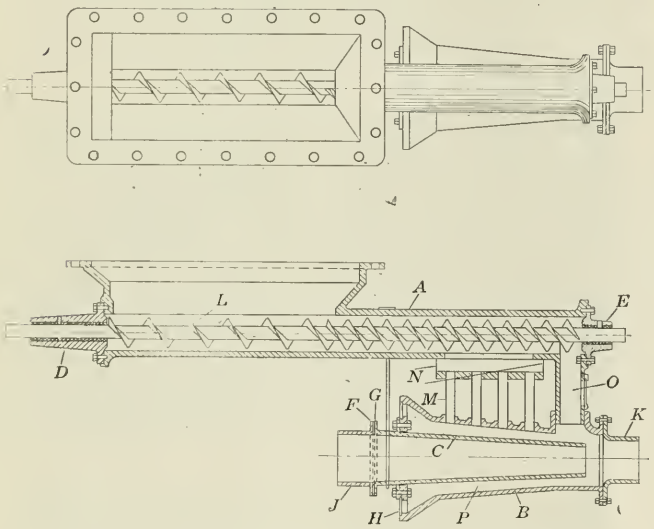

FIG. 1—WARFORD PULVERIZED COAL BURNER

end bearing of the conveyor, E the discharge-end bearing of the conveyor, F and G the blast-air control gate, H the free-air control valve or damper, J the sleeve to connect the blast-air pipe, K the sleeve to connect the discharge pipe to the furnace or fire box, L the screw-feed conveyor, and M connecting pipes between conveyor and mixing chamber.

The feeding device or control of quantity of coal dust required, consists of a screw conveyor enclosed in a dust-tight housing which is bolted to the bottom opening of the coal dust storage hopper, or bin through which the coal dust is fed into the screw by gravity. The screw carries the coal dust forward to the discharge end of the conveyor housing, where it is discharged into four receiving pipes, through a long narrow slot, and what does not go through the slot passes over and drops through a larger opening at the extreme end of conveyor housing.

The air and coal-dust mixing chamber consists of an outer housing through which a blast-air nozzle extends. The coal dust as it drops from conveyor housing through the slot is drawn into and through the four pipes onto blast-air nozzle, and the coal that does not go through slot drops on end of air nozzle, through the larger opening at end of screw conveyor, and all of the coal dust entering the mixing chamber is drawn to end of blast-air nozzle and blown into furnace or fire-box.

The principal claims made for this burner design are as follows:

The slot in the bottom of the discharge end of housing A causes the coal dust to flow in a thin stream, onto pipes M. Free air is drawn in at N and mixed with the coal as it goes through the pipes M, and is drawn onto and around nozzle C.

By having the end opening larger than the other pipes, any clogging of screw conveyor is prevented.

The pipes M, arranged as shown in the sketch, cause

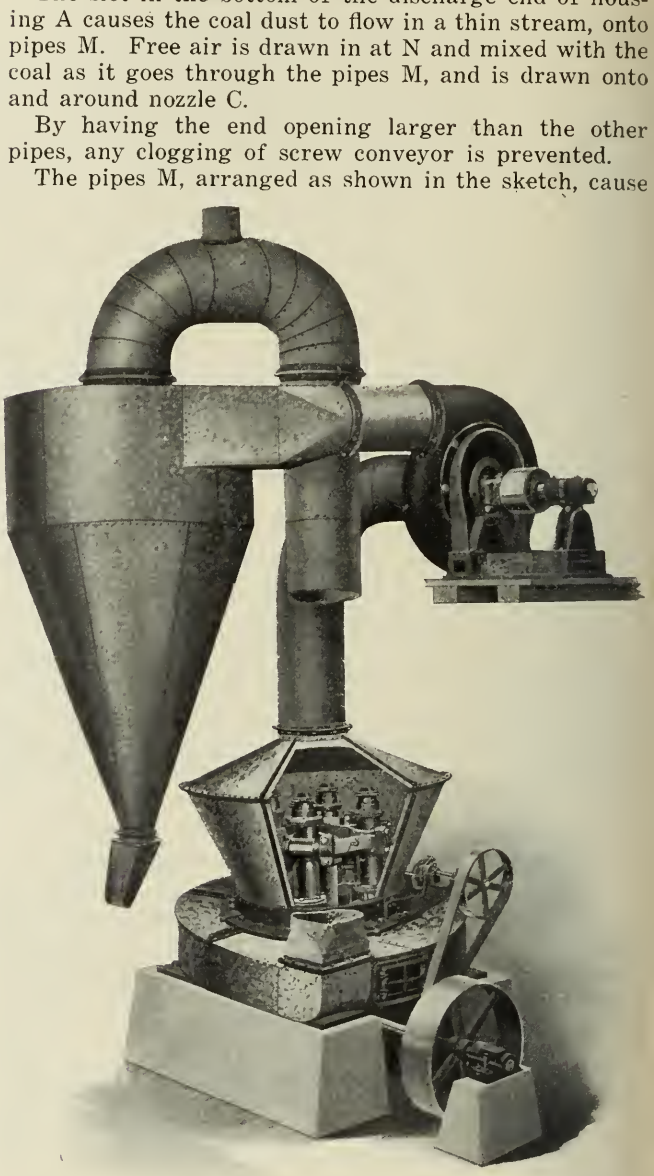

FIG. 2—ROLLER MILL WITH DUST COLLECTOR

the coal dust to get its first supply of free air as it is drawn through and the coal dust is broken up and mixed with this free air.

The free air damper or valve H, is so arranged that any amount of free air can be drawn into the mixing chamber P, up to its capacity.

The mixing chamber housing B, and blast-air nozzle C, are so arranged as to act as a siphon or injector, drawing in the free air, mixing it with the coal dust and injecting it into the furnace or fire-box, using pressure air as the power.

In general, the above claims assembled into one unit give the operator absolute control over both the coal dust and air, and thus enable him to secure thorough mixture of the air and coal dust, whereby a perfect

combustion of the coal dust in furnace or fire-box is obtained.

The Raymond five-roller mill and "cyclone" dust collector, which play quite an important part in the whole installation, are made by the Raymond Bros. Impact Pulverizer Co., of Chicago, Ill. (Fig. 2).

The mill consists of a number of perpendicularly suspended rolls, the capacity required determining the number of rolls, as the mill is built in sizes from two to five rolls. The rollers grind against a grinding ring; the material is thrown up between the roller and the ring by means of plows fastened to the slow-running central shaft, which only operates at a speed of about 115 revolutions per minute. In usual practice the speed of the mill pulley is about 240, with a system of gears of about two to one. The grinding is accomplished by centrifugal force, and as the rollers are free to swing towards the center of the mill, they will run over foreign matter, such as railroad spikes, without damage to the mill.

The mill will take coal crushed to pass a 1½-in. ring and in one operation reduce it to any fineness required from 95 per cent passing a 100 mesh to 95 per cent or 99 per cent passing a 200 mesh.

The fan, which is located above the mill, automatically separates the finely pulverized coal from the coarse and delivers it into the "cyclone collector," from which

FIG. 3—FAN FOR POWDERED-FUEL INSTALLATION

the air is returned to the mill through the return air housing, so that the same air is used over and over again.

On account of the suction of the fan, the mill is dustless in operation, and on account of the air separation a finer and more uniform powdered coal can be obtained.

It is also possible with this system to grind coal with more moisture, if necessary, although the coal should be dried, as it is cheaper to dry the coal on account of the fact that to grind wet coal decreases the output of the mill or increases the horse-power for the same output.

On account of the air separation the coal is taken away from the mill as soon as it is reduced to the necessary fineness. This fact, together with air separation, keeps the temperature of the mill and of the pulverized coal down to the lowest possible point, for which reason it is possible to store the powdered coal in bins for a longer time without danger of the coal taking fire from spontaneous combustion.

The Raymond mill with air separation will grind coal to any given fineness with about one-half the horsepower required for other systems and at the same time grind the finished product finer.

The Jeffrey single-roll coal crusher, which handles the coal coming from the storage bin, is built by the Jeffrey Manufacturing Company, of Columbus, Ohio. This is the type of coal crusher built by this company with a view to bigness, as the standard crusher of this type handles a 40-ton car of bituminous coal in 12 minutes, or more than three tons in a minute.

The drier used at Anaconda is built by the Ruggles-Coles Engineering Company, of New York City, and its construction is fully described in the excerpt from Mr. Bender's paper given above. The fan used in connection with the drier was built by the B. F. Sturtevant Company.

The No. 11 Buffalo fan, shown in Fig. 3, which is used for introducing the powdered coal into the furnace, is built by the Buffalo Forge Company, of Buffalo. It has a one-piece peripheral shell of heavy cast iron, to which side plates are fitted tightly and securely bolted. Either side plate may be readily removed, making it possible to take out the blast wheel when making repairs without entirely dismantling the machine. This fan is capable of delivering air against pressures as high as 18 oz. The one-piece peripheral shell does away with the putty joint, through which leakage is possible when the housing consists of two half shells bolted together along the peripheral line. The bearings are of the dust-proof oil-ring type, especially designed for high-speed service, the length being equal to over five diameters. An oil reservoir of large size is provided for the oil rings, making oiling necessary only at intervals of about once a month. The blast wheel consists of a heavy malleable iron hub with five arms upon which are mounted every alternate blade, there being ten blades in all.

Handling Condensation from Steam-Heating Plants

The Abbe Engineering Company, 220 Broadway, New York, have recently put on the market an automatic pump and receiver for handling the condensation from steam-heating plants. It includes a receiving tank with a special ball float inside of which operates the automatic electric switch. This automatically controls the operation of the pump. The float can be set to operate at any time: that is, it can be set to operate when the tank is half full, or three-quarters full of condensation. The pump returns the condensation to the boiler and it will pump against any pressure up to 30 lb.

The pump has its suction connected directly to the receiver into which the condensation from the heating plant flows by gravity, and the discharge from the pump connects to the boiler. This outfit is used in chemical plants, etc., to remove the condensation from any type of heating system.

The Abbe Engineering Company also has put a vacuum-heating pump on the market. This vacuum pump differs from the condensation pump inasmuch as this pump creates a vacuum in the heating system which allows the heating of largest buildings with about 1-lb. steam pressure, as the vacuum pump removes the air and condensation and returns condensation to boiler. With this latter system, vacuum valves are used on the radiators, and work automatically in connection with the vacuum pump.

Poidometer Test

The Schaffer Engineering & Equipment Company of Tiffin, Ohio, has just completed a series of tests on their poidometers for weighing and regulating the continuous flow of materials on conveyors, as described in our issue of March, 1914 (vol. 12, p. 206).

The test was made by marking the belt off in feet and placing an indicator so as to be able to get the exact travel of the belt. The machine was set to deliver 14 lb. of clay to the foot. A receptacle was placed under the delivery end of the machine and the machine was operated until it would run 6 ft. This would give 84 lb. of material. Each batch or the quantity on the 6 ft. was placed on a pair of very accurate scales and a careful record kept of each. Eighteen tests of this kind were taken. They produced 1517 lb. and should have produced 1512 lb., or, in other words, an accuracy of 99.67 per cent was obtained. The greatest variation between any tests was ½ of 1 per cent.

Fire clay was used in making this test, which was more or less sticky and was prepared so that part of it was fine material and part of it was very lumpy, some of the lumps being as large as 2 in. in size. The material was separated and fed into the machine in a divided manner, so as to produce as large a variation in the condition of the material as possible. By cubical test the material showed that it would vary in weight 20 per cent in accordance with its volume.

One test was made by using plaster containing hair, without any changes being made on the machine from its adjustment for running the clay, and a 99 per cent accuracy was obtained. It will, of course, be understood that this was about a 100 per cent change in the volume of the two materials. One test was made with 1 in. crushed limestone and an accuracy of 99¼ per cent was obtained without any adjustment being made on the machine.

Electric Steel Refining

The Snyder Electric Furnace Company, 53 West Jackson Boulevard, Chicago, is just completing the installation of a second 3-ton furnace for the Otis Elevator Company, Buffalo, N. Y. This furnace will have a basic lining, and will be used in the manufacture of refined steel castings. The contract for this second furnace was closed nine months after the first one was put in operation. It is expected that the new furnace will be running about the middle of April.

The Snyder Electric Furnace Company is also installing a small furnace for the Niagara Electric Steel Corporation, at North Tonawanda, N. Y. This furnace will be lined basic, and will have a daily output of 6 tons of refined steel.

In addition to these two furnaces, the Snyder company is just completing the installation of three different electric furnaces to be used in special chemical work. These will be in operation within the next few weeks.

The same company has recently issued a nicely illustrated pamphlet, entitled "A Better Steel at a Cost Lower Than Open Hearth for Equal Tonnages." The claim is made that the Snyder furnace produces steel of a quality better than crucible steel at a cost below that of an open-hearth furnace of equal capacity. To substantiate this claim, efficiency calculations are made. It is found that a combined gas producer and open-hearth installation has an efficiency of 7.8 per cent, while a combined gas-producer, gas-engine and Snyder electric-furnace installation has an efficiency of 8.6 per cent. The thermal efficiency of the Snyder electric furnace alone is stated to be a trifle better than 70 per cent.

Reliable simplicity is claimed for the Snyder furnace design, which is single-phase with a single electrode at the top. "Snyder 3-ton furnaces in regular daily operation are showing melting costs considerably under $20 per ton for metal in the ladle. One of these furnaces, in operation over a year, has in eight months' time only missed one heat, which it theoretically should have poured. This furnace runs only at night, using electricity purchased from the local power company on an off-peak schedule. The power is turned on at 7 p. m. and shut off at 6 a. m. During this eleven-hour period each night, four heats are made, melting from cold material. Occasionally five have been melted in the same length of time.

"With current at ¾ cent per kilowatt-hour, using a Snyder 6-ton unit, capable of producing ten heats in twenty-four hours, it is entirely practical to put steel into the ladle at a conversion cost equal to the usual records made with 50-ton open-hearth furnaces. This includes all items for labor, electricity, upkeep and repairs, and all fixed charges."

An Improved Diaphragm Material—Electro-Filtros

BY C. J. THATCHER

The lack of a satisfactory diaphragm material has probably hindered or prevented the commercial success of many promising electrolytic processes. At first thought it might seem that there should be no difficulty in obtaining cheap, porous or semi-permeable materials, suitable for prolonged commercial use as a diaphragm in any given electrolyte. Experience, or at least that of the writer, has not warranted any such optimistic view of the matter.

The readers of this journal need only be reminded of what the properties of a diaphragm material should be A diaphragm should be moistened by, but not be permeable to liquids except by diffusion, so that the anolyte and catholyte, or suspended solid constituents therein, will not commingle during considerable periods. A diaphragm is generally used to prevent such commingling of the anolyte and catholyte. For this reason a diaphragm material should either not be porous, or should have such exceedingly fine pores as to offer a high resistance to the passage of liquids therethrough.

But, on the other hand, a diaphragm material should offer little resistance to diffusion or migration of ions, so that the electrical resistance will not be so great as to be prohibitory. This requires that the diaphragm material should be somewhat porous.

These two fundamental considerations limit the range of materials suitable for diaphragms to those which are somewhat, but not very porous. But this is not all that a diaphragm should be. For commercial use it should be strong, of course, so as to stand the wear and tear of factory operations; and it should be permanent, that is, not disintegrated by the electrolytes or products of the electrolysis. If the material is not strong or permanent it should be very cheap, easily replaced, and readily obtainable in all shapes and sizes.

A moment's reflection shows that few, if any, available materials have possessed all of these requisite characteristics, and that the ideal diaphragm material for commercial purposes has not been obtainable. Porous earthenware or porcelain—the so-called Pukal ware—has perhaps approached nearest to the ideal of what diaphragm materials should be. Porous cups, with which all are familiar, are generally satisfactory for laboratory purposes, but not for large scale operations; for they are not cheap and are not available in commercially useful sizes and shapes. The writer at one time sought far and wide in this country, but without suc-

cess, to locate some concern which had, or could manufacture, suitably porous cups holding a gallon or more, or suitably porous earthenware plates 12 by 12 inches square or larger. Perhaps such materials are available abroad; they are certainly not in this country, particularly at the present time when many want them.

Other materials which have been used for diaphragms are paper, parchment and membranes; but these are not strong nor permanent enough for successful factory use in most electrolytes. Asbestos cloth is too porous, and often disintegrates rapidly. Wood can be used in a few cases, as it is in storage batteries, but not in strongly corrosive electrolytes, nor is it very effective as a separator of anolyte and catholyte liquids. There may be other materials which have been found satisfactory in isolated cases, but which the fortunate user has not been anxious to proclaim.

It may be safely said that in most instances the inventor or engineer who seeks to install, on a factory scale, electrochemical processes requiring efficient diaphragms, meets with a serious and often insurmountable problem when he casts about to secure a material suitable for his diaphragm.

Under these circumstances it is gratifying to be able to state that a material which appears to be highly satisfactory for most diaphragm purposes has been produced in this country. This new material is called "electro-filtros" and is being manufactured by the General Filtration Company of Rochester, N. Y. The writer has been using this material in small-scale factory operations for about three months under very severe conditions and feels justified in stating that it is not attacked or altered by dilute or strong acids, and that it has a permanent, low resistance but at the same time effectively and permanently prevents mixing of anolyte and catholyte liquids.

This materials is constructed of grains of finely pulverized, pure, crystalline silica, which are cemented together with a small percentage of a fused, silicious bonding substance by a process which has been patented. During the preparation of the material it is subjected to various treatments for which patent rights are also being obtained. The finished diaphragm material is white or nearly so, strong and rigid, of remarkable uniformity and resistance to acids, weak alkalies and neutral solutions. Electrochemists will perhaps be mainly interested in its strength, permanence, electrical resistance and effectiveness as a separator of anolyte and catholyte liquids.

As regards the strength of the diaphragm, it may be stated that it will stand any mechanical stresses to which it may be subjected. It will not crack nor break with a pressure of 90 pounds per square inch. A cross bend test shows that a plate 12 by 12 by 1½ inches, supported on ½-inch bearings, is capable of sustaining a load of 400 pounds applied to the middle.

In passing it may be stated that the material can be made of almost any thickness from ¼ inch up, but that it usually comes in plates ½ to 1 inch thick and which may be as large as 16 inches in one dimension. The standard shape is 12 by 12 inches, but of course the plates may be made larger or smaller as desired. It can also be made into tubes and cylinders of reasonable dimensions for exceptional processes or devices of special design. Large diaphragms can be constructed by fitting suitably sized plates in a supporting framework of suitable materials, and in which the plates may be cemented with sulphur, paraffin, retort cement, or other appropriate substances.

In the matter of permanence, electro-filtros leaves little to be desired, at least as far as use in acid and neutral electrolytes is concerned. It is not affected by any organic compound nor by any of the acids (excepting hydrofluoric) or their salts. The material is attacked by hot concentrated alkalies, but not by weak alkaline solutions, particularly at low temperatures. The electro-filtros plates which the writer has been using for nearly three months, in both dilute and concentrated acids at low and high temperatures, have not changed whatsoever during this time, as regards either their strength, permeability or electrical resistance.

The electrical resistance of this material depends largely, of course, on the electrolyte, but it is constant with any given electrolyte under constant conditions. As an illustration it may be stated that measurements recently made in an electrolyte consisting of about 60 per cent sulphuric acid and using, as the diaphragm, 12 by 12 inch plates, ¾ inch thick, which have been in continuous use during the past three months, gave the following results:

With the electrodes close against the diaphragm, *i.e.*, about ¾ of an inch apart, and a voltage drop of 5.6 volts between the poles, a current of 33 amperes flowed through the diaphragm. With the same electrodes, placed the same distance apart as before, and in the same electrolyte, but without the interposition of the diaphragm between the electrodes, a voltage drop of 5 volts gave a current of 43 amperes. That is, under the same conditions the resistance per square foot through the diaphragm was about .17 ohms, as compared with a resistance of .115 ohms through a volume of the electrolyte of the same dimensions as the diaphragm. In other words, the resistance through the diaphragm was less than twice as great as that of the sulphuric acid used as the electrolyte. This is practically the relative resistance which the same diaphragm showed when it was first used about three months ago.

Tests with other plates and in other electrolytes have sometimes given a higher relative resistance, amounting in one instance to as much as 3½ times that of the electrolyte; but the resistance has remained constant throughout the period of the test. For convenience most of these latter tests have been made with smaller electro-filtros plates, 3 by 3 by ½ inch dimensions.

With plates of this size, using, in one instance, concentrated zinc sulphate containing about 1 per cent sulphuric acid as the anolyte, and 20 per cent sulphuric acid as the catholyte, and with lead electrodes about 1¼ inches apart, a voltage between drop of 3.5 volts across the poles gave a current of .44 amperes at 12.43 P. M. and of .46 amperes at 5.49 P. M. The electrolysis had been continued during the intervening five hours, during which time the voltage remained constant. This gives a combined resistance through the electrolytes and diaphragm of about 7.6 ohms, for a 3-inch square plate ½ inch thick, which figures to 0.125 ohms per square foot. This same 3-inch square diaphragm was subsequently used for many hours as a separator between the above specified zinc sulphate and sulphuric acid electrolytes, without noticeable change in the electrical resistance through the diaphragm.

Since the anolyte and catholyte in this test were not of the same composition it was impossible to make a comparative test of the relative conductivities with and without the separator, such as that made, as above described, with the larger plate. But a similar, subsequent determination of the relative resistance of this small, 3-inch plate, when used as a diaphragm in dilute sulphuric acid, showed that the resistance through the diaphragm was 2 ohms. Through the same dilute sulphuric acid electrolyte, without the plate, the resistance was 1.26 ohms.

So that the resistance through the diaphragm with a given electrolyte was again less than twice that of the resistance of a body of the same electrolyte of the same dimensions as the diaphragm; and even after this dia-

phragm had been used for many hours as a separator in electrolytes containing a metal salt.

The behavior of this diaphragm material in weak alkaline solutions was determined by the following tests: A small 3-inch square diaphragm was placed in an electrolytic cell, both compartments of which were filled with about 20 per cent sodium hydrate solution. After standing for 24 hours the resistances through the diaphragm and through the volume of the electrolyte of the same dimensions as the diaphragm were determined as above described. The resistance through the diaphragm was found to be 3 ohms, and that through the same sodium hydrate electrolyte, without the diaphragm, 1.3 ohms. The permeability of the plate did not change during the period before specified. Tests showed that the caustic soda solution could be forced to percolate through the plate only very slowly, even under considerable pressure.

The foregoing figures show that the increase in the resistance of an electrolytic cell in which electro-filtros is used as a diaphragm is remarkably low. In electrolytic cells in which the electrodes are placed any considerable distance apart, or in which the electrolytes themselves have any considerable resistance, the increase in the resistance occasioned by the use of electro-filtros as a diaphragm is practically negligible.

For example, in any large electrolytic cell in which the electrodes are, say, 12 inches apart, and in which the total internal resistance of the cell is, say, 0.5 ohms, or $0.5 \div 12 = 0.04$ ohms per linear inch of the electrolyte between the poles, then the interposition of an electro-filtros diaphragm one inch thick between the electrodes would increase the resistance about $0.04 \times 2 = 0.08$ ohms. So that the total resistance between the electrodes, using the diaphragm, would be 0.58 ohms as compared with 0.50 ohms without the diaphragm, and the increased resistance due to the diaphragm would be practically negligible.

That electro-filtros diaphragms offer such a negligible resistance to the passage of the electric current is the more remarkable when viewed in connection with the impermeability of the material and its effectiveness as a separator between electrolytes of different compositions.

The following facts illustrate the impermeability of this diaphragm material, and show how far it prevents mixing of anolytes and catholytes.

One compartment of an electrolytic cell, provided with the 12 by 12 inch electro-filtros diaphragms which have been continuously used for the past three months, was filled recently with dilute sulphuric acid, the other compartment being empty at the start of the test. Since the diaphragm was placed vertically in the cell and the compartment at one side was filled with the dilute acid, there was a head of about 12 inches. The compartment filled with the dilute acid at the start of the test was about 12 by 5½ inches, and of course 12 inches deep. During the course of an hour the level of the acid fell ⅜ of an inch. Neglecting the leaking around the cemented edges (which was considerable), this indicates that only about 600 c.c. of acid could be forced to percolate through the diaphragm with a pressure of 12 inches of dilute acid in one hour. In a similar test of another diaphragm which had also been in continuous use for three months 650 c.c. of dilute acid was forced through the plate in one hour.

All who have had experience with the high rate of flow of liquids through diaphragm materials which have hitherto been available, will appreciate the advantage of a diaphragm material such as electro-filtros, which so effectively resists the passage of liquids through its interior, and at the same time possesses such a low electrical resistance as is shown by the tests previously described. Other tests, which it is unnecessary to describe in detail, show that this new diaphragm material has and retains the same impermeability to other electrolytes, both acid and alkaline, and neutral salt solutions.

These tests, it is believed, establish that electro-filtros is a permanent and effective diaphragm material; that it is not a filtering medium as are most diaphragm materials. This material is permeable, practically, only to diffusing liquids or migrating ions, which accounts for its low resistance to the passage of the electric current and its effectiveness in preventing commingling of the constituents of anolyte and catholyte liquors.

New Cupels

The Joseph Dixon Crucible Company, Jersey City, N. J., have put on the market what they term "Dixon's wonder cupels" for the use of refiners and assayers.

These are made in three sizes, 1¼ in., 1½ in. and 1¾ in. in diameter. They are not only strong and handable, but the absorption of silver into the cupel is much less than with cupels made from bone ash when used under similar conditions. They are made of such strength that they will not break in handling, and, in fact, meet exactly the requirements of the assayer.

The foreign manufacturing districts where clay and sand crucibles are made are in so deplorable a state at present that it has been a question for some time past if it would be possible for them to fill the demand of the laboratories and refineries of this country. The Joseph Dixon Crucible Company have now entered the field of assay crucibles, scorifiers and goods of a like nature, so that at present they have a fairly complete line of this class of goods. So far the sale has not been of so great a volume that they have been able to compete in price with foreign makers, but as scarcity increases and larger orders are secured there is little doubt but that as low, or possibly lower, prices can be made than imported goods of a similar nature now sell at.

The Schaeffer & Budenberg Mfg. Co., of Brooklyn, N. Y., has completed occupation of their new plant at Berry and South Fifth streets, near the Bridge Plaza (Williamsburg Bridge) in Brooklyn. The new building is a seven-floor reinforced-concrete structure with 10,000 square feet floor space to the floor. The company was founded in 1850 and has manufacturing plants in all parts of the world; one of their European factories has upward of 5000 employees. The Brooklyn firm was established in 1878. The products of the company are a complete line of thermometers, gauges, recording gauges, recording thermometers, counters, time recorders, indicating and recording tachometers, electric pyrometers, steam, oil and gas engine indicators, steam calorimeters, gauge testers and other instruments. One-half of an entire floor in the new main office is used as an exhibition room and equipped with a representative and complete line of the many instruments and testing apparatus made by the concern.

The **C. & G. Cooper Company**, of Mt. Vernon, Ohio, has issued Bulletin 54 on Cooper gas engines. It contains brief and well illustrated descriptions of some important gas engine installations recently made in this country. Among them are three 27½ in. x 42 in. twin tandem double-acting Cooper gas engines, direct driving low and high-pressure gas compressors, at the Taft, Cal., station of the Southern California Gas Company. These units deliver 30,500,000 cubic feet of free gas in 24 hours against a delivery pressure of 450 lbs.

What the Panama-Pacific International Exposition Means to the Metallurgical and Chemical Engineer

To be "educational" is the primary purpose of the Panama-Pacific International Exposition, and in the department of mines and metallurgy this motif is perhaps even more evident than elsewhere in the main palaces. It has been said that anyone engaged in or interested in mining and metallurgical work cannot visit the department devoted to these subjects without learning much that is of value. The general public, the young student contemplating his chosen profession, and the expert metallurgist backed by a lifetime's experience, were all planned for by those who arranged the

FIG. 1—EASTERN FACADE, PALACE OF MINES AND METALLURGY

features of the Palace of Mines and Metallurgy and exemplified therein "the natural mineral resources (metallic, non-metallic and fuels) of the world; their exploration and exploitation; their conversion into metal; their manufacture into structural forms and into raw materials for various industries."

Prof. Charles E. van Barneveld, chief of the department of mines and metallurgy, has announced it as his aim to illustrate within the palace devoted to these industries every mineral of economic importance, not merely by mineralogical and geological specimens, but by complete industrial exhibits, which begin with the undeveloped mineral resource, end with the article sold to the retail trade, and show, insofar as possible, the intermediate processes of mining, reduction and manufacture. Especial attention has been given to copper, lead and zinc, while the iron and steel industry is shown by a series of exhibits which Professor van Barneveld pronounces the most complete ever assembled.

The Palace of Mines and Metallurgy is located at the northeast corner of the main group of exhibit palaces facing on the Marina and lying between the Court of Abundance and the Avenue of Progress. The structure itself is rectangular in plan and covers an area of about 6 acres. At its center the roof curves upward into a dome 165 ft. in height and 130 ft. in diameter. Perhaps the most unique feature in arrangement is the idea of supplementing the area available for exhibits by utilizing space underground. A large area was excavated beneath the floor for a complete demonstration mine, where full-sized entries, drifts, stopes and rooms are shown with actual coal and ore faces in place, thus permitting the demonstration of various drilling, conveying, ventilating, pumping, and other equipment.

Throughout all the departments of the exposition a twofold object has been kept in view in the selection and arrangement of exhibits: first, to make the displays contemporaneous rather than historical, and second, to have machines in motion where possible, or to show processes by stages if feasible, so as to facilitate quickly acquiring a comprehensive idea of that which is presented. However, in the Palace of Mines and Metallurgy it has been made possible to go even farther than this. Hardly to be classed as an ordinary "moving exhibit" is the daily explosion which actually occurs in the mine beneath the Palace, followed by the hurried arrival of the mine-rescue and first-aid motor car, the testing of helmets in the foul gas within a glass smoke-room, and then the resuscitation of "victims" actually brought up from below. Ranking still higher in educational value is the experimental work constantly going on in the Government metallurgical laboratory established within the Palace in connection with an open metallurgical forum, which is expected to be a rendezvous for technical experts from all parts of the world.

The laboratory is something of a new departure as an exhibit in that original research is actually being conducted here at the same time that its arrangement and equipment is a display in itself. It is admitted that some interference may be occasioned by giving free access to the laboratory to all who may be interested in the work in hand, but from the number of experts who are expected to spend some time there during the exposition it is believed that the gain from their interest and suggestion will outweigh any hindrance that there may be. The model laboratory and the work under way there is in direct charge of Dr. F. G. Cottrell, chief physical chemist of the United States Bureau of Mines.

A schedule of research work actually being carried

FIG. 2—U. S. STEEL CORPORATION EXHIBIT IN MINING PALACE IN COURSE OF ERECTION

out in the laboratory includes both hydro- and pyrometallurgy, and embraces a general study of the chemistry of ore roasting. An important part of the pyrometallurgical work consists in a microscopic study of the ores under investigation. Tentative plans have also been laid for investigations of methods for the extraction of gold and silver from complex ores and of processes for the recovery of sulphur from sulfide ores. Microscopic examination of slags from copper and lead ores to discover how the metal losses occur are contemplated as well as studies of methods for simultaneously abating the smelter fume nuisance and recovering the materials carried by the flue gases. In the assay work planned, which is under the direction of Prof. G. H. Clevenger, of Leland Stanford, Jr., University, an ef-

fort will be made to develop and standardize methods at the same time that the program of tests is being carried out. In fact, this idea of attempting to standardize processes will be carried out in each department of the Bureau where experiment is conducted during the exposition.

It is not the purposes of this article to chronicle a partial list of the exhibits in the Palace of Mines and Metallurgy, but it is interesting to note that there are here no less than three moving-picture theaters, the better to exemplify processes and methods that could not be brought indoors. One of these, depicting every stage of the mining of iron ore and the manufacture of steel products, has a sufficient length of film illustrating the subject to operate steadily for eight hours without repeating. New details of the processes for treating copper and lead ores are presented, as well as the equipment of latest design used in connection with the recently developed processes. Concentrators, cyanide plants, classifiers and jigs are shown in operation, as well as models of several types of furnaces and converters. As indicative of the diversity of exhibits it may also be noted that a magnificent pipe organ is installed in such a way as to display the metal tubes as a manufacturer's product, at the same time that a musician charms the visitors with selections from the old masters.

It will be a surprise to many metallurgists to see the exhibits placed in the Palace by China and Japan. The display of the latter country is unique in that it shows manufactured articles of various metals, especially sheet copper and copper wire, made in Japan to be shipped to America for competition here with home-made products. The quality and variety of the samples exhibited are of great interest to manufacturers, when it is remembered that these products were made where the labor cost is the equivalent of only a few cents per day.

To recapitulate, the Palace of Mines and Metallurgy is a university where day after day may be spent with its staff of instructors, many of them technical experts, who are at the service of the visitor, ready to demonstrate process or method which is the last word in each particular field. The scope of the field covered is limited only by the range of the industry itself, and never before have such successful efforts been put forth to portray each detail and make readily accessible for the visitor's observation every process of the industries represented. In short, Vice-President Marshall's comment after visiting the exposition applies particularly to the Palace of Mines and Metallurgy. In the course of dedicating the exposition on behalf of the United States, he said: "I came to bear a message. I remained to become a student. This is the university of the world. It has a chair fully endowed to meet the wants and needs of each. The eye, the ear, the mind, the heart, the soul, each may have its horizon here enlarged. If there be anyone in America with a thirst for knowledge and for beauty and a longing for a liberal education such an one can here obtain it. Whoever can, even at a sacrifice of something which for the moment appears necessary, should come to see a real work of art never equalled even by a mirage."

The Sarco Engineering Company, manufacturers of the Sarco steam traps, Sarco vacuum valves and Sarco temperature regulators, have moved their offices to the new South Ferry Building, 1 State street, New York City.

Dr. **Emil E. Lungwitz**, Eastern representative of the Kelly Filter Press, has moved his office to 30 Church street, New York City.

Personal

Mr. **Philip Argall**, manager of Stratton's Independence, has sailed for London.

Mr. **James Aston** has resigned his position as professor of metallurgy in the University of Cincinnati to accept a position in the Bureau of Mines, investigating efficiency and safety in the steel industry.

Mr. **D. D. Berolzheimer**, librarian of The Chemists' Club since 1910 and organizer and manager of the "Library Service" of The Chemists' Club in 1913, has resigned to become librarian of the Barrett Manufacturing Company, New York.

Dr. **Lucien I. Blake** will deliver the Commencement address at the Colorado School of Mines, May 28. For several weeks past he has been lecturing at the school on Molecular Physics.

Mr. **James F. B. Bowles**, formerly physiologist in charge of water supply and purification plants at Panama, and recently sanitary expert with the U. S. expeditionary forces at Vera Cruz, Mexico, has associated himself with the Lederle Laboratories of New York City.

Mr. **E. M. Breed**, who for the past eight years has been District Manager of the Canadian Allis-Chalmers Ltd., with headquarters at Vancouver, has been appointed District Manager of the Pelton Water Wheel Company. He will continue his headquarters at Vancouver.

Prof. Joseph Daniels, of the mining department of the University of Washington, Seattle, will be in charge of the State's mineral exhibit at the Panama-Pacific Exposition.

Mr. **Tenney C. DeSollar**, chief engineer for the Quincy Mining Co., Hancock, Mich., has been spending part of a vacation visiting in Colorado and Missouri.

Mr. **John H. Hall**, 2 Rector Street, New York City, has discontinued his practice as consulting engineer and enters on May 1 the employment of the Taylor-Wharton Iron and Steel Company, High Bridge, N. J., as metallurgical engineer.

Mr. **J. E. Johnson, Jr.**, consulting engineer of New York City, made an address on modern power plants in the iron and steel industry before the State College Engineering Association at State College, Pa., on March 9, 1915.

Prof. **James F. Kemp**, of Columbia University, delivered the address to the graduating class of the Michigan College of Mines.

Dr. **Arthur D. Little** having addressed the American Chemical Society at New Orleans on "The Industrial Resources and Opportunities of the South" on April 1 repeated this address on April 5 before the Atlanta Chamber of Commerce and the Georgia section of the American Chemical Society at the luncheon given by the chamber.

Mr. **K. C. Parrish**, who had been in Colombia for two years developing a mining and metallurgical enterprise, is to return to the United States for a holiday.

Mr. **J. F. Mitchell-Roberts** has resigned his position as chief engineer to the Wilfley Mining Machinery Company of London, to take up private work; he will be absent from London for about nine months.

Mr. **William Russell**, special representative of the Dorr Cyanide Machinery in London, has been visiting the principal metallurgical centers of the United States.

Mr. **Howard See**, of the research department of the American Rolling Mill Co., gave a lecture before the Colorado Section of the A. I. M. E., in Denver, April 9. His subject was "Methods and Processes of Pure Iron Manufacture." The lecture was illustrated by lantern slides showing the production from raw material to finished product.

Mr. **Thomas M. Skinner**, Jr., metallurgist and assayer of Red Cliff, Col., has removed his office to Keeler, Cal.

Mr. **Robert C. Sticht**, general manager for the Mount Lyell Mining & Railway Co., has been elected president of the Australasian Institute of Mining Engineers.

Mr. **B. B. Thayer**, president of the Anaconda Copper Mining Co., is visiting the company's properties in Montana.

Mr. **E. E. Thum**, who has been superintendent of construction at Great Falls for the Anaconda Copper Mining Co., has resigned his position after eight years' service. He has been appointed professor of metallurgy in the University of Cincinnati.

Digest of U. S. Patents

Aqueous Bath, Electrodepositing, Aluminium
(*Complete prior to* 1903)

21,923, October 26, 1858, Luigi Ferrari Corbelli, of Florence, Grand Duchy of Tuscany, and Vincent Riatti, of the Duchy of Modena, assignors to L. F. Corbelli aforesaid.

Relates to the deposition of aluminium and manufacture of calomel. Several electrolytes are given, as follows: rock alum, 5931 parts, and chloride of calcium, 2076 parts; or the same quantity of rock alum with 2190 parts of chloride of sodium; or sulphate of aluminium, 4167 parts, and chloride of calcium, 2076 parts; or other aluminium salts may be substituted. The mixed, well-ground salts are dissolved in about two and one-half times their weight of water, filtered, and placed in a nonconducting vessel containing a layer of mercury on the bottom connected as anode by an insulated iron wire, the cathode being of zinc. A weak current is passed, chlorine being liberated at the anode forming protochloride of mercury, and aluminium separating at the cathode either as blackish powder or in a thin compact sheet.

140,924, July 15, 1873, John A. Jeançon, of Newport, Ky.

Relates to the deposition of aluminium, the electrolyte being any desired salt thereof, such as the sulphate, chloride, nitrate, acetate, cyanide, etc., or the double salt of aluminium and potassium, sodium, ammonium, or other metals, dissolved in distilled water and concentrated to 20 deg. Baumé (at 50 deg. Fahr.). The solution is heated to 140 deg. Fahr., a small quantity of free acid being present, which may be liberated by the addition of sulphuric acid. A plate of aluminium is used as the anode, the articles to be plated being first well cleaned and connected to the cathode. An electromotive force equal to four pairs of Smee's zinco-platinum plates, connected for intensity, is used. During the operation water and acid are added to replace that lost by evaporation, etc. If it is desirable to use solutions of aluminates as electrolytes, the solution must contain an excess of the alkaline hydrate, and the temperature at least 200 deg. Fahr.; the anode should be very small in proportion to the cathode, and is preferably of platinum. The battery power should be eight or ten large elements connected for quantity.

286,359, Oct. 9, 1883, William H. Williams, of Cincinnati, Ohio, assignor of one-third to Paul Mohr, of same place.

Relates to electrodepositing aluminium and prepares the electrolyte as follows: 2 lb. troy of dry clay or of oxide of aluminium, 2 lb. of sugar and 2 gal. of water are thoroughly mixed, allowed to settle, and filtered. To the clear portion is added 2 oz. of muriate of iron, sulphate of iron, or any other soluble salt of iron, and when the solution is effected, dissolve therein 32 oz. troy of tartaric acid. Then add slowly a strong solution of caustic potash, stirring constantly, until the tartaric acid appears to be exhausted. The mixture is then allowed to stand until the precipitate has settled, and filter. The solid portion remaining is a "salt" and may also be made by an alternative process, for which see the patent. Thirty-two ounces troy of the salt or of tartrate of aluminium are dissolved in 1 gal. of water with 28 oz. troy of cyanide of potassium and neutraiized with 32 oz. of tartaric acid. A precipitate is formed which after settling is filtered, the liquid being condensed by evaporation to the point of crystallization, allowed to cool and crystallize and the crystals collected and dried upon a sieve. To prepare the plating bath 9 oz. of the crystallized salt are dissolved in 1 gal. of water for depositing upon copper; and 16 oz. of the crystals to 1 gal. of water for plating upon iron, with 1 oz. of cyanide of potassium for each 4 oz. of the crystallized salt. As anode either platinum or carbon may be used. The strength of the bath may be maintained by immersing therein a porous cup containing some undissolved crystallized salt or oxide of aluminium; or an anode of aluminium may be immersed in the porous cup without the crystallized salt. The cyanide solution obtained just before crystallization may be used as the electrolyte if desired.

436,895, Sept. 23, 1890, John A. Jeançon, of Newport, Ky.

Relates to the electrodeposition of aluminium from an anode consisting of mixed aluminium and preferably about 30 per cent of carbon, the thoroughly agitated molten mass being cast into thin plates. The electrolyte consists of a saturated solution of persulphate of aluminium, that is, an acid sulphate of aluminium requiring a high temperature, preferably about 180 deg. to 200 deg. Fahr., to prevent crystallization. The current is of very low intensity but of great quantity. The process is said to produce a dense and compact deposit of aluminium which may be burnished and buffed.

577,186, Feb. 16, 1897, Caleb Grozier Collins, of Woodsburg, N. Y., assignor to Calvin Amory Stevens, of New York, N. Y.

Relates to the electrodeposition of aluminium and describes a two-compartment cell, the anolyte consisting of a solution of aluminium sulphate made by dissolving alumina in sulphuric acid of 45 deg. Baumé using a carbon anode or a dilute sulphuric acid with an anode of aluminium. The catholyte consists of a 20-deg. Baumé solution of potash to which is added tartaric acid or any other derivative of pure argol in the proportion of about two-tenths by weight of the potash used, there is then added about 2 lb. of phosphate of aluminium per gallon of the solution; when the phosphate is dissolved then add aqua ammonia of 26-deg. strength in the proportion of 3 per cent of the whole solution. Within the catholyte is placed the article to be electroplated.

A **2600-lb. silver nugget** was discovered March 23 on the Townsite property, Cobalt, Canada. The slab was approximately four feet square and ten inches thick. This nugget is much heavier than the famous Cobalt Gem nugget, but not so rich. It was uncovered a few feet below the surface while making an open cut on a vein on the Townsite property.

Book Reviews

Concentrating Ores by Flotation. By **Theodore T. Hoover.** 221 pages, 55 illustrations; price $3.75. London: The Mining Magazine. San Francisco: Mining Press.

To quote the preface, "this is a report of progress in a rapidly developing art". The author was for four years general manager of the Mineral Separation, Ltd., but states that the said company is not necessarily in agreement with all the opinions expressed in the book, "and, in fact, quite properly opposes some of the views set forth." Learning that his friends Sulman and Picard, with whom he had been professionally associated, are preparing a book on "Theories of Concentration Processes Involving Surface Tension," the author has refrained from giving any new and unpublished information of this nature. Aside from this, the reader will find the flotation methods thoroughly considered particularly in their historical, chronological and legal aspects and relations. It is a timely and high-grade book.

* * *

Mining Costs of the World. By **Edmond Norton Skinner** and **H. Robinson Plate.** 406 pages with maps and tables. New York: McGraw-Hill Book Company, Inc. Price (flexible morocco) $5.00.

These two mining engineers have laboriously compiled, for the benefit of engineers, managers, operators and students, from companies' annual reports, financial statements and direct communications, costs and other important operating data on 325 metal mines in different parts of the world. The book is therefore, in one way, not as broad as its title indicates. On the other hand, however, it is broader than its title, since it gives something more than costs; there are added in most cases brief descriptions of the mines, the methods of mining and reduction employed, and general information as to operating conditions. The whole makes a valuable reference book for economic geologists, mining engineers and metallurgists. The maps are poor, but the rest of the book is a credit to the publishers.

* * *

Iron Ores. By **Edwin C. Eckel.** 430 pages, 64 maps and diagrams. Price $4.00. New York: McGraw-Hill Book Company.

The book consists of three sections: I, the origin of iron-ore deposits; II, the valuation of iron-ore properties; III, the iron-ores of the world. Each section is handled in a masterly manner. Valuable chapters in Part II are those on prospecting and tonnage determinations, mining conditions and costs, and ore prices, profits and markets. In the last section the author shows a wonderful acquaintance with iron deposits almost all over the world; he criticises and revises many of the careless estimates made in the "Iron Ore Reserves of the World", printed by the International Geological Congress in 1910, and in particular he discusses most competently what should be called "ore reserves," actual and possible, and the effect of improved metallurgical methods in extending the limits of workable and treatable ore. No such masterful presentation of the subject has been published in any language, and we heartily congratulate the author on the great value of his work.

* * *

Assaying, in Theory and Practice. By **E. A. Wright.** 324 pages, 70 illlus. Price $3.00 *net*. London: Edward Arnold. New York: Longmans, Greene & Co.

"Assaying," says a technological dictionary of date 1846, is "the determining of the amount of gold or silver in an ore." Expanding with developing industries, it became "the determination of the amount of a useful metal in an ore." The subject has now become "dry assaying" and "wet assaying." The former connoting furnace methods, the latter such ordinary analytical methods as are suited to the purpose. The latter differs from analysis only in its singleness of purpose, namely, to single out, separate and determine the amount of the one useful metal.

Mr. Wraight taught assaying, in the broader sense of the term, for twelve years in the Royal School of Mines, London. The book is redolent of the ancient assay laboratory, and at its best when describing the older fire methods, although even here it is inferior to one or more American books which could be mentioned. In the field of "wet assays," where it is to be judged by the methods of advanced analytical chemistry, it is in many places antiquated. It is, moreover, fragmentary to an exasperating degree: no mention whatever is made of determination of, or even testing for, platinum or the platinum metals, in either the dry or wet way; recipes are put forth at times without attempting to explain their why or wherefore.

The practical part of the book is good, as far as it goes, but the work as a whole will be disappointing to those wanting a modern, complete and up-to-date book on assaying.

* * *

The Raw Materials for the Enamel Industry and Their Chemical Technology. By **Julius Grunwald.** Translated from the German, by **Herbert H. Hodgson** 226 pages, 21 illus. Price $2.75. London: Charles Griffin & Company, Ltd. Philadelphia; J. B. Lippincott Company.

This is the third work of Dr. Grünwald's which Dr. Hodgson has translated; the preceding ones were "Enamelling on Iron and Steel" and "Iron Enamelling and Tinning." The present book lays the foundation for these industries by discussing in great detail the character of the materials used in making enamels, their occurrence in nature and their preparation for the application by the enameller. There is little technical literature on this subject, although great advances have been made by the entrance of scientifically trained men into the business. The book treats of the chemical and mineralogical technology of feldspar, quartz, fluorspar, clay, borax, cryolite, pyrolusite, tin oxide, nickel oxide, cobalt oxide, soda, saltpeter, potash, enamelling pigments, and some other miscellaneous materials—all from the standpoint of their use in the enamel industry, but particularly as it has been developed in Germany and Austria-Hungary.

The work, besides being valuable to those making enamels cannot but be useful in progressive men in the ceramic industries, and will also interest students of the chemistry of easily fusible salts and salt mixtures, particularly the low fusing point silicates and slags.

Geschichte des Elektroeisens.—Von Dr. Tech. Oswald Meyer. 15 x 23 cm., 187 pages, 206 illustrations. Price, 8 marks ($2). Berlin: Julius Springer.

A careful compilation of the history of the electric furnace manufacture of iron, complete and well illustrated. It can hardly be called critical, since good, bad and indifferent furnaces and processes are described in somewhat similar and optimistic language. If read critically, however, no harm is done. A very complete table of 238 electric steel furnaces in operation or construction gives a vivid tableaux of the great development of the electric steel industry.

The Ways of the Chemists

All roads lead to the Pacific Coast this summer and American chemists and chemical engineers have their choice. The American Institute of Chemical Engineers will meet in Los Angeles on August 18 and in San Francisco from August 25 to 28, the American Chemical Society in Seattle from August 31 to September 3, the American Electrochemical Society in San Francisco from September 16 to 18, simultaneously with the American Institute of Mining Engineers and the American Institute of Electrical Engineers, and during the following week, September 20 to 25, the International Engineering Congress will be held.

If in view of the inherent unity of all chemical endeavor it is an axiomatic rule that meetings of different chemical societies in different cities should not conflict in date, the corollary would seem to be that meetings in the same locality should be held simultaneously and at least in part jointly. Yet here we have a string of Pacific Coast meetings extending over six weeks. Such are the ways of the chemists.

But who should be blamed? Not the chemists in the first place. When the International Engineering Congress was organized the chemists were considered a negligible quantity and not taken into consideration; this was awfully narrow from an engineering standpoint. If the Chemical Engineers and the Chemical Society stay away from the Congress, it is their good right and affords them an opportunity to strengthen their own individuality. On the other hand, the American Electrochemical Society, unafraid of having its individuality swamped, will enjoy intimate intercourse with mining and electrical engineers and its members will be able to attend the International Engineering Congress. The intercourse of ideas should be mutually helpful and should emphasize that after all the idea of chemistry not being a vital branch of engineering is ridiculously out of date.

The Iron in Lake Ores

A very valuable compilation is annually made by the Lake Superior Iron Ore Association, showing the average iron content, and in some cases also the phosphorus, silica and moisture, in the Lake Superior ores shipped during the preceding season, the Bessemer and non-Bessemer ores of each range being averaged separately. These statistics are carried back to the year 1902. It usually occurs that when one becomes really interested in statistics he desires more, and we confess we should be very glad if these statistics ranged back so that one could note the average iron content in the year when it was highest. We cannot extrapolate, of course, but we may note that from 1902 the average

iron content of all the Lake ores shipped decreased from 56.2233 per cent iron, natural state, to 55.5049 per cent in 1903. From 1903 to 1904 there was an increase of 0.07 per cent, a temporary fluctuation due to the fact that 1904 was an "off" year in iron demand and only the better ores were shipped. In 1905 there was a loss from 1904 of 0.97 per cent, and in 1906 a further loss of 0.74 per cent. Since then the annual losses have been growing less and less, but what the averages were prior to 1902 one can only conjecture.

While the iron content of a given ore deposit is determined by geology, the average iron content of the ores shipped in a season is determined partly by commercial conditions. When demand one year is poor, only the richer ores are shipped, and the average iron content of the season's shipments is certain to show either a gain or a smaller loss than usual. Over a period of years the older and richer deposits are exhausted and other and leaner ore bodies are opened. Of Lake Superior ores there is no end, and while attempts are often made to estimate the total tonnage in the ground of "commercially available" ores one might almost as well essay to determine the volume of a blunt cone without the height being given. As the cutting plane were lowered the volume would rapidly increase.

Of the 1914 shipments the tonnage and average iron content was as follows, low grade, silicious and manganiferous ores being omitted from the reckoning:

	Bessemer		Non-Bessemer	
	Tons	Per cent	Tons	Per cent
Gogebic	2,067,627	54.4771	1,387,006	53.5142
Marquette	380,484	53.9746	1,676,825	53.0141
Menominee	59,380	56.9574	2,360,684	51.5970
Vermillion	741,224	58.4818	262,946	58.7976
Cuyuna	.....	.....	736,573	50.0926
Total old range	3,248,715	55.5773	6,424,034	52.5031
Mesabi	8,075,955	52.5751	12,726,990	49.5887
All ranges	11,324,670	53.3789	19,151,024	50.5663

In 1907 the base guarantees were revised, being reduced from 56.70 per cent to 55 per cent, natural state, in the case of Bessemer ores, and from 52.80 per cent to 51.50 per cent in the cases of non-Bessemer ores. Thus in 1914 the average of old-range ores, Bessemer and non-Bessemer, barely escaped falling below the base analysis, while the Mesabi ores averaged more than two units below the base guarantees, so that as a rule Mesabi ores did not sell in the market for the nominal prices, but had penalties attached.

The cost of making a ton of pig iron has been greatly increased in the past 15 years or so by the loss of so many units of iron, while as a partial offset there have been improvements in processes of manufacture. Freights paid make up so large a part of the cost of assembling the raw materials for a ton of pig iron that the field for refinements in manufacture is limited, for as the iron content goes down, the coke and limestone requirements increase still more rapidly.

While the average iron content of the Lake Superior ores has been decreasing year by year, the cost per ton of mining has been increasing, for the ores must be sought farther and farther underground as the deposits nearer the surface become exhausted. Thus year by year more engineering and metallurgical skill is called for by the iron industry.

Flotation as a Conservation Measure

It seems reasonably probable that the flotation process will ultimately be recognized as one of the greatest agents in the conservation of mineral resources. While its adoption by American metallurgists has been long deferred, to the surprise of foreign engineers who have known of its success elsewhere for the past decade, it is now springing rapidly into prominence. There is scarcely a mill of major or minor prominence at which the process is not under investigation, provided it seems at all applicable to the ore under treatment.

The conservation of mineral resources, as relating to preventable waste, is one of the most important phases of the whole conservation movement. Forests once destroyed can be replaced in time; impoverished soil can be restored to fertility, and the development of water power and irrigation can sometimes go hand in hand and become permanent agents for good. In ore treatment, on the other hand, particularly in ore dressing, that part of the valuable material which "goes down the creek" as slime tailing is usually forever lost. For this reason any means of preventing such loss is a true agent for conservation, and in this realm flotation shines as a brilliant achievement and promise. It is to-day the accepted method of slime concentration for certain ores.

Flotation on a commercial scale was first applied in this country by Hyde on the Butte & Superior zinc ores. Prior to the use of flotation at Butte & Superior, zinc recovery was roundly 60 per cent. For the year 1914, with flotation in use, the average recovery was 88.71 per cent, and in the first quarter of 1915 it was 91.32 per cent. Coincident with the higher recovery came an increase in the grade of concentrates. This increase in recovery from 60 per cent to 90 per cent, or roughly one-third of the present figure, was due largely to the use of flotation. In 1914 Butte & Superior produced zinc at the rate of 15 per cent of the entire zinc production of the United States, and if flotation is to be credited with one-third of the output, we see that at one mill only, flotation was responsible for the production of about 5 per cent of the total zinc output of our country. These are impressive figures, and they emphasize the importance of flotation as a measure of conservation.

The prospective results from flotation in copper concentration are equally tremendous. As shown elsewhere in this issue, the recovery of copper in 1914 at five of the large western "porphyry" copper properties ranged from 66 per cent to 70 per cent. These results were obtained by ordinary methods of wet concentration without flotation. At Inspiration, on the other hand, where flotation plays an important part in the milling scheme, the recovery from sulphide ore in the experimental mill last February was 90.3 per cent, or from 20 per cent to 25 per cent greater than at the five properties mentioned above. Inspiration has been experimenting with flotation since January, 1913, at which time no copper ore was being treated on a commercial scale by flotation in this country. The process has been developed to a point where a combination flow-sheet has been

adopted for the mill now under construction, which will have a daily capacity of 14,400 tons. Production is expected to commence in June.

The results obtained at Inspiration are at least suggestive of the improvement that will be made at other mills treating similar ore, and in which slime concentration has been effected on vanners. Flotation is undergoing experiment at these mills, and may be expected soon to augment the output of copper. If results can be obtained comparable to those at Inspiration, the percentage recovery will be raised from 65 per cent or 70 per cent to about 90 per cent. The Utah, Ray Consolidated, Nevada Consolidated, Chino and Miami copper companies produced last year a total of over 321,000,000 pounds of copper, operating at greatly reduced capacity for five months of the year. Their aggregate ore reserves amount to over 585,000,000 tons of ore, containing an average of perhaps 1.6 per cent copper. If the application of flotation in the treatment of these ores should mean an increased recovery of 15 per cent or 20 per cent, the net increase looms large indeed. It is true that a part of the tonnage mentioned contains some carbonate ore, and on this portion the recovery would be necessarily lower than on straight sulphide ore: but methods have been suggested and may be successfully applied to render carbonates amenable to flotation.

The foregoing relates only to a few of the largest and most important producers of zinc and copper, because they afford an opportunity to gauge the influence of flotation in the future. Added to these, it must be remembered, will be the numerous small producers scattered throughout the West, to whom flotation will bring an even greater measure of conservation, with attendant profit. It must be obvious that on the settlement of pending litigation over flotation patents, the process will receive an impetus that will reveal its true influence and claim for it the recognition it deserves.

Spelter and Other Coating Metals

On Tuesday, May 12, the prices of tin, lead, and spelter stood in a relation that had never before obtained in the history of the metal market. The cost of the terne mixture used in making terne plate was less per pound than the price of spelter. Tin was 38.50 cents, New York, and lead 4.20 cents, making a 70 per cent lead and 30 per cent tin mixture cost 14.49 cents, while spelter at St. Louis was 15 cents. Never before had the terne mixture been cheaper than spelter. The lowest annual prices of both tin and lead fell in 1896, tin being 13.24 cents and lead 2.98 cents, making the value of a 70-30 mixture 6.06 cents. In the same year spelter averaged 3.80 cents, or 63 per cent as much, and 1896 was not spelter's lowest year. Incidentally the same day, May 18, was memorable for spelter in that the metal reached a price precisely double the highest price ever attained prior to the recent rise. That high point, 7.50 cents, was reached in September, 1912.

Everyone now understands that the phenomenal advance in spelter is due entirely to the war, first because the war largely increased the demand for brass for cartridges, and second because the war shut off the exports of spelter from Belgium and Germany. The net effect upon copper produced by the war has been very much less marked, for while the demand is increased the American copper exports that formerly went to Germany have been shut off.

What level the spelter market may attain no one can venture to predict, for when once a market transgresses its former bounds precedents become practically valueless. There is no reason to assume that the recent advance represents only a temporary rise, for purchases of spelter have lately been made, at the high prices, for deliveries late in this year and even in 1916.

With this complete dislocation in the relationships between the costs of the different coating metals, the whole matter of the consumption of metal-coated steel is opened. Spelter for coating purposes may indeed become altogether unobtainable, and in any event the relative costs of metal-coated steels are entirely altered. In 1913 there was produced 808,818 gross tons of galvanized iron and steel sheets, chiefly steel, and 66,664 tons of formed products galvanized after forming, making a total of 875,482 gross tons. It is probable that for a large part of this material substitutes will have to be found. Naturally the preference will not run to the same substitute for all purposes. For roofing purposes the various prepared roofings, which in the past few years have made large inroads on the galvanized sheet roofing trade, will doubtless be more largely employed. Painted steel sheets may be employed for this and other purposes.

For a number of uses tin plate will prove an excellent substitute. The average price of tin the past month has been somewhat under 40 cents, but 40-cent tin as a coating metal is vastly cheaper than 15 or 20-cent spelter, because tin is readily applied at the rate of somewhat less than two pounds per base box of tin plate, 31,360 square inches, or a trifle less than 0.15 oz. per sq. ft., whereas for 28 gauge galvanized sheets almost 1.5 oz. spelter per sq. ft. is required. With 40-cent tin and 20-cent spelter the tin coating could be made five times the minimum and yet leave the cost of the coating metal per square foot the same, producing for certain purposes a vastly superior article. With terne plate the comparison is naturally much more favorable, lead being only a trifle more than one-tenth as costly as tin.

Some of the sheet galvanizers, in order to preserve at least part of their trade, are now disposed to turn to the lead-coated sheet. At various times in the past efforts have been made to place a lead-coated sheet on the market, but very indifferent success has been met. The conditions are now quite altered. The manufacturer can now afford to expend more money and effort to secure a satisfactory product, and the user can afford to pay a higher price. It is already known that two sheet mills in Ohio intend very shortly to place a lead-coated sheet on the market, as a substitute for the galvanized sheet they have been selling and are still endeavoring to sell, and information that may lead to the production of a more satisfactory lead-coated sheet than has yet been made is certainly at a premium.

Readers' Views and Comments

Rapid Analysis of Bearing Metals and High-Copper Content Alloys

To the Editor of Metallurgical & Chemical Engineering:

Sir:—The author has found that the well-known method of Demorest, i.e., dissolving the alloy in concentrated H_2SO_4 and titrating with potassium permanganate and iodine for antimony and tin is inadequate for the many alloys containing considerable copper.

First, 5 per cent or more of copper severely affects the tin titration, and second, with copper over 75 per cent, as is the case in many alloys and scrap metal, the alloy is dissolved in sulphuric acid with difficulty, if at all.

For these reasons the following modification of that method is presented:

Method:—Place 1 gram of the drillings in a No. 3 beaker and add 50 c.c. of 1.20 HNO_3. After dissolving in the cold for a few minutes, place on hot plate and evaporate to about 10 c.c. Now dilute with water and boil a minute or so. After settling decant through a fine filter paper, leaving as much of the precipitate as possible in the beaker. Again boil the precipitate with HNO_3, dilute, filter all the precipitate off on the paper and wash well with hot water.

The filter paper containing all the antimonic and metastannic acids is put without drying into a beaker and 40 c.c. of H_2SO_4 (specific gravity 1.84) poured upon it. The filter paper is immediately blackened and partly dissolved. Now add a small quantity of water (about 15 c.c.) and place on the burner, watching that it doesn't boil over. (The addition of water at this point is done to prevent explosions when the $KClO_3$ is added.) Now add $KClO_3$. By repeated additions to the hot solution the carbon is completely burned out, leaving a colorless solution. If any precipitate still remains, a few minutes' vigorous boiling will dissolve it.

To the clear solution add about ½ gram of sulphur and boil one-half hour. Most of the sulphur will have disappeared at the end of that time, leaving the antimony in the "ous" condition and the tin in the "ic" condition. Cool, remove the ball of sulphur and dilute with three times its volume with water. Any lead that was carried down with the antimony and tin during the original treatment with HNO_3 will occur as $PbSO_4$ at this point and should be filtered on a gooch and weighed. (This usually happens with high tin and antimony alloys.)

The solution from the $PbSO_4$ filtration is heated to 60 deg. C. and standard permanganate run in to a deep pink color. Stir well and titrate back to colorless with standard ferrous sulphate. The iron factor of the permanganate times 1.076 gives the theoretical factor for antimony. It is always well to standardize the permanganate against C. P. antimony. The permanganate solution should be about 1/15 normal.

Tin.—After titrating, pour the solution into a large Erlemeyer flask, add one-third of the solution's volume of strong HCl(1.20) and place on hot plate. If the alloy does not contain 15 per cent or more of antimony add enough of a solution of $Sb_2(SO_4)_3$ to bring it up to that percentage. Heat to boiling and add short lengths of soft iron wire from time to time so as to evolve a rapid continuous stream of hydrogen. A stopper should be loosely fitted to exclude the air and so insure a complete reduction of the tin. Reduce in this manner three-quarters of an hour and then take off hot plate, cooling to tap water temperature with the stopper still in the flask.

When cool filter off the iron wire and precipitated antimony by means of suction through asbestos into a suction flask. Titrate immediately with 1/10 normal iodine to a blue color with starch. One c.c. of a 1/10 normal solution of I=0.00595 tin. This iodine solution is standardized against C.P. tin, reduced as above after dissolving the metal in concentrated H_2SO_4 (1.84).

Lead.—While titrating the antimony and tin, have evaporation of the nitric acid solution of lead, copper, etc., progressing after addition of 15 c.c. of concentrated H_2SO_4. When down to fumes cool and add twice its volume of water and filter off the $PbSO_4$ on a weighed gooch. Wash well and heat to dull redness for a minute or so over a Bunsen flame. This may be done to the best advantage by placing the gooch inside of a larger porcelain crucible. Weigh and $PbSO_4$ times 0.683 gives the percentage of lead. Any lead recovered from previous operations is added, giving total lead.

Copper.—Pass H_2S through the filtrate from the $PbSO_4$ determination, precipitating the copper as sulphide.

(A) If the alloy is of high copper content (around 75 per cent) dissolve the CuS in nitric acid, take down to sulphuric acid fumes and after diluting add ammonia to the neutral point and then 4 c.c. of HNO_3 (1.42). Electrolyze at three volts and 0.3 to 0.5 ampere, using revolving cathode, if possible.

(B) If, however, the copper content is low (around 10 per cent), some of the copper will have been lost previously in the analysis by being occluded with the tin and antimony precipitates and not recovered. A separate analysis is now necessary.

Dissolve 1 gram of the alloy in 40 c.c. of concentrated H_2SO_4 (1.84), boil a minute and cool. Dilute with twice its volume with water, let settle, and filter of $PbSO_4$ on a weighed gooch. Heat the filtrate to 60 deg. C. and titrate for antimony with permanganate and ferrous sulphate as described above. Checks may thus be obtained on both lead and antimony if desired.

To the solution now add 3 grams of tartaric acid, make slightly alkaline with ammonia, and add 3 c.c. of concentrated H_2SO_4. The tartaric acid holds the antimony in solution. (The solution at this point must have considerable volume to prevent the precipitation of ammonium salts.) Heat to boiling, add 2 grams of $Na_2S_2O_3$ and when dissolved add a solution containing about 1 gram of KCNS. Keep hot for fifteen minutes and then filter on a weighed gooch, wash well with hot water, dry at 110 deg. C. and weigh as CuCNS containing 0.5226 per cent of copper.

Iron.—This element occurs sometimes in scrap and should be determined at this point by precipitation with ammonia and either titrated or weighed as the oxide.

Zinc.—Boil off the H_2S from the copper sulphide filtrate and after confirming the presence or absence of iron, treat the solution so as to make it slightly acid. Heat and add 3 to 5 grams of sodium acetate and then an excess of a solution of $NaNH_4HPO_4$, $4H_2O$ and let settle. Filter the precipitated zinc ammonium phosphate on a weighed gooch, and after heating well over a Bunsen burner weigh as zinc pyrophosphate containing 42.9 per cent zinc.

METHOD FOR BEARING METALS CONTAINING ONLY Sn Sb AND Pb (DEMOREST)

Dissolve 1 gram of filings or chips in 40 c.c. of H_2SO_4

(1.84) and determine Pb and Sb as described under Copper (B). To determine the tin, take solution from the antimony titration and after reducing as described under the tin determination titrate with iodine.

Notes.—In spite of many authors' precautions against the oxidation of the reduced tin, no trouble has been experienced in this method. CO_2 has been found to be unnecessary. To make the $Sb_2(SO_4)_3$ solution used in the tin titration, dissolve 1 gram of C. P. antimony in 75 c.c. of boiling H_2SO_4 (1.84) and after cooling add 25 c.c. of water. 1 c.c. of this solution equals 0.01 gram of antimony.

The occlusion of copper in high tin and antimony and low copper alloys makes the above separate determination for copper necessary. The lead carried down is later recovered.

The large amount of $KClO_3$ necessary to oxidize the filter paper does no harm and serves to prevent the volatilization of the tin and antimony as their chlorides.

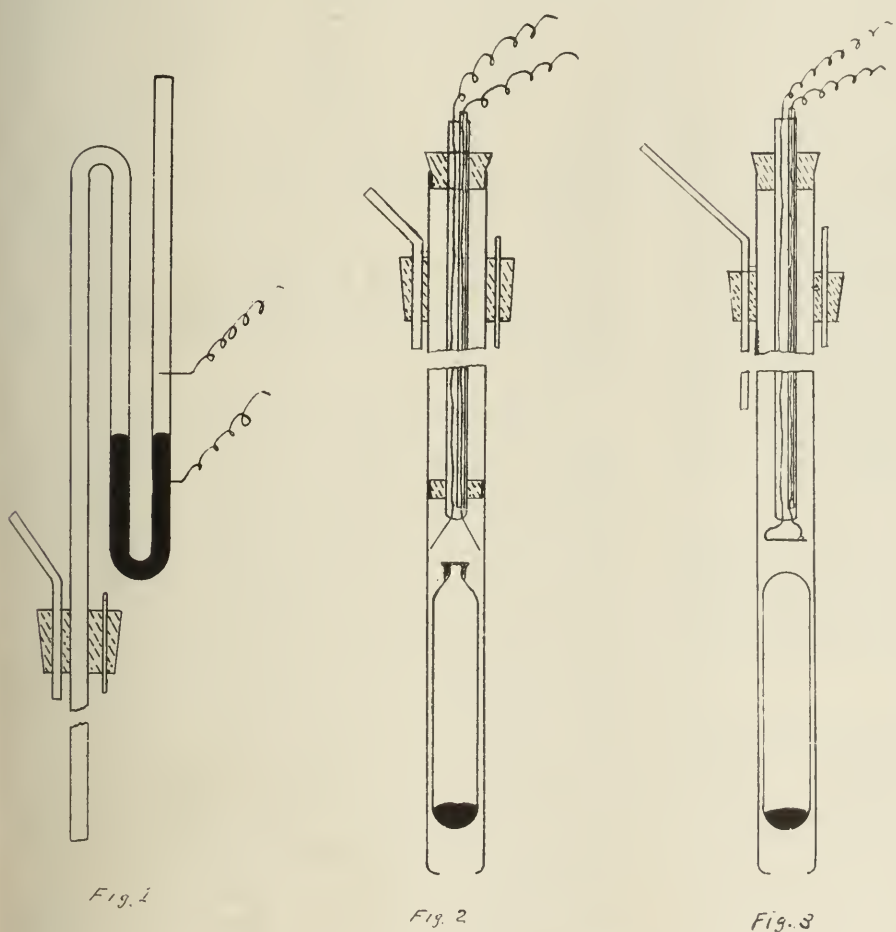
Bottle Filling Alarm

To the Editor of Metallurgical & Chemical Engineering:

SIR:—Keeping in mind water bottles while being filled from a still is positively a nuisance, and most people who have this duty to perform succeed in occasionally allowing them to overflow. To obviate this annoyance the alarms shown in the adjoining sketches were constructed. The leads are connected in series with a battery and bell.



FIGS. 1 TO 3—BOTTLE FILLING ALARM DEVICES

In Fig. 1 the center tube passing through cork reaches almost to bottom of water bottle. The angle tube is inlet and short vertical tube acts as a vent. As bottle fills pressure is produced, causing mercury to rise till contact is made, closing circuit. The contacts by this method are very satisfactory, but the mercury is apt to spill and the volume of air in tube varies with the temperature, causing alarm to ring with water at different levels under varying conditions.

To obviate these difficulties devices illustrated by Figs. 2 and 3, which are self-explanatory, were tried. The floats were made from ½ x 4-in. thin wall test tubes, weighted with mercury. In Fig. 2 the float is capped with a cartridge shell surfaced with silver foil. The wire contacts are of platinum soldered to copper leads with silver solder and fused into glass tube. The curved contact wire in Fig. 3 was rolled out thin to give it necessary flexibility.

These alarms have been in use for about three years, giving entire satisfaction.

E. J. HALL.

School of Mines, Columbia University, New York City.

Carbon Determination by the Combustion Method

To the Editor of Metallurgical & Chemical Engineering:

SIR:—The opening sentence of a communication under the above caption, in the February number furnishes an alluring text for a dissertation, but why go to the trouble—and incur expense and perhaps danger—in correcting a condition which need not or should not exist?

The simple expedient of lining the boat with powdered alundum, prevents the fused metallic residue sticking to the boat.

Boats may be made of any one of a number of different materials, but the writer recommends nickel of 22 gauge—B. & S. Blanks are cut from the sheet and stamped on a steel die; rough edges are then trimmed off and filed smooth. The boats cost a trifle under five cents each and average not less than 40 combustions.

The alundum is 60 mesh and lasts indefinitely except for such mechanical loss as is sustained in removing the fused residue. The residue is simply lifted from the bed of alundum and the boat is ready for the next combustion.

Both boat and alundum are ignited until free from carbon, before being used. The operator has his choice of a number of different materials for lining the boat but alundum is recommended.

This practice is not detailed as embodying anything new, but judging from the article above referred to, it may be new to some.

C. H. RICH.

Alan Wood Iron & Steel Co., Conshohocken, Pa.

Lead Poisoning in Manufacture of Storage Batteries is the subject of Bulletin 168 of the Bureau of Labor Statistics of the Department of Labor. The author is Dr. Alice Hamilton. It is thought that the dangers of the industry can be reduced to a minimum by installing hoods and exhausts to carry off fumes and dusts by substituting machine for hood work, by providing ample washing facilities for the workmen and insisting on strict cleanliness everywhere and by providing a separate lunch room as the only place where food may be kept and eaten.

The Western Metallurgical Field

The Porphyry Coppers in 1914

Among the annual reports issued by mining and metallurgical companies of the United States, none excel those of the great "porphyry" copper companies of the West. In addition to giving the fullest publicity to company affairs in a financial and commercial way, these companies include in their reports many interesting and valuable data on engineering operations, their cost and result. Several of them being under the control of the same group of men, their reports are uniform in arrangement and nature of data presented, thus facilitating easy comparison of the operations at different points. In the accompanying table we give the salient facts regarding the operations of the Utah, Ray Consolidated, Nevada Consolidated, Chino and Miami copper companies for 1914.

All of the companies mentioned operated at reduced capacity during the last five months of the year. The Utah company closed its Arthur plant entirely on August 6, 1914, but continued operations in the Magna plant. The latter handled an average of 12,223 tons daily throughout the year, and the former an average of 9214 tons daily for the period of operation. Recoveries were affected adversely by the presence of considerable quantities of oxidized copper minerals in the ores mined near the surface, but this condition will disappear as further progress in stripping is made. In spite of curtailed operations, however, the cost of production for the last five months of the year was 0.509 cents less per pound of copper than for the first seven months. This improvement was due partly to improvements in operation and partly to better grade of ore treated.

Operations of the "Porphyry" Copper Companies in 1914

	Utah	Ray Consolidated	Nevada Consolidated	Chino	Miami
Ore reserves, tons	342,500,000	74,765,789	41,020,296	90,270,155	36,500,000
Average content copper, per cent	1.45	2.214	1.75	1.75	1.85
Ore treated, tons	6,470,166	2,427,700	2,640,294	1,907,300	1,096,633
Average content copper, per cent	1.425	1.76	1.48	2.12	2.28
Gross copper production, lb	121,779,401	59,044,700	49,244,056	56,841,977	35,048,445
Average recovery, per cent	66.04	67.88	68.48	67.86	69.93
Average copper in concentrate, per cent	18.19	19.25	66.15	18.50	39.31
Average cost milling, cents per ton	35.36	49.88	.....	55.01	49.96
Cost of copper, cents per lb.[1]	8.131	8.839	10.16	7.68	6.46
	7.245	8.763	9.82	7.35	.....
Gold production, oz	34,729	.....	16,046	.....	.....
Silver production, oz	325,351	.....	49,631	.....	.....

[1]First figure based on net production after making smelter deductions and applying credit for gold and silver. In second figure credit is applied for all miscellaneous income.

At Ray the percentage extraction was increased, due to improved methods of operations, and cost of milling also was reduced. During the latter part of the year investigations were completed which will immediately insure lower cost of operation, higher grade of concentrate, increase in recovery and saving in smelting charges.

Nevada Consolidated completed the acquisition of the property of the Steptoe Valley Smelting & Mining Company, the latter company having been dissolved on Nov. 28, 1914. All operations of milling, mining and smelting are now conducted by the Nevada Consolidated company. Improvements at the mill consisted in adding Dorr thickeners and a new set of rolls. In the reverberatory smelting department there was a reduction in costs and fuel ratio. The capacity per furnace was increased from 481 tons per day in 1913 to 598 tons in 1914.

Chino installed an improved plant for enrichment of concentrates, thereby increasing the amount of gold in concentrates sufficiently to be credited under the smelting contract. The gold credit amounts to 2.71 cents per ton of crude ore treated, or 0.1 cent per pound of copper produced.

Miami completed changes in the mill, based on previous experiments, that will result in increased capacity and efficiency. The change consists mainly in finer grinding and additional table capacity on the sand floor, and improved methods of treating slime. The changes in treatment will result in a metallurgical efficiency as high as is possible with the present state of the art.

Flotation at Silverton, Colorado

The American Ore Flotation Company is a newly organized concern which contemplates the application of the flotation process in the San Juan district of Colorado. The company has leased the Silver Lake mill, near Silverton; has purchased the Ben Butler mining property at Mineral Point, above Animas Forks, and has taken options on the Mayflower in Arastra Gulch, and the Champion below Silverton. The mill is being equipped for flotation treatment, but will not be ready for operation until mid-summer. The promotion and operations of the company are reported to be in the hands of E. W. Weybright and D. L. Thomas, respectively, the latter having been previously an employee in the mill of the Butte & Superior Copper Company, where James M. Hyde installed and operated the first successful flotation plant in this country. Contrary to rumor, Mr. Hyde is in no way connected with the company at Silverton. The introduction of flotation in Colorado mills promises to be a large factor in increasing recovery and profits from low-grade mixed sulphide ores, particularly in improving former practice in slime concentration.

Marked Activity in the Joplin District

The continued strength of the zinc market is being reflected in unusual activity in the zinc-mining and milling districts of Missouri and Kansas. According to the Joplin *News-Herald*, the Joplin district produced 82,000 tons of zinc blende concentrates during the first four months of 1915. In view of the large number of mills being built or placed in operation, it is likely that the present rate of production is even higher. Profits for the first four months were not as large as can be anticipated at the present time. During the week ended May 9, deliveries of zinc concentrates were made on a basis of $75 a ton, 60 per cent metallic zinc. This price was previously reached in February for choice grades of ore, but the demand for second grades at that time was not good. The price of $75 represents an advance of $10 within two weeks, and the market is reported firmer than ever before in the history of the Joplin district.

New mills are being constructed and old ones rehabilitated. The Moreland custom mill has begun operations with a capacity of 150 tons per day. The mill of the Century company has been completed and is expected to be in operation shortly. Work has been resumed on the C. & S. No. 4 property after an idleness of fifteen months. The mill has a capacity of 250 tons a day. A new custom mill has been constructed in the Galena district, and nine concentrating plants are reported to have resumed operations at Aurora. A contract has been let

for the construction of a new 400-ton tailing mill for the Rollamo company north of Webb City. Near Stotts City a new 250-ton mill is being built on the Hill land. In the Lawton, Kan., district Greenfield & Lockwood have let a contract for the construction of a modern 300-ton plant.

Resumption of Copper Production in the West

It is reported that the Utah, Chino, Ray Consolidated and Nevada Consolidated copper companies are again operating at about full capacity. The improvement in the copper market and increased demand for the metal lead those conversant with conditions to believe that the increased production is warranted and that there is little or no danger of overproduction. The policy adopted by the companies last August, of retaining their working forces by offering employment at half time, has enabled them to increase production in a short period of time. The flexibility of their operations will enable these companies to curtail the output should the necessity appear.

Cyaniding at Cobalt

Prior to the outbreak of the European war many of the companies operating concentrating mills at Cobalt, Ontario, Canada, were either experimenting with the cyanidation of slime or had made definite plans for the addition of a cyanide plant to the existing mills. Among these the Cobalt Reduction Company had made many experiments which indicated the successful use of cyanidation. The plant has been constructed and was placed in operation about May 1. It will treat about 175 tons of slime per day, cyaniding that part of the pulp which formerly was treated by slime concentration, and producing bullion instead of slime concentrate. In addition to treating current slime from its own plant, the company will handle also the slime from the Cobalt Lake concentrator which will be delivered by a pipe line 1200 ft. long.

Company Reports

In the annual report of the Inspiration Consolidated Copper Company for the year 1914, General Manager C. E. Mills gives the following information under date of March 17, 1915. Copper production will begin during the month of June, the delay in the anticipated date being due to the change in milling plans and the adoption of flotation. The resultant combination flow-sheet involving the use of both ordinary water concentration and oil flotation will show an increase in copper recovery as compared with the use of either of the processes alone. Flotation testing was conducted during the entire year 1914, and at the same time experiments were made on grinding machinery. Parallel tests were run on various flow-sheets and five different flotation machines. The scheme finally adopted is, in brief, as follows: Crushing to 4-in. maximum size in gyratories, and further reducing to 1½ in. in Symons disk crushers. This work will be done at the mine. At the mill the ore will be ground to pass forty-eight-mesh by means of Marcy ball mills. The product will be treated in flotation machines. The tailings from flotation will be separated into sand and slime, the former being treated on concentration tables and the latter retreated in flotation machines. The concentrates will be dewatered in a filter plant.

The experimental plant showed a recovery during the month of February of 90.3 per cent of the copper occurring in sulphide form. The saving of oxidized forms of copper is not fully determined, but probably ranges from 20 per cent to 30 per cent. The average quantity of copper in oxide form in the ore milled last year was 0.16 per cent out of a total of 1.52 per cent copper. In such ore a recovery of sulphides of 86.7 per cent would correspond to a recovery of total copper of about 80 per cent. During 1914 the mill treated 172,722 tons of ore averaging 1.52 per cent copper. Inspiration concentrates will probably contain from 28 per cent to 32 per cent copper, and contain sufficient sulphur to make a suitable grade of matte in smelting. The mill will consist of eighteen sections, each of 800 tons daily capacity. The first nine sections are expected to be completed simultaneously, and the others before the end of this year. The transfer of the property of the New Keystone company to the Inspiration has been effected. Total ore reserves of Inspiration are estimated as follows:

	Tons	Per cent copper
Sulphide ore	46,252,000	2.01
Low sulphide material	28,698,000	1.26
Oxidized material	17,460,300	1.31
Mixed carbonate and sulphide	4,732,700	1.31
Total and average	97,143,000	1.63

The Iron and Steel Market

Developments during May in the steel market proved unexpectedly favorable. As noted in our review a month ago the future of the steel market hung in the balance. The improvement that had occurred during three or four months preceding had not continued through April and unless fresh favorable developments occurred conditions were likely to become distinctly less favorable. When the steel market is bad it may remain continuously bad and when it is good it may be continuously good for some time, but at a midway point it never halts; it must always be swinging towards the one extreme or the other.

The favorable developments in May were distinctly along two lines, export demand and railroad demand. Accurate details of export buying are largely lacking, partly because the orders are largely for war purposes, but it is known that many orders have been placed, others being still in the market, for 10,000-ton and larger lots of steel, chiefly in the form of merchant rounds for rifles and for shrapnel. Apart from war munitions, there has been Russian buying of both freight cars and rails, 9000 cars being placed in the United States and 6000 in Canada, with 7000 still to be placed. Rails purchased by Russia already exceed 50,000 tons, and statements of the total tonnage to be bought range from 100,000 to 500,000 tons.

Apart from 2500 freight cars placed at its Altoona shops the Pennsylvania railroad system has bought 14,000 cars and is understood to have arranged for 138,000 tons of rails and about 200 locomotives and about 200 passenger cars, some of the locomotives to be built in its own shops. The total tonnage involved in all these purchases is not far from 550,000 gross tons.

There has been tentative inquiry in the market for 15,000 or more cars for other roads, and a few locomotives. It is expected that the liberal buying policy adopted by the Pennsylvania will cause other roads to purchase more freely.

March exports of iron and steel totaled 175,000 gross tons, for commodities returned by weight, and with steel involved in machinery and other manufactures exported the exports may have represented 10 per cent of the steel industry's capacity. The export movement has undoubtedly increased since March and June exports may easily represent 15 per cent of capacity. In the early months of the year railroad material shipped probably did not exceed 5 per cent of capacity, but there are distinct possibilities that within a month or two railroad material may involve 15 per cent of the capacity. With such increases the recent operating rate of

70 per cent of capacity may mount to well above 80 per cent, or to a point at which the supply of labor may prove to be an important element. It is doubted whether the steel industry could find sufficient labor to operate at capacity on short notice, seeing that increases in steel demand are naturally attended by more employment outside the steel manufacturing industry.

Fabricated steel contracts let in April are reported at 107,500 net tons, against 110,000 tons in March. The monthly average in the seven months preceding was but a trifle above 50,000 tons, so that the March and April showings, while low compared with normal times, represent a great improvement.

Pig Iron

The consumption of merchant pig iron has been increasing, but very slowly. There is somewhat freer buying, but scarcely in larger lots, for given periods, than formerly. A few idle merchant furnaces have been blown in, but the total increase in production is small. It is the general opinion that few more idle stacks will be gotten into blast unless materially higher prices are offered for iron. Pig iron prices have been phenomenally steady for a long time, at low levels, but in some quarters there is an expectation that a phenomenal advance may occur within a few months to break the monotony. In the past five months the average price of all descriptions of pig iron has not varied by 25 cents a ton, but conditions are perhaps such as to encourage a very sharp advance, once one is started. Southern iron is definitely higher than a month ago, by fully 25 cents a ton. We quote No. 2 foundry, delivered Philadelphia, $14.25 to $14.50; f.o.b. furnace, Buffalo, $13; delivered Cleveland, $13.25; f.o.b. furnace, Chicago, $13; f.o.b. Birmingham, prompt, $9.50; third and fourth quarters, $9.75 to $10; at valley furnaces, 95c higher delivered Pittsburgh; Bessemer, $13.60 to $13.75; basic, $12.50 to $12.65; No. 2 foundry, $12.75 to $13; gray forge, $12.50 to $12.75; malleable, $12.75.

Steel

Fresh market transactions are very limited, consumers being covered by contracts on which occasional private adjustments are made. Prices are largely nominal at $18.50 to $19 for billets and $19 to $19.50 for sheet bars, at maker's mill, Youngstown, and at about 50 cents higher at maker's mill, Pittsburgh, with forward deliveries commanding somewhat higher prices. Rods are firm at $25, Pittsburgh.

Finished Steel

Demand for merchant bars has been excellent, as reinforced by the requirements for war purposes, and prices are strictly maintained. Plates continue weak. Galvanized sheets were advanced by the American Sheet & Tin Plate Company on May 17 from 3.40 cents to 3.60 cents, but only limited tonnages were sold at the new price, and the extreme scarcity of spelter makes it probable that further advances will occur, if indeed galvanized sheets do not disappear entirely from the market. The decrease in galvanized sheet production has caused more active competition for black sheet orders, and the black sheet market is weaker if not actually lower. On May 1 the National Tube Company advanced steel pipe, boiler tubes and line pipe by one point or about $2 a ton, other makers as a rule following the advance.

Current quotations are as follows for ordinary deliveries and are f.o.b. Pittsburgh unless otherwise noted:

Rails, standard sections, 1.25c for Bessemer, 1.34c. for open-hearth, f.o.b. mill except Colorado.

Plates, tank quality, 1.15c. to 1.20c.

Shapes, 1.20c. to 1.25c.

Steel bars and bands, 1.20c to 1.25c., base; hoops, 1.25c. to 1.30c., base.

Iron bars, 1.20c. to 1.25c., Pittsburgh; 1.17½c. to 1.22½c., Philadelphia; 1.15c. to 1.20c., Chicago.

Sheets, blue annealed, 10-gage, 1.35c.; black, 28-gage, 1.80c.; galvanized, 28-gage, 3.60c.; painted corrugated, 28-gage, 2.00c.; galvanized corrugated, 3.65c.

Tin plate, $3.10 to $3.20 for 100-lb. coke.

Steel pipe, 79 per cent off list.

Steel boiler tubes (less than carloads), 3½-in. to 4½-in., 74 per cent off list.

The Non-Ferrous Metal Market

During the month that has elapsed since our last report the market for lead has remained about stationary, while tin has receded. Spelter, on the other hand, has had a remarkable rise, and copper also has advanced. The demand for all metals continues strong and the prospect seems good for continued high prices.

Copper.—Early in May the price of electrolytic advanced to 18.30 @ 18.80 cents, New York, but quieted later to about 18.50 @ 18.60. Some sellers continued to ask up to 19 cents, but did little or no business in competitive markets. The demand for copper continues good and some very large orders are pending.

Tin.—This market has declined steadily during the month, and is generally quiet. May tin is quoted at about 40 cents, New York.

Lead.—Business continues fair, with apparently ample supply to meet the demand. Inquiry for military purposes lends interest to the market. New York lead is quoted at 4.20 @ 4.25 cents, with St. Louis at 4.12½ @ 4.15 cents.

Spelter.—After receding somewhat from its previous high level of prices, this market experienced a remarkable rise in the face of a comparatively light domestic demand. Smelters are being operated to capacity but have no stocks and are unable to produce enough for immediate needs. The latest quotation is 12½ @ 13½ cents, St. Louis.

Other Metals.—Aluminium is in greater demand and the New York quotation is firm at 19½ @ 19¾ cents for No. 1 ingots. Prices for antimony have risen again in the face of decreasing supply. Ordinary brands are quoted at 35 @ 37 cents, with special brands at 40 @ 45 cents. Quicksilver is somewhat higher, bringing $74 per flask of 75 lb., New York.

Paint Remover Patent Decision Before Court of Appeals

The decision[1] of the United States District Court, Southern District of New York, in the suit of the Chadeloid Chemical Co. against the Wilson Remover Co. and J. McN. Wilson, in favor of the complainant and upholding the Carleton Ellis patent 714,880 of December 21, 1902, has been upheld by the United States Circuit Court of Appeals (Judges Coxe, Ward and Rogers).

From the decision of the Court of Appeals, written by Judge Coxe, we quote the following:

". . . Neither do we think that the testimony of learned experts and chemists, who have made many experiments to prove that the paint remover of the patent which does the work and satisfies the trade, is old and inefficient, can be relied on in the face of proof showing its widespread popularity and satisfactory results. Ellis was the first to produce such a remover. It is the hunter who actually brings down the game who is entitled to carry it home. The need

[1] See Metallurgical & Chemical Engineering, February, 1915, p. 129.

of an efficient and harmless paint remover had been felt for many years by the trade. Efforts to supply it were many but unsuccessful. Caustic alkali removers were tried and failed; they got rid of the paint but injured the wood. Carbolic-fusel oil removers were tried, but the carbolic acid proved dangerous to the workmen and injured the new paint when applied to the wood. All of these matters were considered in the litigation in the District Court and they were held not to negative the invention of the non-corrosive harmless removers of the Ellis patent.

"The Bennet and Arnstein removers were considered in the original case but were held not to defeat the invention of the Ellis patent and to belong to the same class as the other prior carbolic-fusel oil removers, where wax and similar substances were used as thickeners, and were not mentioned to retard evaporation. If the old removers were satisfactory and did the desired work why are they not used today? How can we account for this persistent effort, during ten years of litigation, to use the Ellis product, upon any other theory than that the prior removers were wholly insufficient? The necessity for a practical remover was felt and many experiments were tried, but no practical result was reached until the Ellis composition was produced.

"The testimony in support of this proposition is clear and persuasive; it is not necessary to review it in detail further than to say that it comes from manufacturers and large dealers and is to the effect that the carbolic acid-fusel oil removers were ineffective, dangerous to health, destructive to the wood, offensive in use and lamentable failures generally.

"The Ellis composition solved a problem which prior to 1902 had baffled the efforts of those who realized the dangers and shortcomings of the existing removers but seemed incapable of remedying them. The solution was not the result of a mere guess but was due to persistent effort by Ellis, who is an educated chemist of standing and reputation, who studied the problem with care and reached a solution which has solved the problem successfully. This is done without injuring the wood operated upon or endangering the health of the workmen. No one before had achieved this result.

"We see no ground for criticism of the patent *per se*. In fact we think the patentee and the officials of the Patent Office are to be commended for having issued a chemical patent where the description and claims cover less than a page. The patent is clear, concise and intelligible to laymen. The criticisms are not well founded. It was not necessary or wise to specify the exact proportion of wax, as this differs according to the work being done. Had the exact percentage been named, anyone could evade the patent by using more or less than the specified amount and thus could have secured all the advantages of the invention without the payment of a dollar."

International Engineering Congress

The International Engineering Congress will be held in San Francisco from September 20 to 25, 1915, under the auspices of the American Society of Civil Engineers, the American Institute of Mining Engineers, the American Institute of Mechanical Engineers, the American Institute of Electrical Engineers, and the Society of Naval Architects and Marine Engineers.

The membership fee is $5, and should be remitted to W. A. Cattell, treasurer, Foxcroft Building, San Francisco, Cal.

This membership fee entitles the member to

(a) Full participation in the Congress.

(b) A volume reporting the general proceedings of the Congress and containing indexes and digest of other volumes.

(c) Any single volume of the Transactions which the member may select.

There will be ten volumes, as follows: Vol. 1, The Panama Canal; Vol. 2, Waterways and Irrigation; Vol. 3, Municipal Engineering; Vol. 4, Railways and Railway Engineering; Vol. 5, Materials of Engineering Construction; Vol. 6, Mechanical Engineering; Vol. 7, Electrical and Mechanical Engineering; Vol. 8, Mining and Metallurgy; Vol. 9, Naval Architecture and Marine Engineering; Vol. 10, Military Engineering.

Pacific Coast Meetings of National Chemical Societies

All the three national chemical societies of this country will hold their autumn meetings in the West.

The start will be made by the **American Institute of Chemical Engineers**, which will hold a meeting in **Los Angeles, Cal.**, on the evening of Wednesday, **August 18th** (jointly with the Southern California Section of the American Chemical Society), and a four day meeting at **San Francisco** from **August 25th to 28th** (Wednesday to Saturday).

The next in time will be the **American Chemical Society**, which will hold its meeting in **Seattle**, Wash., from **August 31st to September 3rd** (Tuesday to Friday). On September 2 the party of the American Institute of Chemical Engineers will be in Seattle and attend the meeting of the American Chemical Society.

The **American Electrochemical Society** will hold its meeting in **San Francisco** on **September 16th, 17th, 18th** (Thursday to Saturday) simultaneously with meetings of the American Institute of Mining Engineers and the American Institute of Electrical Engineers. Joint sessions are planned. On Monday of the following week (September 20) the International Engineering Congress starts.

Exposition of Chemical Industries

A national exposition of chemical industries is proposed to be held in the New Grand Central Palace, Forty-sixth Street and Lexington Avenue, New York City, during the week of September 20 to 25, 1915.

While expositions of chemical industries have been held before in Europe, this will be the first chemical exhibition to be held in the United States.

The time for holding the exposition is undoubtedly well chosen. The psychological moment has come to place the achievements of industrial chemistry visibly before a wider and vitally interested public and to bring the manufacturers of machinery and apparatus for the chemical industries in such close contact with industrial chemists as the facilities of an exposition afford. If properly managed such an exposition must be of great benefit to the industry.

An advisory committee has been formed consisting of Messrs. Raymond F. Bacon, Charles H. Herty, A. D. Little, R. P. Perry, Wm. Cooper Procter, E. F. Roeber, George D. Rosengarten, T. B. Wagner and Utley Wedge.

The exposition is being organized and will be managed by Messrs. Charles F. Roth and Adriaan Nagelvoort, with offices at the New Grand Central Palace, Forty-sixth Street and Lexington Avenue, New York City (telephone Murray Hill 6990). Associated with them in the management is the International Exposition Company, which has successfully managed the Automobile Show, the Horticultural Show and others.

Beta Iron

"Satire Allotropique," presented at the dinner of the Iron and Steel Committee of the American Institute of Mining Engineers.

BY ALBERT SAUVEUR

Fer bêta, conception du grand allotropiste,
Contre toi, profitant de la sortie du maître,
Se rangent tes rivaux faciles à reconnaître,
Mirmidons entrainés par propos carbonistes.

Hadfield l'avait bien dit: le carbon seul durci.
Alpha, bêta, gamma, composants inutiles,
Ne pouvant arrêter le moindre projectile,
Doivent être relégués, et cela sans merci.

Arnold, chacun le sait, toujours a préféré,
Par lui seul découvert, un carbure éphémère,
Une formule étrange, véritable chimère,
Création fabuleuse qui ne peut qu'égarer.

Quant à Henry M. Howe, de nous tous le mentor,
Avec une justice qu'on rarement rencontre,
Il pèse sans faveurs les pours et les contres,
Et nous dira bientôt qui a raison ou tort.

Stead est décourageant par sa neutralité.
Tschernoff et Belaiew, fidèles amis slaves,
Des nouveautés anglaises ne seront pas esclaves,
Ce qui prouve après tout pour leur mentalité.

Guillet, Grenet, Charpy, Henri Le Chatelier
(Pour Frémont ces questions ont trop de théorique,
Son fort étant plutôt celui de la pratique)
Ne sont pas de bêta des ardents chevaliers.

Rosenhain avec lui semble jouer cache-cache:
Il l'attrape, il le tient, proclame qu'il est dur.
On accourt, on regarde, cette fois on est sûr,
Mais hélas aussitôt, voila qu'il le relâche.

C'est un slip band dit l'un, un simple glissement.
Du ciment dit un autre, un rien allotropique,
Pas même un métastable, un point mathématique,
Un décristallisé à chasser vitement.

Benedicks dans gamma le veut ensevelir,
McCance l'écrouir, Edwards en faire des mâcles:
Le malheureux bêta devant cette débâcle,
Se soumet à son sort, se résigne à mourir.

Il attend son destin, triste et mélancolique,
Abandonné de tous, même de martensite,
Qui prétend n'être plus que rides d'austénite.
Il deviendra amorphe. Adieu son point critique.

Pour comble de malheur, et sans le consulter,
Un docteur Suédois le veut mettre sous terre,
Assisté dans sa tâche, par Monsieur Carpenter,
Car, dit il, il est mort, on le peut constater.

Etant de phlogistique tellement dépourvu,
Qu'on ne sait en tirer le moindre point thermique,
Ni dans sa courbe voir la plus petite crique.
Tel manque de chaleur s'est très rarement vu.

Le verdict est rendu, le sort en est jeté:
D'un certain diagramme if faudra qu'on efface,
(Car on doit obéir à la règle des phases)
Ce déséquilibré, enfantement raté.

Quand vous aurez, Messieurs, fini vos beaux discours,
Et que l'heure viendra, pour gagner votre pain,
De durcir vos aciers et d'assurer vos gains,
Il faudra que bêta vienne à votre secours.

Obituary

Franklin Guiterman, director of the American Smelting & Refining Company, and manager of its Colorado department, died from pneumonia in New York City May 2. He was 59 years of age. Through his many years' experience in mining and smelting in the West, and his association with numerous companies for over 35 years, he was widely known as a competent metallurgist and business manager.

Mr. Guiterman was born in Cincinnati, O., where he received his early education. Later he attended Columbia University and finally graduated at the Bergakademie at Freiberg, Saxony, in 1877. Returning to the United States he became associated with some of his Freiberg classmates who were then engaged in the pioneer operations of mining and smelting in Colorado. Georgetown and Leadville, Colo., and Hartville, Wyo., were some of the scenes of his early work. Subsequently he went to Utah as superintendent of the Mingo plant of the Pennsylvania Lead Co. Returning to Denver in 1888 he entered the employ of W. J. Chamberlain & Co. as manager of the ore-buying business of that concern. In 1895 he was appointed manager of the Durango smelter in the San Juan district of Colorado. When the American Smelting & Refining Co. was formed he was made manager of its Pueblo plant and two years later he was made manager of the Colorado department of the same company, with headquarters at Denver. On March 1, 1912, he was transferred to New York, where he had charge of the research and technical investigations of the company and continued as manager for Colorado.

Mr. Guiterman was a prominent member of the Colorado Scientific Society, and as president of that organization for two years had much to do with its prosperity. He took an active interest in the affairs of national societies and belonged to the American Institute of Mining Engineers and the Mining & Metallurgical Society of America. In 1911 he was appointed a trustee of the Colorado School of Mines, but resigned when he removed to New York.

In 1886 Mr. Guiterman was married to Miss Mary B. Sproat, of Taunton, Mass. He is survived by his widow and one son, Kenneth S. Guiterman, chief chemist of the refinery of the Perth Amboy plant of the American Smelting & Refining Co.

Rewards for methods of utilizing alcohol for industrial and technical purposes have been offered by the Ministry of Finance, Russia, according to Consul General John H. Snodgrass, Moscow.

The premiums to be awarded are as follows:

(1) A premium of 100,000 rubles ($51,150) will be awarded for the invention of a new method of utilizing alcohol for the manufacture of a product that will be essentially different from the alcohol used for its production. Examples of such products are vinegar, ether, chloroform, etc.

(2) A premium of 75,000 rubles ($38,625) will be awarded for the invention of a new method of utilizing alcohol for the manufacture of a product in which alcohol and its derivatives (sulphuric ether and others) form the component parts of the product or the solvent, and from which it will be impossible to extract alcohol with a view to profit (as, for instance, pharmaceutical preparations).

(3) A premium of 50,000 rubles ($25,750) will be awarded for the invention of a method in which alcohol and its derivatives would serve as a temporary intermediary solvent (as in the manufacture of smokeless powder and artificial silk).

(4) A premium of 25,000 rubles ($12,875) will be awarded for the increase of the heating value of alcohol by the addition of substances that will make the use of alcohol as fuel advantageous.

(5) Three premiums of 5,000 rubles ($2,575) each will be awarded for the invention or improvement of apparatus for the utilization of spirits in internal-combustion engines and for heating and illuminating purposes.

Inventions must be presented by January 1, 1916. They must be presented to the Chief Administration of Taxes and Sale of Drinks, written in French or Russian, in special envelopes bearing some motto. In another envelope, bearing the same motto, must be stated the name and address of the sender.

The papers must contain a detailed description of the conditions of the adaptation of alcohol, indicating the cost of the method when calculating the price of alcohol at 2 kopecks (1 cent) per degree on the alcoholometer.

Premiums will be awarded only such inventions or improvements as will involve a considerable consumption of alcohol.

The Action of Certain Colloids on Ions During Electrolysis

BY A. MUTSCHELLER

Reports of investigations for the purpose of discovering suitable "addition agents" for electroplating and metal refining baths, are found to date back to as early as 1885 (M. Kiliani[1]). It had then already been recognized that the addition of certain substances to the bath had certain specific effects on the form and consistency of the deposit on the cathode. The nature of these investigations is purely qualitative, but more recently efforts have been made especially by Kern and his coworkers to find a theoretical explanation of the function of these "addition agents."

In reviewing the literature on this subject, especially the valuable articles of Kern,[2] certain analogies were found, as for instance, the general improvement of the deposit when the electrolyte is heated, or, that the quantity of an "addition agent" was found to be of importance, etc. These suggest that the additions must perform specific functions and that they do not act by their presence only. A selection from those substances which improve the deposit were recognized to be colloids and, as a rule, of the amphoteric or reversible type, hence colloidal phenomena were anticipated to be in play here. A further suggestion was found in the fact that the temperature coefficients on the rate of change of the migration velocity of the ions involved in the electrolysis are such that they tend to make the velocity of the two ions equal as the temperature rises. Moreover, the form of the deposit itself, such as it is obtained from a pure electrolyte in the form of striæ or branches was a sufficiently powerful inducement to a hypothesis that the regulation of the relative velocity of the ions should constitute the influencing factor in question. A few preliminary experiments substantiated this assumption and a more systematic continuation of these is herewith presented.

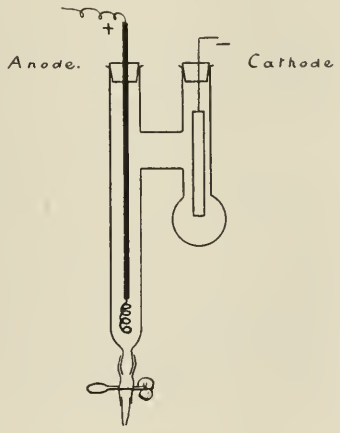


FIG. 1—HITTORF MIGRATION TUBE

EXPERIMENTAL PART ON SILVER NITRATE

The determination of the relative velocity of the ions was made in the customary manner by electrolyzing a salt solution in a so-called Hittorf's migration tube. This consists of an H-shaped tube about 1.5 cm in diameter of which one leg is about 15 cm long and closed by a rubber connection, a pinch cock and a glass tip. The other leg is short and closed at the bottom. The capacity of the tube is about 40 cc. (Fig. 1). For the determination, a foil of platinum about 6 cm^2 in area was placed in the shorter tube and made the cathode; in the longer leg was placed a glass tube through which a mercury connection was made and to the lower end of which was sealed a piece of the pure metal the migration velocity of whose ion was to be determined. This electrode was then connected with the positive pole of the electric current. The tube was filled near to the upper end with a solution which was prepared from c.p. chemicals and carefully distilled water. The current used was taken off along a resistance of about 36 ohms after it had passed from 2 to 6 incandescent lamps. The time of run was ordinarily from 1 to 1½ hours; care being taken in every case to prevent disturbance of the apparatus during the experiment.

The first series of experiments on silver nitrate, the results of which are given in Table 1, were performed in the above described tube and the determinations were made as follows:

After the electrodes (the anode in this case consisting of pure silver) had been put in place and the solution poured into the tube the apparatus was allowed to stand in a shady place for about 15 minutes. After everything had come to rest the circuit was closed.

In the meantime 5 weighing flasks were prepared and 5 cc. of a 1 10 normal NaCl solution and 2 drops of K_2CrO_4 solution were placed into each flask, after which the weight of each one was carefully determined.

After the run, the silver nitrate solution from the longer tube of the apparatus was run into the first weighing flask until the next drop produced a reddish precipitate or coloration. Then the other four flasks in turn were titrated in the same way, always employing care not to agitate the contents of the apparatus. After reweighing of each flask and deducing from the difference the known weight of $AgNO_3$ added (since the contents of the weighing flasks with respect to Cl' were of known titre, always the same weight of $AgNO_3$ was added to each flask), the remaining difference gave the weight of the water that contained the known amount of $AgNO_3$.

An increase of concentration of silver nitrate was thus easily found, and as a rule, the third weighing flask (and, of course, the fourth and fifth) contained the same and constant amount of $AgNO_3$.

The use of diaphragms, therefore, did not appear to be necessary so long as there was an increase of silver at the silver anode in the long leg of the tube. When the contrary was observed the arrangement of the electrodes was reversed so that it never happened that a solution of higher density was placed above one of lesser density. Vitiation of results due to diffusion seemed, therefore, satisfactorily prevented.

From the results obtained in this way the ionic migration velocities were calculated in accordance with the principle developed by Hittorf.[3] Calling c the amount of silver deposited on the cathode, r the amount of NO_3 (all expressed as $AgNO_3$) and n the migration velocity of the anions we have

$$c:r::1:n$$

and 1-n as the migration velocity of the cations.

In this series of experiments the concentration of the electrolyte consisting of a normal solution of silver nitrate was kept constant for all determinations, except that for each run a varying addition of a 1 per cent solution of gelatine was made. The results of these additions on the migration velocities of the ions are given in Table 1 and are plotted in curve No. 1.

The ordinates represent the relative migration velocity of the NO_3- when varying additions of gelatine solution (1 per cent) have been made, as correspondingly represented as abscissæ.

A pure white and well adhering deposit of silver was obtained when the migration velocity of the NO_3 is near zero. Before that, so long as there was less gelatine added than was necessary to bring about this condition, the deposit was loose, brittle and in the form of trees and striæ. It was also distinctly noted that gelatine gathered around the anode in the form of a slimy, gelatinous layer. When more gelatine was added the deposit on the cathode was gray and black, but firmly adherent. The deposit was washed with water, alcohol

and ether, very slightly warmed and after cooling in a dissicator weighed as such. Subsequent heating when the addition of gelatine was more than 2 cc, changed its color which was evidently due to the burning off of organic matter which had deposited along with the silver.

A second series of experiments was performed in exactly the same way and under the same precautions, but varying the conditions in the way of keeping the gelatine addition constant, but varying the concentration of

the electrolyte. As constant addition of gelatine was kept that quantity which, with a normal silver solution reduces the migration velocity of the NO_3^- to zero. Varying then the concentration of the electrolyte with this constant addition of 1 per cent gelatine solution from 1/10 normal to 3 normal, the results given in Table 2 were obtained. The analytical methods and

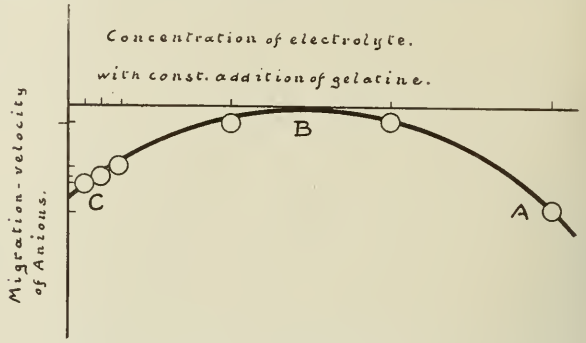
methods of procedure were exactly identical with those for the first series.

The form of the deposit along part *CB* of Curve 2 is gray and black, gelatine having deposited. At point B the deposited silver is pure and stronger heating of the platinum cathode did not cause any loss of weight. Considerable loss was observed on heating the same in the case when lower concentrations of $AgNO_3$ solution



CURVE 2—CURVE OF MIGRATION VELOCITIES

were employed (part *BC* of the curve). Along part *BA* the deposit was pure but with a tendency to form striæ and loose deposit.

EXPERIMENTS WITH COPPER SULPHATE

Valuable information was expected to be obtained by studying the effect of adding gelatine solution to an electrolyte consisting of bivalent ions; copper sulphate was chosen for this purpose. A further point kept in view was to determine the change of concentration around both electrodes. This, however, cannot be done satisfactorily in the usually employed Hittorf tube above described, and a special tube was constructed to meet with the above requirements. Its diagram is given in

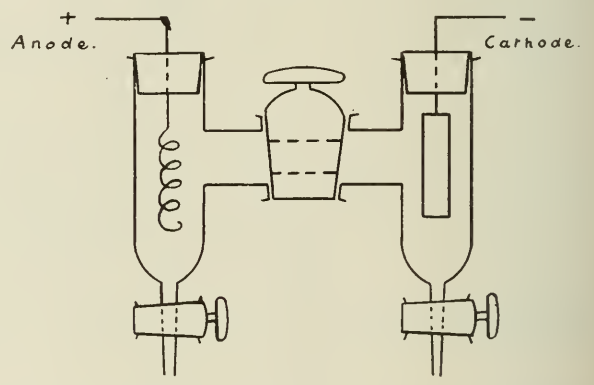


FIG. 2—TUBE FOR DETERMINATION OF CONCENTRATION

Fig. 2 and in use it was found to answer the purpose very satisfactorily.

It consists of two separate compartments for the electrodes, each one provided with an outflow closed by a glass stopper. These two compartments are connected by a side branch connection in the middle of which there is a large glass stop cock. The purpose of this middle large-hole glass stop cock is that by closing the same after the experiment all diffusion can be prevented.

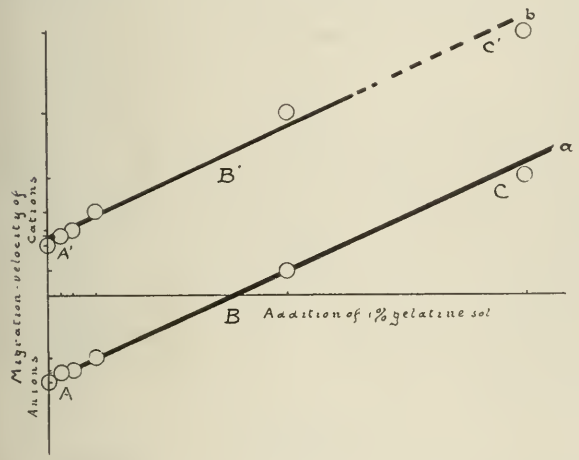
During the experiment the stop cock was kept open and it is, of course, necessary to prevent agitation or disturbance of the apparatus. After the experiment and turning off of this stop cock the electrodes are removed and so the possibility of local action due to stay of the electrodes in the solutions is excluded. Once these precautions have been applied, the contents of the vessels can then be analyzed at leisure. The capacity of this apparatus with the electrodes in position is about 45 cc.

For this third series the technic of analysis was

altered and titration of the copper by KCN solution was found to give satisfactory results. The solution of one compartment was run into an accurate burette for the purpose of determining its volume. From this burette an aliquot volume was run into a beaker, NH_4OH was added until the maximum of blue color was reached and the volumetric KCN solution was run in until the last drop caused the disappearance of the blue color. From this the concentration of the $CuSO_4$ was calculated and by comparing this with a blank determination before the electrolysis the change of concentration was calculated.

In weighing of the platinum foil which had served as cathode the same method was followed which is washing with distilled water, alcohol, and ether, very slight warming, cooling in the dissicator and rapid weighing. Hence, in this case also, all organic matter which had deposited along with the copper when the large additions of gelatine were made was weighed and expressed as copper. However, we are now to recall that, when smaller additions of gelatine were made the gelatine gathered around the anode, whereas the cathode remained pure and did not lose any weight on heating. Only then, when larger additions of gelatine were made did stronger heating cause a loss in weight of the cathode. This is also the result of the first series; when there is an excess of gelatine it deposits on the cathode as a black layer.

For this reason the first part of Curve 3 (from *A* to



CURVE 3—CURVES OF MIGRATION VELOCITIES

B) includes pure deposits of copper and hence represents true migration velocities; from *B* on, however, the part representing the relative velocity of Cu^{++} larger than 1, is not a representation of real migration velocities. Moreover, this illustrates that gelatine takes part in the electrolysis in accordance with its electric charge.

The results obtained in this series are given in Table 3 and are also represented in Curve 3. Comparing the numerical results and inspection of the curves show that they run parallel.

DISCUSSION

These experiments lead to the general result that, if to a given concentration of an electrolyte gelatine solution is added in a small quantity, the velocity of migration of the anions is decreased and gelatine, together with the absorbed anions, migrate to the anode. On increasing this addition a point is reached where this gelatine-anion complex ceases to migrate while the relative migration velocity of the cations has become equal to 1. If, finally, this addition is further increased it is found that the complex gathers on the other electrode, the cathode, where it deposits with the metal.

Furthermore, it follows from these data that the

Form and quality of deposit: Streaky, not well adherent in 1, 2, 3, 4
Smooth and pure in 5, 6

*(In Table 3.) In some of the experiments for curve 3 it has been necessary to add for example 100 or 200 cc. of a 1 per cent solution of gelatine to 40 cc. of electrolyte, which would amount to a considerable further dilution. For this reason a stronger solution was added but represented in terms of a 1 per cent solution. This might slightly influence the numerical results, for, gelatine solutions at different dilutions exhibit different colloidal properties; considering, however, the remarks on this part of the curve, the differences become negligible.

$\frac{1}{2}(SO_4^=)$ requires an addition of gelatine solution which is about 45 times that which is required to cause the same effect on the NO_3^-. This ratio can be read off directly from the curve, thus for example, the distance from the ordinate axis to the intersection of Curve 1 is to the same distance of Curve 3 as 1 is to 45.

The phenomenon here observed is not a chemical reaction between the electrolyte or one of its ions and gelatine nor a mechanical mixture, but has all the characteristics of a process called absorption. J. M. van Bemmelen[4] and H. Freundlich show that absorption phenomena between colloidal gels and dissociated crystalloid solutions are phenomena of very frequent occurrence. They also show that, especially if the absorbing substance is an emulsoid, the crystalloid very often is split in parts of which but one is absorbed. J. M. van Bemmelen[5] has compared the absorption phenomena with the distribution of a solute between two immiscible solvents, whereby $\frac{C_1}{C_2} = f(k)$, thus k in the case of a process of absorption is a function depending on a number of factors and not a constant as it is in the case of a solution.

The investigations of H. Freundlich[6] on the absorption of the liquid by the solid phase led to the formula

$$\frac{x}{m} = ac^{\frac{1}{q}}$$

which formula has been applied and is considered as typically representing the process of absorption. The exponent varies little, between 0.5 and 0.8.

The coefficient a, however, while constant for one and the same substance differs widely, especially with the chemical nature of the absorbing substances. W. M. Bayliss[7] found that its value changes decreasingly with the anion branch of the Hofmeister series.[8] Again H. Freundlich[9] shows that the precipitating power of monovalent ions on positively charged colloidal $Fe(OH)_3$ is to that of divalent ions as 1 is to 40 or 50, or about 45. It is also shown that the cations have an influence on this ratio, so that this result is in fair agreement with the results obtained. Whetham,[10] working on the scale of approximation, found this ratio of the power of precipitation of monovalent and divalent ions as 1 is to 40 ($M':M'':M''' :: 1:40:1600$).

The observed effects resulting from the addition of gelatine to electrolytes, therefore, are the same as those that characterize typical absorption phenomena; hence, we may conclude that gelatine absorbs selectively the anions of the electrolyte and that whichever is present in greater quantities, the anions or the colloid, determines the character, such as the electric charge, etc., of the absorption complex.

The investigations of S. E. Linder and H. Picton[11] cleared the nature of migration of colloids under the influence of the potential gradient (cataphoresis). W. B. Hardy[12] observed that the addition of an alkali to a solution of albumin caused the same to migrate to the anode, whereas addition of acid reversed the direction of their migration. Moreover, Wo. Pauli[13] confirmed these results and found that a carefully dialyzed albumin solution did not show any migration of the albumin.

We must, therefore, assume as probable that the colloidal gelatine carried a positive charge of electricity and when absorbing the anions either partly or fully or overneutralized their electric charge, according to the relative amount of colloid present compared with the anions. Evidently at the point where the migration velocity curves of the anions cross the axis of abscissae, the charge of the anions was just balanced by the charge on the colloid, for as reported in this case the colloid and the anions ceased to migrate in either direction.

The nature of the observed phenomenon, therefore, being that of an absorption process we might with J. Duclaux[14] and Malfitano look upon the electrical charge of a colloid as an absorption potential, and if we continue this analogy we would have to look upon a colloidal particle as a complex ion and a combination of an ionized salt with a colloid in a solution as a highly complex electrolyte.

Electrically neutral particles, neutrions or isocolloids are known not to migrate under the influence of the potential gradient. The anions and the colloid having entered into such a neutral union, which at the same time is hardly at all ionized itself are, therefore, rendered unsusceptible to the influence of the electric field, which, it is to say, is at the point where the velocity of the anions has been reduced to zero.

Calling now the mobility of the anions and the cations l_a and l_k respectively and E the current which passes through the cell, then $\frac{l_a}{l_a + l_k} E$ of it is carried to the anode by the anions and $E \frac{l_k}{l_a + l_k}$ to the cathode by the cations, hence

$$E \frac{l_a}{l_a + l_k} + E \frac{l_k}{l_a + l_k} = E. \qquad (1)$$

From this expression follows, that whatever velocity is lost by one ion is correspondingly gained by the other and that the curves representing the relative velocities of the ions must run parallel. This is realized experimentally in Curve 3.

Again, finding experimentally that the addition of gelatine to the electrolyte causes the velocity of the anions to decrease to zero it follows that,

$$E \frac{l_a}{l_a + l_k} = 0 \qquad (2)$$

Introducing this in (1) we obtain

$$E \frac{l_k}{l_a + l_k} = E \qquad (3)$$

Thus, the cations carry the whole charge of the current and consequently must migrate as fast as they deposit. The concentration of the cations around the cathode must, therefore, remain unchanged.

From these experiments it is evident that there exists a deposition optimum at the point where the negative charge of the anions is exactly neutralized by the colloid. The isocolloid formed is known not to migrate and so, through continued electrolysis we would obtain an accumulation of isocolloid in the electrolyte. At the anode, therefore, we should not have the regular secundary reaction taking place, which otherwise is,

$Ag^+ + NO_3^- = AgNO_3^\circ$ (and $AgNO_3^\circ = Ag^+ + NO_3^-$ etc.)

Instead, however, the following reaction takes place:

(1) $Ag^+ + HNO_3^\circ = AgNO_3^\circ + H^+$.

The hydrogen ion formed in turn reacts on the colloid and isocolloid in accordance with the following reaction:

(2) $H^+ + gelat.NO_3^\circ = HNO_3^\circ + gelat.^+$; thus rendering the gelatine once more available to perform its function.

But, in order to liberate all of the bound gelatine, the isocolloid must be brought near to the anode by stirring and it appears as if the force of the electric field to which the electrically neutral particle is unsusceptible must be supplied by mechanical power from a stirring apparatus. In accordance with the above equations, there would be no expenditure in acid nor any of gelatine.

It must be considered, however, that gelatine is a highly complex molecule which, under the strain of the various chemical and electrical treatments would be expected to break down into its component parts. In this sense, then, will there be a slight expenditure of gelatine.[16]

The expenditure of gelatine is considerably greater if the electrical charge of the anions is overbalanced by an excess of gelatine in the acid solution. The particles formed migrate to the cathode and deposit there as the observed black or gray deposit of gelatine. Conversely, if not enough gelatine was added to the bath the gelatine migrates to the anode where it is separated from the acid radicle and forming the observed slimy layer on the anode. Both of these deposits are irreversible and constitute a loss probably in both gelatine and acid.

CONCLUSION

The conclusions derived from the foregoing experimental data are:

First.—Colloidal gelatine in an acid electrolyte forms an absorption compound with the anions, thereby either partly or totally neutralizing or reversing their initial charge according to the quantity of gelatine added.

Second.—The gelatine is combined with the anions in such a way that in one case (part A-B of the curve) their velocity of migration is greatly reduced. In another case (point B) their velocity is zero, and in the third case (part B-C of the curve) the direction of their migration is reversed, i.e., the anions migrate to the cathode instead of to the anode.

Third.—Through the decrease of the velocity of the anions the cations gain in velocity proportionally, so that at the point where the anion-migration-velocity is equal to zero the cations carry the full quantity of electricity across the electrolyte. In this way the cations migrate to the cathode as fast as they deposit, and experiments show that at that point only, where the relative migration velocity of the cations is near 1, the metallic deposit on the cathode is smoothest and purest.

This property of gelatine is evidently analogous to

16. This "breaking down" of gelatine has led a number of investigators to believe in a reducing effect of the gelatine when added to the electrolyte.

the property of certain colloids, which property Zsigmondy[17] designated as their "protective action" or "Schutzwirkung," a property which he has measured quantitatively by the action of such colloids on a colloidal gold solution of an intensely red color. The quantity of colloid necessary to prevent the change of color of 10 c.c. of this red gold solution, which contains a known quantity of gold, over into blue after the addition of 1 c.c. NaCl solution he expressed as the "Goldzahl" or gold number of the colloid. The reciprocal of this "Goldzahl" then expresses the protective action of the colloid upon colloidal gold, which, as we know, also carries a negative charge.

Among a series of colloids gelatine has the value of approximately 200. Gum arabic has the value of about 5; whereas soluble starch has the value of about 0.04. Using these last two colloids instead of gelatine, it was found that their action of neutralizing the charge of anions is proportional to the reciprocals of these ratios.

Chemical Laboratory, Pathol. Dept., German Hospital and Dispensary, New York City.

Comparative Furnace Efficiency

BY R. J. WEITLANER

When dealing with heating or melting furnaces in the iron and steel industry the words "efficiency" and "economy" are often used and are still more often confused with one another. It seems therefore pertinent to define these expressions more carefully. We should, for instance, distinguish between "pyrometric" and "thermic" efficiency of a furnace. "Pyrometric efficiency" I call the ratio of heat in metal to the heat in fuel used, or in other words: the ratio of the heat utilized in metal to the heating power of the fuel consumed during this process. This pyrometric efficiency is usually in our mind when we speak of furnace efficiency.

"Thermic" efficiency or "effect" of a flame or a fuel I call the ability of a fuel to develop more or less heat-units in a given space at a time. This is usually expressed as the "intensity" of the flame. If the heat exchange between flame and metal is purely by radiation and not by conduction it is, according to Stefan, proportional to the difference of the fourth powers of their respective absolute temperatures; therefore higher "thermic efficiency" is mostly the cause of a higher "pyrometric efficiency."

Thirdly, if we consider the lower or higher cost of heating or melting we arrive at a third conception, that of "economy." This treats the value of fuels and furnaces from a mere financial standpoint and takes into consideration cost of fuel, labor, maintenance, power, investment and it may be that the latter items (labor, maintenance, etc.) exceed the fuel cost (water-gas).

A few examples may serve to illustrate the practical meaning of these definitions.

17. "Kolloidchemie."

Taking, for instance, an ordinary coal-fired heating furnace for billets at a temperature of about 2200 deg. Fahr., we may have an average coal consumption of 450 lb. of coal per ton (2000 lb.) of metal heated. We find the "pyrometric furnace efficiency" from the formula:

$$E = \frac{2000 \text{ lb.} \times 360 \text{ B.t.u.} \times 100 \text{ per cent}}{450 \text{ lb.} \times 14{,}000 \text{ B.t.u.}}$$

wherein 360 B.t.u. represents the heat-content of 1 lb. of steel at 2200 deg. Fahr., and 14,000 B.t.u. the heat value of 1 lb. of coal. This gives the "pyrometric efficiency"

$$E = 11 \text{ per cent.}$$

The "thermic efficiency" of such a coal-fired furnace as represented by the obtainable flame temperature will be somewhat limited on account of incomplete combustion, excess of air, etc.

If we now replace for this same furnace the method of direct coal firing by the use of powdered coal, we may be able to reduce the coal consumption to 300 lb. of coal per ton of metal. This gives a "pyrometric efficiency" of approximately 17 per cent. This increase in efficiency for the same furnace with the same fuel was only possible through an almost theoretical combustion of the powdered coal and a subsequent higher flame-temperature or thermic effect.

If the cost for pulverizing 1 gross ton of coal amounts to about $1 and the gross ton of coal costs $3, we obtain the cost for heating 1 ton of steel as follows:

$$\text{For direct firing } \frac{300 \times 450}{2240} = 60.3 \text{ cents.}$$

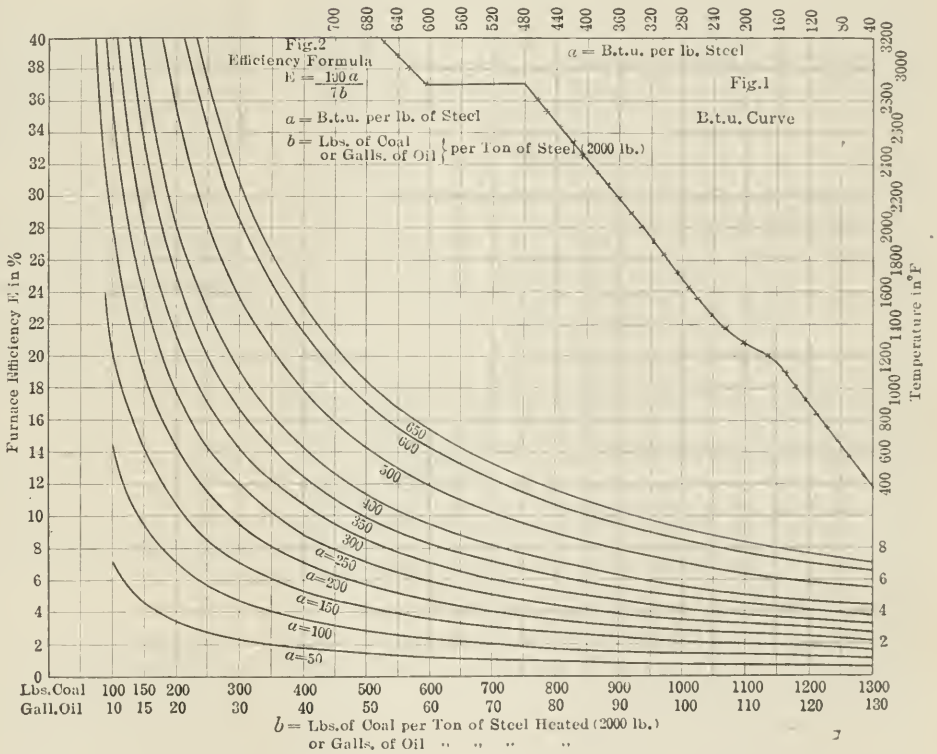

Fig.2
Efficiency Formula
E = 130a / 7b

$$\text{For powdered-coal firing } \frac{400 \times 300}{2240} = 53.6 \text{ cents.}$$

We see that in this specific case we obtain not only a superior thermic and pyrometric efficiency by the use of powdered coal, but also a higher economy.

Let us further assume that for some reason this furnace should be changed to fuel oil. We know that on account of the concentrated form of this fuel the thermic and pyrometric efficiency will be higher than when ordinary coal firing is used. Here, however, the price

of fuel oil will set a limit to its ability to compete commercially with coal.

Basing the substitution of coal by oil on their respective heat values, we would have 1 gal. of oil equivalent to 10 lb. of coal. But on account of the higher "thermic effect" we assume that 1 gal. of oil is equivalent to 13 lb. of coal. For the oil equivalent to 450 lb. of coal required per ton of steel we therefore get

$$450 \div 13 = 34.6 \text{ gal.}$$

60.3 cents $\div$ 34.6 = 1.74 cents is the price we can afford to pay for 1 gal. of fuel oil, provided no other reasons speak for the use of this fuel.

We may consider it a safe rule to assume that the higher the temperature to which the metal is to be heated the higher the "thermic effect" of the flame must be to insure a fair "pyrometric efficiency" of a furnace.

Through selection of the fuel or of the furnace system we have it to a great extent in our hand to obtain the desired result. This is quite plainly illustrated in an electric furnace. While the electric furnace has the highest pyrometric efficiency of any metallurgical furnace, yet it is more economical to melt the cold charge in an open-hearth furnace and to treat the molten steel afterward in an electric furnace, in which we are able to obtain a wide temperature difference between the molten metal and the electric arc, this fact being so essential for a high pyrometric efficiency.

The writer of this article has tried to bring all the different fuels and systems of firing into certain relations with each other and to develop simple formulas by the use of which we should be able to calculate and compare efficiencies and economies of all kinds of fuels and furnaces.

It must be understood, however, that all the following figures were calculated for special assumed cases and that they are therefore subject to modifications in each particular case, as to the heating value of fuels, cost, etc., and will have to be worked out separately for each locality or plant.

The principle upon which all the calculations and formulas are based is the heat content of the material which was heated or melted.

This heat content as given in Table I is taken from J. W. Richards' "Metallurgical Calculations," page 201, and gives the heat in iron in calories per kilogram, or in British thermal units per pound at different temperatures. In Fig. 1 a curve is given for the British thermal units per pound of steel as function of the temperature in degrees *F*. For convenience we call this value *a*. Let us further designate with *b* the amount of fuel used in any furnace to bring 1 ton (2000 lb.) of metal up to the temperature for which the heat content was *a*.

From these two items the efficiency and cost formulas for different fuels shall be derived.

Coal

According to our definition given before the efficiency of a furnace in per cent is the ratio

$$\frac{\text{heat in metal} \times 100}{\text{heat in coal used}}$$

Assuming an average heat value per pound of coal of 14,000 B.t.u. we have

$$E_{coal} = \frac{a \times 2000 \times 100}{b\,(\text{in pounds}) \times 14{,}000 \text{ B.t.u.}} = \frac{100a}{7b}$$

This simple formula will be of use in most cases where the heat value of coal is not far from the one assumed.

Table II.—Efficiencies. With Varying "a" and "b"

600	2912			42.858	28.560	21.540	17.142	14.286	10.716	8.574	6.594
650	3130				30.94	23.335	18.570	15.476	11.609	9.288	7.143

In Table II the values of *E* are given for varying *a* and *b* and the results are plotted graphically in Fig. 2.

To arrive at an example for cost formulas we assume that 1 gross ton of coal costs $3 and that 50 cents is the expense of handling it, so that the total cost of 2240 lb. of coal is $3.50, hence that of 1 lb. 0.1563 cent.

The cost for heating 1 ton (2000 lb.) of steel will be $C = b \times 0.1563$ cent. From the efficiency formula we obtain $b = \frac{100a}{7E}$ and the cost formula is

$$C = \frac{100a \times 0.1563}{7E} = \frac{15.63a}{7E} = \frac{2.232a}{E}$$

This, of course, holds good only for the above assumptions.

Producer Gas

Using producer gas as a fuel the combined efficiency of producer and furnace will remain the same, only the cost of preparation will be higher. We assume a cost of $3.50 for 1 gross ton of gas coal and an additional cost of $1.25, or a total cost of $4.75 per gross ton, or 0.212 cent per pound of coal.

$$E_{coal} = \frac{100a}{7b}$$

(b = pounds of coal gasified per ton of steel.)

$$\text{Cost } C = b \times 0.212 = \frac{21.2a}{7E} = \frac{3.03a}{E}$$

Powdered Coal

Again we have

$$E_{coal} = \frac{100a}{7b}$$

Let us further assume the cost of 1 gross ton of gas slack to be $2.50, and the cost of pulverizing $1.25, so that the cost of 1 gross ton of powdered coal is $3.75, or 0.1674 cent the cost per pound.

$$\text{Cost } C = b \times 0.1674 = \frac{16.74a}{7E} = \frac{2.391a}{E}$$

Oil

Turning to oil we can establish similar formulas by taking b in gallons per ton of steel heated and assuming an average heat-value of 140,000 B.t.u. per gallon of fuel oil:

$$\text{Efficiency: } E_{oil} = \frac{a \times 2000 \times 100}{b \times 140{,}000} = \frac{10a}{7b}$$

In order to obtain the cost formula we assume the cost of 1 gal. to be 2.45 cents and the cost of handling 0.55 cent, hence total cost per gallon is 3 cents.

Cost of heating 1 ton of steel:

$$C = 3b$$

$$b = \frac{10a}{7E}$$

$$C = \frac{30a}{7E} = \frac{4.3a}{E}$$

With varying oil prices we get, for instance,

4 cents per gal. + 0.5 cent for handling Cost $C = \frac{6.43a}{E}$

6 cents per gal. + 0.5 cent for handling Cost $C = \frac{9.3a}{E}$

Wood Fired Furnaces

Although of relative low and greatly variable heating value, wood is still sometimes used for moderate temperatures, for instance, in annealing furnaces.

One cord of pine wood weighs about 2000 lb.

One pound of pine wood with 25 per cent H_2O (air dried) develops approximately 6000 B.t.u.

$$E_w = \frac{a \times 2000 \times 100}{b \times 6000} = \frac{100a}{3b}$$

b = pounds of wood per ton of steel.

We may assume the cost for one cord of pine wood to be $4, including handling.

1 lb. dry wood = 0.2 cent

$$\text{Cost } C = \frac{100a \times 0.2}{3E} = \frac{6.67a}{E}$$

Electric Power

Derived similarly, we obtain from

1 kw = 3412 B.t.u.

b = kilowatt-hours per ton of steel heated or melted

$$E = \frac{a \times 2000 \times 100}{b \times 3412} = \frac{58.617a}{b}$$

with varying prices of 1 kw-hr.:

1 kw-hr. 1 cent: $\frac{58.617a}{E}$

1 kw-hr. 1.25 cents: $\frac{73.27a}{E}$

1 kw-hr. 1.5 cents: $\frac{87.926a}{E}$

After having established these formulas it should be understood that said efficiencies are based only on such a fuel consumption which was necessary to bring the material up to the desired temperature to melt or to perform a certain metallurgical process. This efficiency is termed by Prof. J. W. Richards the "specific efficiency."* From this we have to distinguish such fuel consumption as is necessary to keep or "hold" the material at that temperature.

Such cases, for instance, occur mostly in annealing furnaces where the steel, after having been brought up to the desired heat, is kept for a certain period at that temperature. This is called by Professor Richards "generic efficiency" or "holding efficiency" as we may also term it. Even under similar conditions of temperature and "holding time" the fuel consumption b has to be given in pounds, gallons, kilowatt-hours per hour† and the cost will be figured directly from this fuel.

The fuel consumption per hour in each furnace will, of course, be a function of the temperature at which the furnace is held.

For the sake of comparison, a number of cost formulas were worked out for various fuels, prices of fuel and handling cost and arranged in Table III. Although these figures are merely given for comparison and must be figured for each individual plant they are perhaps not far off from actual practice.

The purpose of preparing such a "cost sheet" was to enable us to compare with one another the cost of heating or melting 1 ton of steel in different furnaces and under different efficiencies, and was based finally upon the temperature of the metal, in other words to make the cost of heating metal a function of its temperature and furnace efficiency.

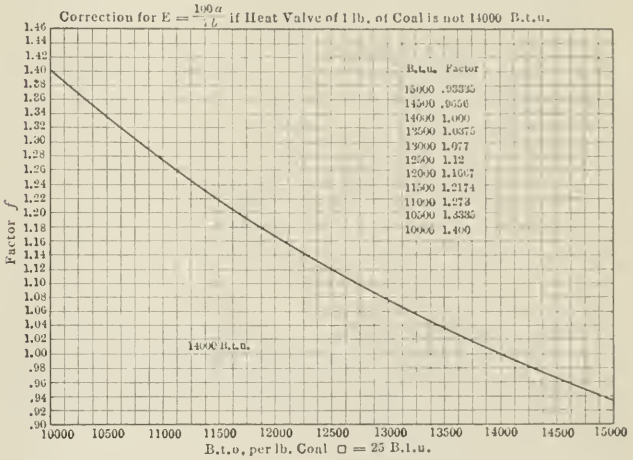

FIG. 3—CORRECTION FACTOR CURVE

To express the performance of any furnace by the amount of fuel used per ton metal heated, without paying attention to the heat in fuel and metal, does not give a clear picture of how much of the heat in fuel is actually absorbed in useful work, whereas, if we say, for instance, that a furnace has an actual efficiency of 10 per cent we come to realize at the same time the great amount of heat lost in such a process of heating or melting. We will try to find the causes of such losses and to improve the process.

Of two furnaces having similar construction, one may have a much lower fuel consumption than the other, yet after figuring their respective efficiencies the relation may just be reversed, on account of the poorer fuel value or different temperature of the heated material. The advantage of expressing furnace performances in percentage efficiencies can thus be seen.

Looking once more over the efficiency formulas we find that those for electricity and fuel oil are almost theoretically correct, whereas for those for wood and coal corrections will be necessary if the heat value does not

*See Richards, Metallurgical Calculations, Vol. I, p. 76.

correspond with the value given. Fig. 3 gives these correction factors with which $E = 100a/7b$ is to be multiplied if the coal used has a higher or lower heating value than 14,000 B.t.u. Similar correction curves can be plotted for wood, etc.

If the metal charged into the furnace has a higher than ordinary temperature, a will be represented by the difference of the two respective heat contents.

This I think is a good illustration of the usefulness of an efficiency formula instead of expressing the furnace work in the amount of fuel used. In such a case the latter would hardly mean anything to us.

Returning to our cost table, No. 3, a few explanations may serve to illustrate the use of the same. Under columns I and II different fuels and their efficiency formulas are given. In colume V the cost formulas were derived from the fuel cost and cost of preparation. This additional cost, on account of being more liable to changes, makes the cost formulas more fluctuating and can therefore be omitted if desired.

Under VI the factors are given with which a has to be multiplied to obtain the actual cost of heating or melting 1 ton of steel in a furnace whose efficiency was E.

E in percents is first figured from a and b and the cost looked for under E for respective furnace system and fuel cost.

(1) We readily see, for instance, that an oil-fired heating furnace (with oil at 2.5 cents per gal.) must have an efficiency of 10 per cent to compete economically with a hand-fired coal furnace of about 5., per cent efficiency.

(2) We can also say what price we are able to pay for a certain fuel (for instance oil) to compete with a coal-fired furnace of the same or higher efficiency (which is the reverse of example 1). In both these cases a was eliminated since we assumed that the temperature of the steel was the same in either furnace.

(3) Should the heating temperature of a furnace be increased or decreased for a certain period or should a new furnace be constructed of the same design as the one whose efficiency is known to us, but for a different temperature, we have for example:

$$\text{Cost } C_1 = \frac{E_1}{3.033a_1} \text{ (See cost formula.)}$$

$$\text{New furnace: Cost } C_2 = \frac{3.033a_2}{E_2}$$

If the temperatures are not too far apart we may assume:

$$E_1 = E_2$$

and therefore

$$\frac{C_1}{C_2} = \frac{a_1}{a_2}$$

in other words, roughly speaking, the cost of heating is in direct proportion to the heat content in steel and consequently to the fuel consumption

$$\frac{C_1}{C_2} = \frac{a_1}{a_2} = \frac{b_1}{b_2}$$

This assumption that the efficiencies of one and the same furnace were alike for moderate temperature differences is not correct since the losses by radiation and conduction also increase with higher temperatures and the conditions become quite complicated. It will also be influenced by the range of these two furnace temperatures from the flame temperature which in itself is not a constant.

These were only a few examples to show how this table can be used.

To facilitate this use it will be advisable after fuel

prices for special cases have once been settled, to construct the cost in form of curves, in which either fuel cost or a can be made variable, similar to the curves in Fig. 2.

Résumé.—In the foregoing the writer has tried to bring the question of comparing furnace efficiencies on a more uniform basis by means of the heat content in metal and he has given simple formulas by which this may be easily obtained.

Incidentally these formulas can also be used to develop a uniform system of cost comparison.

Noble, Pa.

Chemical Engineering in Nitrocellulose Manufacture

BY S. L. STADELMAN

This article bears on modern methods for the manufacture of cellulose-nitrate gun powder or nitrocellulose powder.

We shall avoid as much as possible material which can be gleaned from text-books and other magazine articles on the subject. Machines of standard make and patents on record, beyond merely sketching, will not be described in detail.

The quality of the American product, if we may diverge, is very high. Only one circumstance may mar it, namely, a possible failure in the manufacturing of a sufficiently pure diphenylamine (see Nitrocotton Powder Manufacture, under Mixing). The German product is a clear light yellow, the American is a dirty gray.

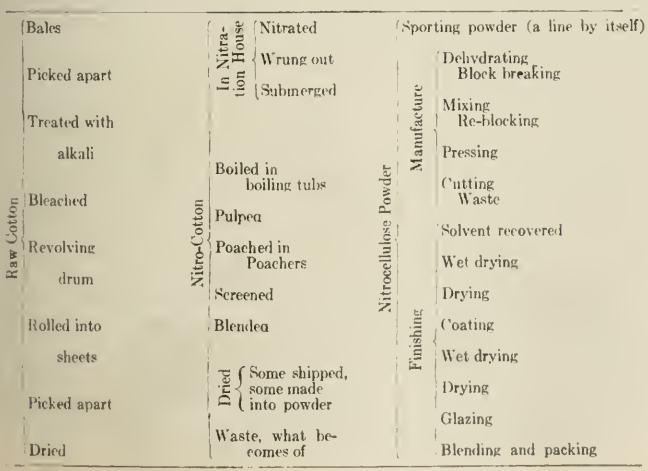
Only recently, in the latter part of April, there was recorded a big explosion in a Russian powder mill. We surmise that they are having the same difficulty. The material that exploded was probably nitrocellulose, and also, most likely, in a powder magazine. Rarely does a big explosion occur in a manufacturing plant where everything is run in small units on purpose to limit such possibilities. The Russians use nitrocellulose very largely. Even if it were another material that exploded, the fundamental cause could still be an impure member of the benzol series.

The cost of nitrocellulose powder manufacture, as near as we can judge, is between 35 and 40 cents a pound.

The manufacturing of nitrocellulose powder may be divided into several stages: the treatment of the raw cotton preparatory to its nitration; nitration and purification of this nitrated cotton preparatory to its being made into powder; the making of gun powder from the fluffy nitrated cotton, and lastly, the powder-finishing processes till shipment is made.

The accompanying flow table gives a fair idea of the whole process:

FLOW SHEET



Raw Cotton

For a raw material the shortest-fibered and cleanest, ripest cotton obtainable is used. The shorter the fiber the less the pulping (q.v.) required later to open the cells in order to free possible acid secretions.

The cotton comes in the ordinary compressed bale, which is opened and thrown into a picking or carding machine, where the fibers are picked apart from one another.

The cotton now receives a boiling of about eight hours in dilute alkali solution of about 1 lb. NaOH to every seven or eight gallons of water. The solution is drawn off and another free boiling with fresh water is given the cotton. Besides its dissolving effect on impurities the alkali saponifies the oils and the soap formed removes the dirt.

The cotton is next bleached to remove lignin substances that form unstable nitrates. This is done generally with calcium hypochlorite because of its cheapness. This material requires extra precautions in order to free the cotton of it, which is accomplished by a revolving drum screen through which plenty of water flows. Thus also is the dirt screened out.

In these two treatments care must be taken to avoid severity lest there should be formed either oxycelluloses with their resulting unstable nitro-compounds later, or hydrocelluloses with their different rates of nitration.

In order to obtain a uniform dry fluffy cotton, free of lumps which are hard to dry, it is next forced between heavy rollers and pressed into wide felt-like sheets. Again is the cotton, now in the form of sheets, subjected to a picking process—tearing fiber from fiber.

The cotton next takes about a thirty minute journey on an endless belt through the dryer at a temperature of 105 to 110 deg. C., and is dumped out with less than 1.1 per cent of moisture on an average. Sometimes though it contains 1.5 per cent or even 1.7 per cent, to overcome which the heat is driven upward, causing occasionally rather inconvenient but not seriously dangerous fires. Straightway on the cotton's dumping out it is packed in large tared tin cans, the lids are clapped on to avoid hygroscopic moisture and the cotton is ready for the weigher. The weigher sends each can to the nitrating house containing from 12 to 17½ lb. each of cotton, according to whether a nitro-cotton of high or low nitrogen content is being nitrated.

Regarding products of high nitrogen content or of low nitrogen content it may be said that throughout all the operations greater care and greater precautions are observed in proportion to the amount of the nitrogen content.

The cotton, scrupulously freed of all grease, oil, fat, lignin, water, dirt, etc., is ready for nitration.

Cellulose Nitrate

NITRATING

We shall call this nitro-cotton, since it is still cotton-like to the sight and to the touch.

We have now to deal with one of the most important parts of the whole operation, the nitration house and the nitrating of the cotton.

The nitrating house is a four-storied building with plenty of exits to outside fire escapes, plenty of windows to allow air circulation, and draft pipes sucking away the fumes from every fume-generating point. At some points, such as the neck of the nitrating pots, the suction of the draft pipes is shut off or opened by a valve connected to the lid; thus these draft pipes are opened only when necessary. The fumes collected are carried out and sent up a big terra-cotta standpipe, where they are condensed and collected for further use.

A nitrating house holds from four to eight nitrating

units. A nitrating unit has its parts on each floor of the building. On the fourth there is for each unit a vertical motor. The vertical shaft from the motor in passing down through the third story goes through the center of a square in each corner of which is set one of four nitrating pots. The shaft connects on the second floor with the bottom center of an iron basket of a centrifugal wringer. On the first floor or basement is the submerging pot directly under the wringer.

The motor on the fourth floor is under the control of the wringer-man on the second floor. Attached to the motor is a tell-tale indicating the number of charges the wringer runs off. The motor has two speeds: low or about 300 r.p.m., and high or 1100 r.p.m. Taking into consideration that the wringer basket has about 40 in. diameter it will be seen that at the high speed the circumferential velocity is about one and one-half times that of the old usage, or about 210 ft. per second, compared with the old-time usage of 140.

Each nitrating pot on the second floor has two agitators, interlocking with each other and revolving in opposite directions. The agitators have a low-speed of about 25 r.p.m. and a higher of about 60 r.p.m. The agitators are run by overhead shifting pulleys and belts connecting with shafts running lengthways of building and near the ceiling at both sides of the building.

The cotton ready for nitrating comes into the building at the third floor. Along with the proper "acid mixture" running in on top of it and with the agitators on the higher speed, the cotton is dumped into a nitrating pot. After thorough immersion has taken place the agitators are put on low speed.

After nitration the now nitro-cotton and the acid are drawn off by gravity from the pot, through a 6-in. pipe connected to its bottom, and run directly into, but against the side of, the slowly revolving wringer basket underneath. The wringer is speeded and the acid flung to the circumference of the basket runs through the holes therein and is collected in the basement below for future use. For a 12-lb. charge of raw cotton the wringer is run on high for one and three-quarter minutes and for a 30 or 35-lb. charge the wringer is on high for three and one-half minutes.

The acid wrung out, the wringer-man pulls up a valve plate, which surrounds the shaft and closed a circular hole in the bottom center of the basket. Through this hole with a brass-tipped pitch-fork he works the nitro-cotton. It drops directly into the submerging vessel below, where each fork lot is suddenly submerged by a heavy stream of water. From here the nitro-cotton and water are pumped to the boiling-tub house.

The wear and tear on a nitrating building is enormous. Parts for renewal must be zealously kept on hand and constant vigilance maintained against the least sign of a breakdown. As for fires, just as long as a good clean cotton is used they will be a rarity, taking it for granted that no dirt, oil, water, etc., is introduced into the cotton while nitrating and wringing out. It is said that a minute drop of water dropped in a charge when in a wringer will cause a fire.

So much may be said on the mechanical part. The chemical considerations next absorb our attention.

Since some part of the waste acids spoken of above would if revivified make the acid holdings on hand more than is necessary, this part is generally used for the manufacture of nitric acid. Oleum is used to revivify waste acids, which use reduces very considerably the loss from excess waste acids. Two or three kinds of fortifiers are used. The use of any special one on a particular case depends upon the kind of nitro-cotton being made, which in turn governs the proportionate loss between the acids in a charge and the water gain of a charge. On account of the variability of the loss or gain over the rectified acid in the sulphuric acid percentage of waste acids, a strong nitric acid fortifier is added first. This throws the H_2SO_4 percentage below what it should be if it is not already so. Now a 1 to 1, or some such other fortifier, can be used. Another consideration is in so running the waste acid batches that those which cannot be brought back to their original use can be changed to the nitration of another grade of nitro-cotton.

We shall in this article consider only three grades of nitro-cotton. First, a high-nitrogen cotton of from 13.30 to 13.45 per cent. Second, a middle grade nitro-cotton, pyrocellulose, of from 12.45 to 12.75 per cent of nitrogen, or even 18.85 per cent. Third, nitro-cotton of about 12.25 per cent N used as a component of gelatin dynamite.

The temperature of nitration of the high nitrogen material is from 15 to 20 deg. C. That for the lower nitrogens is from 35 to 40 deg. C.

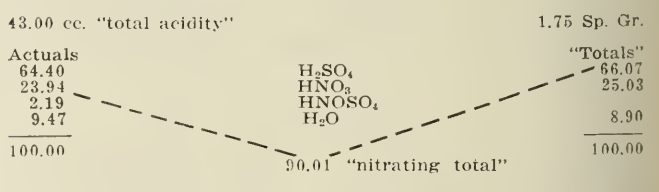
The time of nitration of the high nitrogen material is from fifteen to seventeen minutes. That for the lower nitrogen is about twenty-five minutes, although this is subject to a few minutes shortening. Both times are often considerably lengthened by delays, but without particular harm.

The cotton charge of the high nitrogen material is one can containing 12 lb. That for the low is two cans containing 17½ lb. each or 35 lb. Sometimes with an unusual fibered cotton 30 lb. per charge is used.

The theoretical yields of the three grades from the raw cotton is as follows: Multiply the raw cotton used by 1.65 to obtain the weight of the output of the high-nitrogen material. For the pyrocellulose multiply by 1.58. And for the 12.25 per cent material multiply by 1.50.

From the foregoing figures it will be seen that the theoretical output of one nitrating unit per day of twenty-four hours is 5702 lb. for the nitro-cotton of high nitrogen, 10,618 lb. for pyrocellulose, and the same for the low nitrogen product. If everything works smoothly the output of the two latter may be increased possibly 3000 lb. more each; since it is not injurious to cut down the time of nitration on them a few minutes. However, owing to breakdowns, etc., in actual practice the output of the high grade is about 4800 lb. a unit per day, and for the others it is about 10,000 lb. The percentage of acid mixture lost is between four and six. However, when the loss runs over 5 per cent, careful search should be made for leaks.

Because of its rough feeding to the nitrating pots, the quantity of acid put in each charge varies between 900 and 1000 lb. But there is no such wide diversity allowed in the composition of the acid mixture itself. We subjoin a typical analysis of an acid mixture used for making high-grade nitro-cotton:



This nitrating total is derived by adding together the two percentages indicated by the dotted lines. The right-hand column of percentages is deduced from the number of cubic centimeters of the total acidity and the specific gravity. The $HNOSO_4$, iron salts, etc., are not reckoned with in this column, therefore the H_2SO_4 and HNO_3 are high and the H_2O is low. In the "actuals"

column the HNO_3 and $HNOSO_4$ have been determined by nitrometer and by titration respectively, their sum subtracted giving the actual H_2SO_4 direct from the total acidity.

The "nitrating total" is the governing consideration. The actual nitric acid is generally figured at 24 per cent for a high-grade nitrating mixture for nitrating high-grade nitro-cotton. But if it runs under or over, then the "totals" H_2SO_4 will have to run a corresponding percentage in the opposite direction in order to keep the nitrating total around 90. An acid mixture of this analysis ought to give a product of about 13.37 per cent N, $\pm$ 0.07.

In the acid mixture used for making pyrocellulose the HNO_3 is kept close to 19.30 per cent and the nitrating total at 83.75. Sometimes the nitrating total may be run up to 84 when the fiber to be nitrated is coarse or tough. For dynamite nitro-cotton the HNO_3 is about 26.5 to 27 per cent and a nitrating total of 83.30. This means a low H_2SO_4 content.

Regarding the water content the principle is to maintain it as high as compatible with obtaining the desired nitrogen percentage. High water content tends to increase the solubility of the product (see Blending).

On leaving the nitrating house the submerged nitro-cotton is pumped to the boiling-tub house. A tub has a capacity of about 1200 lb. Everyone is familiar with them, with their double bottoms, the uppermost one perforated and with perforated lead steam coils lying between.

After draining off the submerging water and adding fresh, the high-grade nitro-cotton is given five boilings here altogether. The first is for thirty hours, the water is drained off through the perforated bottom, fresh water added, brought to a boil, and boiled for five hours. Three more five-hour boilings follow, changing water each time.

The pyro-cotton receives first a twenty-five-hour boiling, then follow three five-hour boilings, again changing the water each time.

The dynamite-cotton receives an entirely different treatment. In a separate tank especially for the purpose water is heated to 70 deg. C. and no heat or steam whatsoever besides the preheated water is allowed in the tubs where the dynamite cotton is. The first steeping with this 70 deg. water is for one hour. The water is run off and more pre-heated water added. This, the second steeping, is for two hours, the third steeping is for three hours, the fourth is for twenty-four and the fifth is for twenty. Ten pounds of Na_2CO_3 is added to the first steeping water.

Counting all the times of boiling, draining off, filling up with fresh water and bringing the water to boil, the sum in the case of high grade is about 64 hours, for pyro-cotton it is about 52 hours and for dynamite cotton it is about 55 hours. To these times ought to be added about 4 to 5 hours more in each case to have a fair idea as to how long a charge of each grade is in the building.

A fair amount of nitro-cotton is strewn about tubs on the floors of the building and becomes waste. It is collected and thrown into a tub by itself. Eventually it follows through the same treatment as the pyro-cotton till it joins the sporting nitro-cotton in poacher house. It finally ends as sporting powder (q. v.).

In draining the boiling waters from the tubs through the perforated bottoms, material is again lost. Big settling troughs, through which the waste water is led, are built to collect this material. After a sufficient quantity has collected, it usually is sent direct to the sporting nitro-cotton poachers in poacher house.

About this stage the future blending is beginning to be looked after. A careful tracer kept of every tub lot of nitro-cotton shows, by referring to the analysis of acid mixtures as per number given on card, and referring also to the characteristics of the cotton, etc., etc., about what percentage of nitrogen the nitro-cotton will have. On this basis it is generally several tubs of high nitrogen pyrocellulose (about 12.70 to 12.80 per cent) which are selected for the future blending. Outside of giving the pyrocellulose in these tubs one hour less pulping (to be known as seven-hour pyrocellulose) it is not treated differently from ordinary pyrocellulose used for cannon powder.

After these boiling treatments the nitro-cotton is, after draining, forked out of the tubs into high-sided cars and delivered to the pulping house.

PULPING

The pulping machine used is the same as is employed by paper manufacturers. A pulping machine or "beater" will have about one-fifth less capacity when pulping nitro-cotton compared with paper pulp. The horsepower required is considerably greater.

The washer connected with the beater carries off a good deal of fine nitro-cotton in liquid suspension. This liquid is run into large circular settling vats of iron. The waste from the floors is also dumped into the settling vats. In fact, they are the recipients of a great deal of waste from various sources, as we shall see as we go along. What is done with this waste will be told under sporting powder.

The beaters are set down in the floor, which makes it easy to dump the nitro-cotton from the cars into them. During the course of the pulping of a charge enough Na_2CO_3 is added to make a slight alkalinity.

The high-grade nitro-cotton is pulped twelve hours—rarely less. This length of time is allowed it so that it may be fine enough to incorporate well in the colloid (see mixing) so that it can more easily pass through the fine screens of the macaroni press. In pulping to such fineness care must be taken that the material becomes not so fine as to clog seriously in the dehydration press (q. v.). This is overcome somewhat by allowing its co-constituent (seven-hour pyrocellulose) to retain some of its coarseness by not pulping it so much.

Pyro-cotton is pulped eight hours ordinarily. Dynamite cotton is pulped for eleven hours. Boiling water cannot be used on dynamite cotton at any stage; therefore, it must be well pulped to assure freedom from acid, salts, etc.

In the pulping of high-grade and pyro-cottons we do not know of any case where hot water is in use, although it is supposed to be a considerable advantage.

From the beaters the pulp-filled water is pumped through pipes to the poachers.

POACHING

Poachers are large, deep, round wooden tanks with facilities for introducing steam into them, for draining the water from the top downward and for stirring the charge. They have a nitro-cotton capacity when in a desirable thickness of water suspension, of about 7000 lb.

When a poacher is first filled the charge is allowed to settle, the supernatant water drained off and clear water added. High-grade nitro-cotton receives four five-hour boilings. Twenty pounds of Na_2CO_3 is added the first boiling and 15 lb. the second. The stirring is kept up during the boiling. After the boiling the high-grade has ten cold-water washings. Each washing is stirred for a half hour.

Pyro-cotton is treated according to the U. S. Government specification (see page 191 of "Military Explo-

sives" by Weaver, 3rd edition), except that 35 lb. of Na_2CO_3 are added the first boiling. The sampling and testing is carried out substantially the same as described in Weaver's book, page 192.

Dynamite-cotton receives ten cold-water washings only. All washings from this and the other nitro-cottons are run into the big iron settling vats.

It is in the poachers that one of the two principal blendings is done. The object of blending is to obtain a product of definite qualities, but the blending at this stage is made necessary by the desire to obtain a small-arms colloidal powder high in nitrogen content. Nitro-cotton of 12.85 per cent nitrogen can be made that will be soluble in a mixture of thirty-six parts alcohol and sixty-four parts ether, and a colloid powder be made of it, but above this percentage of nitrogen the solubility rapidly decreases till at 13.40 per cent N only about 8 per cent + is soluble. Now, to obtain a powder of 13.20 per cent N, the 8 per cent soluble high-grade is blended with the entirely soluble pyro-cotton (seven-hour pyro) to make a mixture of about 29 or 30 per cent soluble, which is enough to give when treated with ether-alcohol, a good colloidal body which will encase the non-colloids.

Also in blending it is not desirable to attempt to cut down on the quantity of the non-colloids. They should rather be maintained as nearly as possible at a definite percentage, for it is the presence of these fine detonating particles which gives the powder extra explosive force.

The mechanical part of the blending is done simply by taking a predetermined weight of wrung-out seven-hour pyrocellulose and dumping it into a poacher of high-grade nitro-cotton containing a known weight and stirring them thoroughly together.

DRYING

Centrifugal wringers are again made use of, this time to drive out the water. The rather thick water and nitro-cotton is pumped over the wringer through a pipe line which has side connections easily handled by the wringer man. Again the waste water goes to the iron settling tanks. The wringer baskets are much smaller —possibly 8 in. less in diameter—than those in the nitrating house; consequently their circumferential velocity is much less although they make the same number of revolutions per minute.

With the high-grade—now, a high-grade and pyro blend—and the pyrocellulose it is desirable to wring the water content down to as low as 30 per cent. The lower the water content the greater the saving of alcohol in the dehydration. With seven-hour pyrocellulose and dynamite cotton it is not so necessary. The first goes back to a poacher, anyhow, and the latter has to be only dry enough for a drying barrel to handle it.

The blend of high grade and pyro and the pyro are forked through the bottom of the wringer into a blending barrel. When full the barrel is turned over a few minutes, opened, and the contents dropped into a car. Thence they are hauled to steam-heated storage sheds and are ready for dehydration.

Occasionally the pyrocellulose is taken out of its cars, put into a packing press, pressed into oblong blocks, packed in zinc-lined boxes and shipped as pyrocellulose.

The dynamite cotton, after dumping in cars, is taken to a large revolving drying barrel where it is dumped in and dried till the moisture is brought down to 25 per cent. From here the dynamite is sifted through a large mesh screen, pressed into zinc-lined boxes and is ready for shipment to a dynamite manufacturing plant.

SCREENING

In pumping the mixture of water and nitro-cotton from the poachers to the wringers or from one poacher to another according to exigencies it is screened to take out the knots, the larger sized fibers, sticks, dirt, etc. The bottom of the screen is vibrating up and down and is made of metal full of short, narrow slits.

Manufacturing and Finishing

SPORTING POWDERS

We now come to a branch which is practically by itself.

We have had occasion before to speak about big, round iron settling vats. It will be remembered that the very greatest bulk of this was that which crept through because of its fineness. In fact, it is so fine that alum has to be used to insure its settling to the bottom of the vats. This fineness is what fits it for sporting powder. The nitrogen in this low-grade nitro-cotton runs about 12.40 per cent.

After a vat is full the fine nitro-cotton settled and the supernatant water drawn off, the nitro-cotton is pumped with a little water into a poacher. Here it is given two five-hour boilings, followed by the customary ten cold-water washings. Thence it goes to the wringers and is wrung out to about 38 per cent H_2O. After adding enough high-grade nitro-cotton to it to bring the nitrogen to about 12.50 per cent, it is ready for turning it into powder.

The principle of a sporting powder is simply to make grains of nitro-cotton, which on the outside are hard and impervious, yet have somewhat the explosive effect of uncolloided nitro-cotton.

The manufacture of E. C. powder is familiar and we do not know of any improvement on its manufacture within recent years. Some firms use Chilian saltpeter instead of the potassium salt, which is apparently a good idea, since the grains are water-proof. Aurine is still used in the coating and ether-alcohol in the gelatinization of the water. The speed of revolution of the nitro-cotton granulating drum regulates the size of the grains.

Another powder is made somewhat as follows. The nitro-cotton is held in suspension in a solution of 6 per cent calcium nitrate and 20 per cent potassium nitrate by bubbling upward through it a mixture of benzene (C_6H_6) 60 per cent and amyl-acetate 40 per cent. The size of the grains formed depends on the rate of the bubbling. The grains must have a certain weight and size and be granular and round. The whole solution with grains is carried over and screened. The amyl-acetate and benzene are recovered by distillation.

Frequent ballistic tests are made of this powder.

DEHYDRATION

In the process of dehydration all materials are tested alike except that sometimes an exceptional or say a balky lot may be filled with a different quantity of alcohol preparatory to using a different quantity of ether in the mixing house, thus using a differently proportioned colloiding mixture.

The principle of a dehydrating press is as follows: The nitro-cotton is dumped in and pressure applied to drive out as much water as permitted by the space demanded by the quantity of alcohol that is wanted in it. Ordinarily this pressure is about 3000 lb. Finally alcohol introduced under pressure at one end drives the water ahead of it out of the other end. The pressure is broken, the alcoholic nitro-cotton cake is released, test-weighed and canned immediately to avoid evaporation.

From the storage sheds (see Drying, 3d paragraph) the cars of nitro-cotton are put directly in the dehydration house. A definite quantity, enough to make 40 lb. of dry nitro-cotton, is weighed and dumped into the press. If the weight of this, including the water con-

tent, is 57 lb., then 7½ to 8 gal. of alcohol will be required to dehydrate it. If the weight is 61 to 63 lb., then about 10 gal. are required. This shows the value of a low water content. It saves steam and the wear and tear on the apparatus in the recovery by distillation of the alcohol.

The time of a complete cycle of the dehydrating press is about three minutes and fifteen seconds to three minutes and thirty seconds. It has been brought down to an average of two minutes and forty seconds. These operations (see also macaroni presses) depend so entirely upon the working conditions and the momentary efficiency of the plant that it is hard to give definite data.

Although the U. S. specifications allow the use of alcohol as low as 92.3 per cent by weight, yet the usual strength is 95 per cent. The quantity of alcohol left in each dehydrated block is between 12 and 24 lb., according to what might be called the "workableness" of the nitro-cotton that is being handled at the time. The average quantity of alcohol left in it is about 16½ lb.

BLOCK BREAKER

The alcoholic cakes or blocks of nitro-cotton have to be broken up and rather finely sifted so that they will colloid better in the mixers. The block-breaker does this work. It doesn't need be described. The workmen break up the blocks and small lumps on the floor, which is lead covered.

MIXING

A mixer charge comprises, with the 60 lb. or more blades is familiar to everyone. The mixers are surrounded by a cold-water jacket to prevent overheating. But the coldness of the water has also a great effect on colloidization—cold accelerates colloidization and helps to colloid nitro-cotton otherwise not colloidable, and it should be allowed for accordingly. To prevent evaporation of the solvent there is a heavy air-tight lid. The whole mixing machine with its charge is so arranged that it can be dumped of its contents.

At the side of and above a mixer is a small scale with a tared container on it for the weighing of the ether. In this ether there has been dissolved diphenylamine in sufficient quantity to leave one-half of one per cent of it in the finished powder. Diphenylamine is, as everyone knows, the stabilizer. Its agency is to absorb the acidic decomposition products of the nitro-cellulose, thus preventing their deleterious effects, and also, by not permitting their escape, it helps to maintain the ballistics of the powder.

A mixer charge comprises, with the 60 lb. or more of alcohol impregnating it, 200 lb. of nitro-cotton in cans fresh from the block breaker. Enough ether, while the mixer is running, is added to make up at least 64 per cent of the total solvents used, allowing for alcohol evaporation. The mixing is continued thirty minutes or more till the material is suitable for the macaroni presses. To tell when this stage has been reached takes an experienced man. Speaking for himself the author must say that although he has examined these charges repeatedly, yet he can hardly give specific rules to govern telling when this stage is reached. The lumps must have homogeneity—no uncolloided material inside—and there is a certain general consistency which is the outcome of so much solvent on so much soluble nitro-cotton. Sometimes an operator is not satisfied and he adds more ether. Rarely, although it would not be necessary if properly blended, acetone in small percentage is added to increase solubility. Nitro-cellulose powder colloided with acetone is apt to have irregular pressures.

So far we have described the mixing as if the high-grade pyrocellulose mixture and the pyrocellulose nitro-cottons were treated alike. This is so, with the exception that graphite is incorporated in the high-grade pyrocellulose mixture. This is the material of the higher explosive force and is used only for making small arms powder, which means it is made into very small grains. These small grains, unless they had some such material as graphite to make them conducting, would become charged with static electricity which would make them inconvenient for handling and for examination. The larger grains for the larger calibred guns are coated later with graphite.

REBLOCKING PRESSES

The charges from the mixers are first taken to a press where they are pressed into an easily handled cylindrical shape of the right diameter to fit the macaroni presses. The whole mixer charge is not pressed into one block, but into two or three, all of which make a macaroni press charge.

MACARONI PRESSES

(GRAINING PRESSES OR FINISHING PRESSES)

Ordinarily these presses are horizontal. At the end through which the colloid is pressed is a heavy perforated plate set in a heavy band locking door on hinges. This door swings open and the charge is put in and before closing a fine copper screen, of about 60 mesh, we should judge, is put on the inside of the perforated plate.

The colloid is forced through the fine copper screen, through the perforated plate, then through ten to twenty dies, and is carried away from each die by a downward sloping smooth tin tube which coils up the now string-like (although for big guns some is rope-like) colloid in the bottom of round boxes. When a box is filled, it is delivered to a cutting machine and another box is substituted in its place.

It is hard to describe a die and to give a good idea of how it works. The part of the die nearest the press consists of a small round perforated plate, from the center of which, outward and away from the press, projects a needle—to take a simple case—clear through the center of a funnel. A cross-section is shown in Fig. 1.

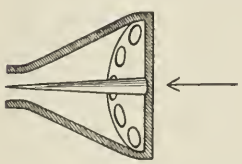


FIG. 1—SECTION OF DIE

The arrow indicates the direction of flow. The colloid squeezed through the holes in the perforated plate is compressed around the needle in the funnel chamber and on going through the outlet it has the desired hole lengthways throughout the center.

The area of the holes in the die must be at least one and one-fourth times the area of the cross-section of the die, lest the part compressed in the funnel should not be thoroughly enough compressed, resulting in an imperfect grain. The initial pressure on these presses is about 2700 lb. and the pressure mounts to about 3300 lb. at the end. A wide divergence is an unfavorable indication of the quality and purity from dirt.

By the output of these presses may be judged the efficiency of the whole plant. By "output" is meant quantity and quality. True, other operations are yet to follow, but they affect the output not so much as the prior operations, and neither do they indicate so well as the presses the quality of the prior operations.

The efficiency capacity of a press is about sixteen charges for twenty-four hours working time, but such an output is obtainable only by the exercise of high intelligence by every man connected with all the prior

operations. If the output of the presses be on an average of thirteen and one-half charges every twenty-four hours it could be classed as highly satisfactory. Ordinarily the run is nine to eleven charges. These figures for efficiency capacity apply to the output of a press that is pressing small-arms powder. For larger arms the output mounts as high as four times the above figures.

CUTTING MACHINES

In this machine the colloid strings, coiled up in round boxes and fresh from the presses, are fed between rollers, then through guiding holes, immediately on the far side of which they are cut into definite length grains by knife-edges set in the periphery of a revolving disk. The speed of the feeding, which is rarely varied, and the speed of the disk govern the length of the grains. The proportion of the parts of the grains is specified in the United States Government's tests. The sizes of the grains required to meet the specifications for the muzzle velocity desired and maximum pressure allowable is a subject beyond the scope of this article. However, we understand there have been one or two good books recently published on interior ballistics.

From the cutters the grains are collected in bags and sent to the solvent recovery. With the bigger grains it pays, even while the grains are collecting, to make arrangements to save the large amount of solvent evaporation from them.

From the presses and from the cutting machines there is a considerable waste of colloid nitro-cellulose. It is thrown into covered cans and when a sufficient amount has accumulated it is put in a small mixer, specially used for this purpose and mixed over again.

SOLVENT RECOVERY

The solvent recovery building is a long building with many brick fire-limiting walls. With handy connections, there are in each section pipes carrying warm air and other pipes carrying a refrigerating mixture. In each section is a narrow-gage track.

The solvent recovery cars are specially constructed. They are rendered vapor-proof by water sealing of the lids. Lengthways of one side is an air-warming apparatus which causes the air to rise on that side. The air flows over and down among the powder grains collecting the ether and alcohol vapors on its way. At the bottom the air strikes refrigerating coils and promptly gives up its vapors. The powder is in shallow trays, with copper screens on bottom, and set one on top of the other. The recovery process is continued till the small amount which would be recovered does not pay.

The ether and alcohol mixture that is recovered is sent back to the ether house, treated with H_2SO_4 and all made into ether.

WET DRYING

It sounds rather paradoxical to speak of wet drying, but the idea is to maintain the powder under water at 65 deg. C., in order to "boil" out the ether and alcohol mixture the more effectively. The principle of using cars is employed again, but the powder is set in deep copper screen baskets. What the length of time of this treatment is we don't know. It is probably not very long.

DRYING HOUSE

Here the water is dried off the grains.

COATING MACHINES

These give each grain a coating of trinitrotoluol. Which one of the trinitrotoluols it is we are uncertain.

This matter of coating the grains has a great deal of significance. There are probably three or four reasons for doing it. If, as it seems to be, America, by such a simple expedient, improves nitro-cellulose powders, without the addition of injurious ingredients, then we can claim some originality for ourselves. What England has attempted to do in her cordite and France in her nitrate powders, America does in a simple manner.

WET DRYER, DRY HOUSE, GLAZING BARREL

We have now another wet-drying process, this time to take out the solvent used in the coating process. It must have been a rather heavy coat which was applied in the coating process.

Again the water is dried off in a dry house.

The glazing barrel is used for glazing every grain with graphite.

Graphite has two uses; it protects the grain from sudden shock, and makes a conducting skin to carry off static electricity caused by friction of the grains over each other. Sometimes, before this skin is put on, the powder will take fire in an inexplicable manner.

BLENDING AND PACKING

The high-grade and pyrocellulose rifle powder blends are blended in the poachers as we have seen. The pyrocellulose cannon powders have so far come through with a percentage of nitrogen running between 12.45 and 12.75. The scheme is to blend these powders to meet the government specifications of 12.60 per cent, $\pm$ .01 per cent. After taking two lots of powder and calculating the proper proportions in which to mix them, this is done by putting those proportions of the powders in a square wooden funnel with an opening at the bottom. This opening is opened and the powders are allowed to run into another wooden funnel beneath. This in turn is opened, running the powder into another funnel, etc., till the powders are thoroughly mixed together, or about three or four times altogether.

Regarding packing, see United States Government specifications.

Library Service Bureau of United Engineering Societies

The United Engineering Library (Engineering Societies Building, 29 West 39th Street, New York City, 12th and 13th floors) is installing a Library Service Bureau along the lines of the former Library Service Bureau of The Chemists' Club. For the purpose of inaugurating this service, the three founder societies of the mining, mechanical and electrical engineers will provide the necessary funds, but the bureau is expected to become self-supporting.

The object of the bureau will be to place the facilities of the United Engineering Library at the disposal of anybody anywhere. Its work will consist in supplying reference cards on articles published anywhere on any special technical subject desired, in supplying copies of articles or of parts of books, in translating articles from foreign languages, making searches on any technical subject, etc. This work will be done at cost. Mr. E. Gybbon Spilsbury is the chairman of the "Library Service Committee" which will act in advisory co-operation with the executive committee of the library board of the United Engineering Society, of which Dr. Samuel Sheldon is the chairman.

Burma is the principal tungsten-producing country of the world, the United States coming second with about half the Burmese production. The bulk of the domestic output comes from Boulder county, Colorado.

The Relative Efficiency of Various Amalgams in the Recovery of Gold

BY FRANCIS A. THOMSON AND ROBERT KEFFER

In these days of the almost universal cyanidation of gold ores, the ancient and honorable process of amalgamation would appear to have been relegated to the rear. This is truer, however, of the literature of gold metallurgy than of the practice of the art, for we find that in 1913 21.5 per cent of the gold production of the United States was recovered by amalgamation.[1]

It would seem, therefore, that although somewhat unusual and contrary to the present vogue, one need make no apology for a discussion of certain important principles involved in the recovery of gold with the aid of mercury. Many years ago C. H. Aaron[2] stated that he had investigated zinc and cadmium amalgams and had found cadmium-amalgam especially to be remarkably free from tarnish under conditions where mercury-coated copper plates were quickly discolored.

This was the starting point of the investigation here reported. It was thought well, however, to extend the research to include a determination of the efficiency of various amalgams from the point of view of gold recovery, as well as of resistivity to film formation.

The senior writer of this article suggested the investigation and in a general way guided the research; he has also edited the report for publication. Further than this he disclaims any credit for the work done or the conclusions drawn.

As the first step in the investigation a number of amalgams of the commoner metals were prepared. These were then placed in turn on copper plates and the ore passed over the amalgamated plates a standard number of times under standard conditions. Samples were taken of the pulp during the first, third and fifth passage over the plates, and the samples were assayed to determine the amount of gold removed. The difference between this assay and the assay of the original ore was considered the extraction in each case.

Two tests were made to determine the number of passages over the plates necessary to secure the maximum extraction. The ore was run through the apparatus ten times and samples taken during alternate runs. In both cases no further change in the assay of the tailings took place after the fifth passage so the succeeding tests were run through only five times.

To further investigate the properties of the amalgams, a series of tests was made under difficult conditions. The ore was mixed in turn with manganese sulphate, zinc sulphate and ferrous sulphate, and each mixture passed over the plates five times. Two samples were taken—after the third and fifth passage —and assays were made as in the first series of tests. The sample of the first passage of the ore was omitted in these tests, as it had previously been found that little gold was removed by the initial run over the plates. A sulphide ore was also tried with a number of amalgams, but it gave such small extraction and yielded such inconsistent results that further tests along this line were abandoned.

Preparation of Amalgams

The common metals that amalgamate with ease are: gold, silver, zinc, tin, cadmium, lead and bismuth.[3] With the exception of bismuth and with the addition of sodium, potassium, aluminium and magnesium these metals constituted the list selected for the tests. Of these, potassium, aluminium and magnesium yielded amalgams of such an unstable nature that they were unsuited for use on the plates. The tests were, therefore, confined to the remaining seven metals. The method of preparation employed varied greatly and each metal will therefore be discussed separately.

1. **Silver Amalgam.** The silver amalgam was prepared according to the method given by Richards.[4] The reaction was practically complete in twenty minutes and the final amalgam (composition, silver 32 per cent, mercury 68 per cent) was a thick paste.

2. **Gold Amalgam.** The gold amalgam was prepared by dissolving pure gold, beaten into thin plates, in boiling mercury. It was found that the gold dissolved very slowly at ordinary temperatures, but went into solution in a few minutes when the mercury is near its boiling point. Fifty grams of mercury were used with 4.121 grams of gold and the resulting amalgam was pasty. On standing a very thick amalgam settled in the bottom of the tube, the remainder being perfectly liquid.

3. **Sodium Amalgam.** In the preparation of sodium amalgam 100 gm. of mercury were warmed in a casserole, and sodium metal added in small pieces, about the size of wheat grains. The sodium combines violently with the mercury, with evolution of yellow light; but as more sodium is added the reaction decreases in violence. Towards the end the mercury must be heated to boiling and the sodium stirred in. A total of 5.4 grams of sodium was required to saturate the mercury. On cooling the amalgam becomes hard and brittle, breaking with a rough fracture. It is soluble in mercury in any proportion and keeps indefinitely in a tightly corked bottle.

4. **Potassium Amalgam.** The potassium amalgam must be prepared in a test tube or other vessel with a narrow opening, which exposes but little surface to the air. In an open dish the potassium is oxidized to a greenish powder, practically as rapidly as added. The reaction between potassium and mercury is much less violent than that with sodium and the mercury must be hot to start the combination. The potassium was added in small, clean pieces, about the size of wheat grains and combined readily with the hot mercury with flashes of violet light. Towards the end of the reaction violent stirring and a temperature about the boiling point of mercury were required to cause combination. The mercury required 5.1 grams of potassium per 100 grams mercury for saturation (at boiling point of mercury). On cooling in the closed tube the amalgam hardened to a solid mass. When the cold amalgam was exposed to the air by breaking the tube decomposition set in immediately. The potassium oxidized very rapidly, occasionally with flashes of flame, forming a dull, greenish powder and liberating mercury. On account of its unstable nature this amalgam was not used in the tests.

5. **Lead Amalgam.** This was prepared by dissolving pure lead foil in warm mercury. It went into solution very readily, yielding a homogeneous fluid, which solidified to a pasty mass on cooling. On standing several hours the amalgam showed a marked tendency to separate into a thick, pasty amalgam and a very fluid amalgam, in a manner similar to gold amalgam. Composition—lead 50 per cent, mercury 50 per cent.

6. **Tin Amalgam.** Tin amalgam is prepared by dissolving tin foil or granulated tin in warm mercury. It resembles lead amalgam in its properties, except that it showed no tendency to separate as in the case of lead amalgam. Composition—tin 43 per cent, mercury 57 per cent.

[1] Mineral Resources 1913, Part I, p. 882.
[2] Eng. & Min. Jour., Vol. 48, p. 118.
[3] Schnabel. Handbook of Metallurgy. Vol. II, p. 254.
[4] Richards. Textbook on Ore Dressing. p. 114.

7. **Zinc Amalgam.** This amalgam was prepared by grinding 20-mesh powdered zinc in an agate mortar with mercury. Forty grams of zinc were dissolved in 100 grams of mercury, after about two months grinding. On standing the amalgam solidified to a hard, brittle mass, readily soluble in warm mercury.

8. **Cadmium Amalgam.** Pure cadmium in the form of ¼-in. sticks was dissolved in warm mercury. The cadmium went into solution very readily, being completely dissolved in five minutes. On cooling, the amalgam solidified to a hard, brittle, crystalline mass, which broke with an uneven fracture. It is very stable. Composition—cadmium 32 per cent, mercury 68 per cent.

9. **Aluminium Amalgam.** This amalgam was prepared with considerable difficulty. The usual methods of preparing amalgams were tried without success. The aluminium, in the form of dust minus 150-mesh, was boiled in mercury, but did not combine. Prolonged grinding with mercury in the agate mortar was next tried and failed to form any amalgam. The mercury was then heated with aluminium powder and dilute hydrochloric acid over night, without results. A quantity of aluminium strips was melted in a muffle at about 700 deg. Centigrade and the molten metal poured into cold mercury. This resulted in the formation of considerable liquid aluminium amalgam. The amalgam produced by this means was very unstable and, on cooling, a film of alumina formed over the surface and rapidly increased to a thick, fluffy coating.

To determine whether this instability was an inherent property of the amalgam or due merely to the high temperature of formation by addition of molten aluminium, a second lot of amalgam was prepared cold by treating sodium amalgam with a suspension of aluminium powder in water, as mentioned by Schnabel for the preparation of iron amalgam.[5] On standing twelve hours the sodium amalgam was completely decomposed with formation of sodium hydroxide and liberation of hydrogen and mercury.

$$Hg_xNa_y + yH_2O = xHg + yNaOH + \frac{y}{2} H^2$$

The liberated mercury combined with the aluminium to form aluminium amalgam. This amalgam was divided into two parts. Part 1 was tested qualitatively for aluminium and showed a large amount present. Part 2 was exposed to the air in a test tube and in six hours it had formed a "tree" of bulky alumina above the amalgam. This tree was of the same diameter as the button of amalgam, an inch and one-fourth long, and free from the tube on all sides. It was light gray, fairly coherent and showed to a remarkable extent the unstable character of the amalgam. The remaining mercury in part 2 was then tested for aluminium and showed only a trace of that metal. This amalgam was not used on account of its unstable nature.

10. **Magnesium Amalgam.** This amalgam is easily prepared by shaking the powdered magnesium in very hot mercury in a test tube. The amalgam is of a bright, silvery color. It was very unstable and on cooling decomposed rapidly, yielding a black powder (probably magnesium oxide) and mercury. It was not possible to get enough magnesium to combine to produce a solid amalgam on cooling in a closed tube. This amalgam was not used on account of its unstable nature.

Preparation of the Ore

The ore used was a quartz carrying free gold from the Anaconda claim, Ten Mile Camp, Idaho County, Idaho.

A 50 lb. lot was run through small rolls and then through a Braun pulverizer so that all passed through 40 mesh. It was then sampled very carefully by coning and quartering, followed by riffles.

As determined by a large number of check assays, the ore averaged 2.49 oz. gold and 2.7 oz. silver. The silver was not considered in the subsequent work.

Design of Apparatus

After considerable experimenting with an apparatus designed to change the direction of pulp flow after every 18 in. of plate length, it became apparent that such a machine was not a success. A second type of apparatus was, therefore, designed, consisting of a straight launder, in two 6-in. x 51-in. sections, with a drop of 2 in. between sections. The bottom of the launder was covered with six 6-in. x 18-in. copper plates, overlapping at the ends in the direction of pulp flow. The launder had a uniform slope of 1½ in. per foot.

The pulp was fed onto the upper plate from an 8-gal. conical sheet-iron tank, through a ½-in. valve. On account of the narrow plates used no spreader was found necessary to secure an even layer of pulp over the plates. The pulp, after passing the plates, flowed into a tailing tank of a capacity of 5 gal.

Preparation of the Plates

The plates were amalgamated as recommended by Richards.[6] They were rubbed with fine sand with a block of wood until the plates had a uniform red surface, dried and polished. A mixture of 10 sand to 1 ammonium chloride was then made, slightly dampened, and mercury was sprinkled into it. This mixture was rubbed into the plates until they had a uniform, mirror-like surface. They were then allowed to stand several hours and the green stains which developed scoured off and re-amalgamated. The plates were again allowed to stand and the foregoing process repeated until a resistant coat of mercury was obtained.

The plates covered with the different amalgams were prepared as follows: The plates were cleaned and amalgamated with pure mercury. The amalgam to be used was then diluted with mercury until it reached a thin pasty condition, and painted on the surface of the plates in a thin coat. All six plates were given an even coating, no attempt being made to give the top plate any different treatment from the others. When necessary the plates were scrubbed until the amalgam was of uniform texture.

After the runs with each amalgam the plates were cleaned up by first scraping with a piece of belting nailed to a small wooden block and lastly by scraping with a smooth piece of rubber stretched over a metal straight-edge. They were then scrubbed with sand and amalgamated for the next run. The gold amalgam was run last to avoid the possibility of salting the tailing from any other run.

Method of Operating

In order that all the tests might represent the same conditions, it was necessary to decide upon a standard method of procedure for use throughout the experiment.

The thickness of pulp which gave the best results was found to be 8 lb. of water per pound of ore, and this dilution was closely followed in all the tests. The pulp was stirred by hand in the tank until it reached a nearly uniform thickness; the valve opened and stirring continued while the pulp flowed over the plates.

The number of times that it was necessary to run the ore over the plates to secure a good extraction was

[5] Schnabel Handbook of Metallurgy. Vol. II, p. 254.

[6] Richards. Textbook on Ore Dressing. p. 114.

determined experimentally with pure mercury and with lead amalgam. These were run ten times with assays as shown in Table No. 1.

TABLE No. 1

	1st Run		3rd Run		5th Run		7th Run		10th Run	
Mercury	2.58	2.64	0.60	0.60	0.56	0.56	0.56	0.60	0.56	0.58
Lead Amalgam	2.56	1.82	0.80	0.80	0.80	0.78	0.80	0.76	0.82	0.80

From Table No. 1 it appears that no further extraction resulted after the fifth run and the remaining tests were therefore passed over the plates five times.

Samples were taken by allowing the entire stream to flow into the sample bucket for a number of short intervals, uniformly spaced through the run. Samples were taken during the first, third and fifth runs, but since it soon appeared that there was little extraction in the first run samples were discontinued. The tests in the presence of impurities were run in the same way with the addition of 5 per cent of the injurious substance to the ore before adding the water.

The standard conditions used may, therefore, be briefly stated: 1. *Dilution*—8 lb. water to 1 lb. ore; 2. *Agitation*—by hand to a uniform thickness; 3. *Number of times over the plates*—five; 4. *Samples*—lip samples during the first, third and fifth runs: 5. *Impurities*—Five per cent added to the dry ore.

Description of the Tests

1. **Pure Mercury.** Five tests were run with plain mercury, two on pure ore, and one each with admixture of 5 per cent zinc sulphate, manganese sulphate and ferrous sulphate. All conformed to the standard conditions laid down. Of the two tests on plain mercury with pure ore, one was made at the beginning of the series and one at the end, and these gave closely concordant results. With the addition of the sulphates the plates coated badly, which without doubt accounts for the marked lowering of the extraction under these conditions.

2. **Sodium Amalgam.** The amalgamated plates were painted with 1 per cent sodium amalgam, which gave an exceedingly clean surface, and also by the slow evolution of hydrogen and formation of free alkali kept the plates free from coatings with pure ore.

However, under the influence of the sulphates there was still much tendency to coat. Four tests were run with this and with all the subsequent amalgams: one of pure ore and one with the addition of each of the three sulphates, in the order of zinc sulphate, manganese sulphate and lastly, ferrous sulphate.

3. **Tin Amalgam.** Tin amalgam formed a very bright, clean surface when painted on the amalgamated plates, and proved very resistant to coating by the sulphates.

4. **Lead Amalgam.** The lead amalgam formed a rough, somewhat gritty surface, with dirty, black spots on it that were very difficult to scrub off. However, it was scarcely tarnished at all by any of the sulphates, proving more resistant than any other amalgam tried. It seems possible that the slightly gritty surface aids in catching the gold particles and that this may explain the extraction obtained with the pure ore, which is higher than several amalgams giving an apparently better surface.

5. **Zinc Amalgam.** This amalgam formed a fairly good surface on the plates, but the extractions obtained were very poor throughout. It coated badly under the influence of the sulphates.

6. **Cadmium Amalgam.** The cadmium amalgam gave one of the best of appearing surfaces of any tried and remained quite clean and bright throughout the tests with the sulphates. Nevertheless, it gave one of the poorest sets of results of any in the series for reasons not at present apparent.

7. **Silver Amalgam.** This amalgam gave a good surface, but coated considerably with the sulphates. It was applied in the proportions recommended by Richards[7] by painting on after the plates were amalgamated with plain mercury.

8. **Gold Amalgam.** The gold amalgam of the consistency of thin paste was painted onto the plate in a similar manner to that used for the silver amalgam. It furnished a slightly gritty surface which showed a tendency to tarnish under the influence of the sulphates. The results were very disappointing, but the rise in the assay of the tailing with each succcessive run (see the tables) would seem to indicate the probability of salting from the gold used. If the assays of the first run (0.76 and 0.72) be taken, the extraction is as good as was obtained by sodium amalgam.

A total of 4.121 grams of gold were used and 1.699 were recovered on cleaning up the plates. The loss from gold remaining on the plates and carried off by the pulp stream was thus 58.9 per cent.

Tabulated Results

The results obtained by the assays of the tailings are recorded in ounces per ton in the following tables, the assays being in duplicate. The assay of the original ore was 2.49 oz. gold per ton.

Ag Amal	1.40	2.04	1.18	1.18	52.6
Au Amal	...	...	1.04	1.08	57.4

In order to compare the extraction made by the various amalgams, the percentages are tabulated in Table No. 6, placed in order of the efficiency of the amalgam with pure ore.

TABLE No. 6

Amalgam	Pure Ore	Ore & $ZnSO_4$	Ore & $MnSO_4$	Ore & $FeSO_4$
Plain Hg	76.9	55.2	43.0	43.4
Na Amal	70.2	41.8	51.4	55.2
Pb Amal	68.2	55.4	59.5	65.9
Ag Amal	63.9	55.2	43.4	52.6
Sn Amal	56.3	62.9	61.9	63.6
Zn Amal	55.4	27.7	52.6	44.3
Cd Amal	43.0	41.0	40.9	52.6
Au Amal	32.4	27.7	50.4	57.4

When the average extraction under all conditions is considered, the amalgams are placed as in Table No.

[7]Richards. Text Book on Ore Dressing. p. 115.

7. These figures are obtained by taking the average of the extractions obtained with a given amalgam when used with pure ore and in the presence of the three sulphates.

Table No. 7.

Amalgam.	Average Under All Conditions	Pure Ore	Ore and $ZnSO_4$	Ore and $MnSO_4$	Ore and $FeSO_4$
Pb Amal.	62.2	68.2	55.4	59.5	65.9
Sn Amal.	61.2	56.3	62.9	61.9	63.6
Plain Hg.	54.6	76.9	55.2	43.0	43.4
Na Amal.	54.6	70.2	41.8	51.4	55.2
Ag Amal.	53.8	63.9	55.2	43.4	52.6
Zn. Amal.	45.0	55.4	27.7	52.6	44.3
Cd Amal.	44.3	43.0	41.0	40.9	52.6
Au Amal.	41.9	32.4	27.7	50.4	57.4

To determine which of these interfering elements had the greatest effect in reducing the extraction, the mean of all different amalgams, when used with the same impurity was calculated. The percentage of the extraction compared with that obtained with pure ore was also determined, as set forth in Table No. 8.

Table No. 8.

Substance	Average Ext.	Per Cent. of Ext. with Pure Ore
Pure Ore	63.1*	100.0
Ferrous Sulphate	53.2	84.6
Manganese Sulphate	50.4	79.9
Zinc Sulphate.	46.8	74.2

*Gold amalgam values omitted as unreliable.

Conclusions

The results in Table 7 show that plain mercury excelled any of the amalgams in the treatment of a simple gold ore, when free from impurities. In the presence of sulphates, such as are frequently found in oxidized ores, the extraction was much reduced and plain mercury no longer gave the best results. With 5 per cent of zinc sulphate, plain mercury dropped to fourth place; with manganese sulphate, to seventh place; and with ferrous sulphate, to eighth place. When their average performance under all conditions was considered, lead and tin amalgams gave the best results with plain mercury third.

Table 8 shows the relative effect of the sulphates in lowering the extraction. Ferrous sulphate caused an average drop of 15.4 per cent; manganese sulphate, of 20.1 per cent; zinc sulphate, of 25.8 per cent. The injurious effect is due to the coating of the plates caused by the presence of the sulphates, and in general the amalgams which gave high extractions showed less tendency to coat than the others, as may be seen from the results in Table 7.

From the foregoing considerations, it appears that mercury has a greater affinity for gold when pure than when any other metal is amalgamated with it.[5] In these cases where an amalgam shows a higher extraction than mercury alone, the effect is not caused by any increased efficiency due to the presence of the foreign metal; but rather to the superior resistance of the amalgam to the effects of impurities.

In ability to remain bright and clean in the presence of sulphates we have confirmed Aaron's results so far as cadmium-amalgam is concerned, this heading the list; the other amalgams follow about in the order named: Lead, tin, gold, silver, sodium and zinc. Plain mercury was coated worst of all.

State College of Washington,
Pullman, Washington

An alloy of silver and cadmium is patented by Edward D. Gleason, of Flatbush, N. Y. It is characteristic of sterling silver, being ductile, durable, brilliant and resistant to oxidation. The composition is about 55 per cent silver and 45 per cent cadmium.

[5]Gold amalgam should probably be excepted from this statement owing to the unsatisfactory nature of the results obtained with it.

Metallurgical and Chemical Engineering in Great Britain

(From Our London Correspondent)

The General Situation

So far as scientific progress is concerned we are marking time. We do not feel any shame that the general level of papers read this winter before our technical and scientific societies is so poor. One cannot say with confidence that even the Iron and Steel Institute may not fall short of their past high standard in their meetings next month.

The blast furnace, steel foundry and the rolling mill have in one sense never been busier, but it is a business conducted by reduced staffs working at high pressure. Under these conditions the writing of papers becomes a burden which even the keenest are glad to leave aside. There is only the professional element—and that is reduced numbers now left to write papers.

When the war is over we shall pick up the pace again and research will appeal with a new zest. But just now, spare time, thought and talk is given to considerations of what will have to be done when the war is over, with reference to the organization of over-sea trade. Many little informal conferences have been held. Civilian manufacturers and ex-manufacturers in khaki, who have been able to leave their regiments for a few hours have fore-gathered. Difficulties have been frankly recognized, and on the whole the feeling may be described as one of cautious optimism.

The Sheffield Exhibition of German Cutlery

Your correspondent makes no apology for quoting in extenso the following two paragraphs from the Times Engineering Supplement of February 26, which he had overlooked in his last letter. They illustrate in regard for one industry alone some of the difficulties the recognition of which was mentioned above.

"The opportunities offered by the elimination of Germany's rivalry in the cutlery trade have been very effectively brought home to Sheffield manufacturers by the exhibition of a remarkable collection of German cutlery. The exhibition has been arranged by the Cutler's Company in co-operation with Mr. Walter Tyzack, head of one of the principal cutlery firms in Sheffield, who lent a collection from English agents who have been selling German products to export merchant houses and to retailers. The prices at which these goods had been sold are such as to show how formidable a task it will be for Sheffield manufacturers to secure the two million pounds worth of trade in cutlery which Germany has sacrificed by the war. There were pocket knives at 7½d. a dozen, large two-bladed penknives at 3d. and 4d each, champagne knives at 2s. 6. and 3s. 6d. a dozen, table knives at 1s. 5d. a dozen, safety razors from 3d. each, folding scissors at 1s. 7d. a dozen, and ordinary scissors at from 1s. a dozen. In many cases the prices of the finished articles are less than the bare cost of grinding in Sheffield, and the bulk of the specimens shown had been sold at about one-third or fourth the average price asked for Sheffield products of similar class. In quality and appearance the German goods were by no means to be despised; the workmanship was good and there was evidence of a strongly developed artistic instinct.

"To enable Sheffield makers to compete with such products some changes in methods, plant and working conditions of a revolutionary character would have to be made. Sheffield cutlers in the past have

by no means been so sympathetic towards the introduction of labor-saving machinery as were the Solingen operatives; but of late a much more reasonable spirit has prevailed and the exhibition—which was visited by crowds far in excess of the accommodation available—will serve to bring home to the workmen a better appreciation of the difficulties with which employers have had to contend in maintaining their businesses."

The War and the French Iron and Steel Industries

Although the invaded districts in France at present in German occupation is only 3.7 per cent of the area of France, it is largely industrial, containing before the war 8.2 per cent of the population. Prominent among the industries of the occupied area are those of iron and steel. The following percentages of the total French works are in the enemy's hands:

Iron pipe works	100	per cent
Iron mines	90	"
Pig iron	85.7	"
Iron girders	88.3	"
Coke	78.3	"
Cast steel	76.9	"
Steel rails	76.6	"
Steel ingots	76.0	"
Puddled steel	62.4	"
Iron plates	63.2	"
Iron wire	52.2	"

If in the progress of further conflict much injury is done to these districts France will be badly injured industrially.

The economic outlook in northern France and in Flanders is gloomy in the extreme.

Electric Steel-Making Furnace

The April issue of the Journal of the Institution of Electrical Engineers contains a paper read by Mr. T. D. Robertson before the Manchester local section of the I. E. E. with the above title. In its scope the paper was mainly historical and dealt with elementary principles of the Kjellin, Stassano, Heroult and Girod furnaces. The rest of the paper was given to a description of the "Electro-Metals" furnace of Grönwall, Lindblad and Stalhane. The description is characterized by an absence of data, unless the following particulars of the energy consumption of this furnace can be called data: "When melting cold scrap, using two slags and refining to a best quality, the approximate energy consumption decreases from 850 kw. hours per ton, in the case of a two-ton furnace to 750 kw. hours per ton in the case of a five-ton furnace. Those taking part in the discussion emphasized the need for figures apparently unaware that various papers read before the Iron and Steel Institute gave figures for other than the Electro-Metals furnace. It was in reply to this that the author gave some typical figures for the Electro-Metals furnace. For a 25 cwt. furnace producing 1406 tons a year about 850 kw. hours are estimated per ton. Taking electrical energy at 1 cent per kw. hour, and allowing for cost of raw material, labor, electrodes, repair and maintenance and raw material, the cost per ton works out at £6 5s. 6d. For a 2-ton furnace, producing 2250 tons per annum, about 800 kw. hours per ton are required.

Calculating on the same basis as before the cost per ton works out at £5 17s. 8d., and the 5-ton furnace producing 4050 tons per annum at 750 kw. hours per ton, works out at £5 11s. 3d. per ton. Management, laboratory and capital charges are not included in these prices.

The Institute of Metals

Absence from London at the time prevented your correspondent attending the March meeting of this Institute, and he has been dependant on the technical press for an account of what took place. Professor H. C. H. Carpenter of the Royal School of Mines presided. Perhaps the most interesting papers were those by Professor Huntington on "The Effects of Heat and Work on the Mechanical Properties of Metal," by Mr. S. Whyte on "The Micro-Chemistry of Corrosion," and by Professor A. A. Read and Mr. R. H. Greaves on "The Properties of Some Nickel-Aluminium and Copper-Nickel-Aluminium Alloys." In regard to the last two papers the common interest of corrosion phenomena linked them together, and it is in this connection that your correspondent would remark upon the apparent necessity for a revision and standardization of corrosion tests. While the index afforded by loss of weight through either direct chemical action or through local galvanized action on any test plate cannot be ignored, a better index and one more quickly ascertained is that of the determination of the e.m.f. (measured, of course, by a potentiometer) between the metal under test and those other metals with which it is likely to be used industrially. The electrolyte should always be the liquid with which the metal under test will come into contact.

Engineering Training

In the multitude of councillors there may or may not be wisdom, but of a certainty there will be difference of opinion. Over here we have sharply marked schools of thought as to how engineering education should be imparted, and in what proportions and in what sequence theoretical and practical training should be blended. The latest contribution to the consideration of this subject is Mr. A. P. Fleming's paper recently read before the Manchester section of the I. E. E. The author pointed out that "of the various plans of training for technical positions the following are the most common:

(a) By a trade apprenticeship combined with evening or part-time study. This method is particularly applicable to manufacturing.

(b) By a short period in works, then a college course, followed by works' apprenticeship. This plan is recommended by the Institution of Civil Engineers.

(c) By taking a complete college and then a works' course.

(d) By sandwiching college and works' training in varying periods.

(e) By taking a complete works' apprenticeship prior to technical training. This is not a satisfactory method for training for technical positions in manufacturing.

Of these plans, a, b and c are most suitable from the manufacturers point of view; but whichever method is adopted it is desirable that the practical training should terminate in the works, since a better opportunity is afforded to the student for obtaining permanent employment with the firm in which he has obtained his training. It is also most important that the entire training be preceded by thoroughly sound general education.

There is a wide diversity of opinion as to how long a period of practical training a technically educated man should have, and what its nature, should be. Some firms adhere to the five-year apprenticeship scheme as applying to all young men, whether they are being trained as workman or for technical positions, but the more modern tendency is to arrange a shortened course for the latter. While long practical experience is excellent it is not the mose effective

method of attaining the end in view. Moreover, a man who has had his intelligence developed by a technical college course should be able to acquire practical experience at a much quicker rate than one not so educated. The object is to afford an insight into manufacturing methods and economics, and to acquire a knowledge of how to handle men.

The author describes the methods employed by the British Westinghouse Co. at their works in Manchester in training their apprentices. The apprentice school method of instruction has been adopted. Instruction averaging about 5 hours per week is given during working hours to all "bound" apprentices, numbering about 300, in a school situated in the works. The regular rate of wages is paid during the time spent in study, and all the cost of books and stationery is borne by the firm. The teaching is done by twelve members of the firm's engineering staff, supplemented by lectures from the leading foreman and shop engineers, which deal specially with the trade subjects. The contact between the foreman and the apprentices in the school produces excellent results, and removes the diffidence which many of the apprentices feel in approaching the foreman with their difficulties. Where it is required to illustrate specal processes or describe particular apparatus, which cannot readily be done in the school by lantern projection or drawings, practical demonstrations are given in the works.

The most promising of the apprentices are selected for work in the testing departments and drawing office, and in other respects are allowed a wider range of work than that covered by their own trade. Each year about ten apprentices are selected as a result of their school work and shop progress and sent for one whole day each week to the course for engineering apprentics at the Manchester Municipal School of Technology. The cost of tuition, books, etc., is borne by the firm, and no deduction is made from the wages during the time spent at the school. Such youths are marked for advancement in the company's service as suitable opportunities occur.

Through their work in the school the interest of the foreman is aroused, and as a result increased attention is paid by them in the shops to the practical training of the apprentices.

This apprentice school has only been in operation for about a year, but so far the results both from the point of the company or of the apprentices are most encouraging.

It is early as yet to claim the method and routine employed by the British Westinghouse Co. as a final solution of the problem. For one thing under changing industrial, social and economic conditions there is no finality. Yet the problem before us is an insistent one. The old pride of handiwork and craftsmanship is disappearing, indeed has almost disappeared before the machine too and the factory system.

The pace at which industrial change takes place prevents our ever getting back to the old system and its intense pride of work. Yet some substitute must come. Not only do we do need it for the sake of those who rise by sheer force of character from the ranks, but it is obvious that the daily toil for daily bread of the bulk of our populations should have its intelligent interests and not lead to a mental atrophy of all brain power.

Electrolytic Corrosion of Gas and Water Mains

On the 23rd of February a paper was read before the Institution of Civil Engineers on "The Electrolytic Action of Return in Electric Tramways on Gas and Water Mains, and the Best Means of Providing Against Electrical Disturbances," by Mr. H. E. Yerbury. The author reviewed and criticised the Board of Trade Rules and Regulations and their revisions, from 1894 to the present date, and dealt with the influence of a leakage current on reinforced concrete. The preventive measures proposed by British and Continental authorities in order to reduce the potential differences between tramway tracks and pipes were classified, and a description of the function of a negative booster was given in detail. The author stated that where the rails and mass of earth were positive to pipes in the vicinity of the track there could be no danger to pipes in that area, as they were cathodic. On the other hand, danger existed to all pipes and metallic structures (where imbedded in soil) which were positive to the rails, as it was the flow of current out of the pipes that had a tendency to cause corrosion and pitting. The danger, however, was nothing like as great as would appear from a theoretical standpoint.

He pointed out that as current density and duration of current were the most important factors in connection with injurious electrolytic action on gas or water pipes, potential readings were misleading; it was well known that where a comparatively high difference of potential existed there was, as a rule, less injurious current passing. In his opinion the Board of Trade regulations in respect of leakage currents could easily be complied with on all tramway undertakings, and were absolutely effective in safeguarding the property of other authorities. Up to 600 volts could be allowed between overhead conductors and earth, and this increase of voltage would reduce the cost of feeders and also the heavy currents now dealt with.

Market Prices

(April, 1915)

Copper opened £69.10 and appreciated to the 12th, £72.12.6, then fell off slightly to £71.17.6 (13th), but recovered and continued rising to £76.12.6 (19th); was lower on the 20th (£75.17.6), but recovered to £77.12.6 on the 21st and was up to £81.5.0 on the 27th.

Tin opened £168, and was lower £166.10.0 on the 6th, recovering to £170.0.0 by the 8th. On the 9th it had eased to £168.10.0, but recovered and was £171 on the 13th. It then fell away to £164.10.0 on the 16th. On the 19th it had risen to £167.15, but was lower after to £164.10 on the 21st and the same price on the 27th.

Hematite opened 95/- and remained at this price throughout the month.

Scotch pig opened 73/9, and was 75/4½ on the 6th, then declining to 73/3 on the 8th. It recovered to 74/9 on the 12th, but was again down to 73/- on the 13th. Recovered a little 14th and 15th, but afterwards declined and was 70/6 on the 21st.

Cleveland opened 67/9 and was much harder on the 6th at 69/4½. It then declined to 67/3 (8th) and recovered to 68/9 (12th). Another falling off brought it to 67/- on the 13th, and after reaching 66/9 on the 16th, it dropped to 64/6 on the 21st, closing at 65½.

Blast-Furnace Plant Auxiliaries and General Arrangement

BY J. E. JOHNSON, JR.

In addition to the apparatus previously described which is required for each furnace there must be a considerable amount of other equipment for the plant as a whole. Of course, it goes without saying that the enormous tonnages involved at modern blast furnaces can only be handled by first-class railroad track and equipment, both of cars and locomotives, and in sufficient amount, and that at practically all plants of any size cranes for handling heavy parts, cleaning up "messes," and doing innumerable kinds of work that was formerly done by hard manual labor, are extensively used. Very frequently they are arranged to operate grab buckets and magnets as well as serving for general utility cranes. These also are standard equipment and do not need to be specially described here.

The Water Supply System

The water supply system is one absolutely indispensable portion of the equipment which to judge by the location and the design of some plants was forgotten at the time of their construction and put in subsequently as an afterthought.

The modern furnace depends upon water-cooling for its very existence, not from minute to minute, but literally from second to second, since the tuyeres, coolers and cooling plates are exposed to the most intense heat and the severest conditions of scouring by iron and slag, not occasionally, but in many cases continuously, and only a thin surface of the highest possible conductivity cooled by a violent circulation of moderately cool water prevents their instant destruction.

For this purpose water in considerable quantity must be provided. Its quantity varies very greatly with the size of the furnace and the method of cooling adopted. Cooling plates require more than bosh jackets, and, of course, when cooling plates are used above the mantle they add their quota to the total requirements, since a certain minimum velocity must be maintained for each plate, the minimum depending upon the temperature to which the plate is exposed.

For an ordinary five hundred-ton furnace from 1200 to 2000 gallons of water per minute are required for cooling the tuyeres, hearth and bosh. In addition to this the water necessary for boiler feed, and very generally for condensers, must be supplied, and in modern practice great quantities are being used for gas washing also. This amounts to about 4 gals. for primary cleaning for every 100 cu. ft. of gas or about 2000 gals. per minute if all the gas is washed. It should be noted that the furnace cooling water can be and generally is used over for either condenser or gas cleaning. The consequence is that each blast furnace requires a very respectable volume of water, from 3,500,000 to 6,000,000 gallons per day, and a plant of several blast furnaces needs a supply which makes that of many large cities look small in comparison.

Plants have too often been designed with little or no consideration for their location in regard to water supply. There are perhaps more important considerations such as the arrangement of tracks, etc.—but in a number of cases that have fallen within my own experience a location close to the water supply would have been not only as good but better in other respects than the location actually chosen, at some distance from it, with the necessity of long lines of communication and long-distance supervision of the pumping plant, for, of course, in modern practice long suction pipes are rightly not tolerated, and the pumping plant must be close to the water supply and within a moderate distance above the water level. Moreover, the pumping plant must be able to run and supply water to the furnace irrespective of fluctuations in the height of the supply. These conditions are easy to fulfill if the plant be on the border of a lake or a stream whose level does not greatly fluctuate, but very difficult to meet in some cases where the source of the water supply is a stream with a rise and fall of many feet, such, for instance, as have the Monongahela and Ohio rivers in the Pittsburgh district.

The design of the pumping station must be based on the local conditions and on the size of the plant. Where a very large plant is needed on the banks of such a river it is often desirable, if not necessary, to sink a huge caisson down below low water level from a point high enough above the river level to be out of danger of floods, and run a tunnel of brick or concrete from this out into the river itself. This, of course, requires a cofferdam of some extent for the construction of the tunnel.

The pumps are located at the bottom of the caisson or pit and the flow of water into it is controlled by valves at the inner end of the tunnel so that no matter how high the river may rise the pumps cannot be drowned out.

The screening of the water is done in the pit, no attempt being made to erect screens over the mouth of the tunnel since they would be inaccessible in times of flood.

In other cases a masonry forebay is built at the bank of the river and extending well down below water level its front being entirely open to the river except that it is guarded by screens. These may either be fixed or arranged to be removed for cleaning. The latter, of course, can only be done by having two separate chambers both of which can be entirely cut off alternately, or by having two sets of screens, one in front of the other so that each one alternately can be raised for cleaning. The possible variations of these methods are of course almost infinite, but the question is one of great importance because the water supply of furnaces is more apt to be interrupted by floods than by any other kind of accident whatever. The likelihood of dangerously low water can be foreseen, and the necessary arrangements for an additional supply made in ample time, but when a flood arises, especially in a mountainous country, two or three hours may see a change from placid operation to one of absolute disorganization on account of water supply. This is for the reason that when these violent floods occur they pick up vast quantities of silt, leaves, and sticks, so that the consistency is almost like soup in extreme cases, and this combination can stop up a screen in a short time almost as effectively as could a plasterer, while owing to the location of the screens it is not always possible to clean sufficient of their area to let through the water necessary to the life of the plant.

Several years ago having occasion to provide a water supply for a small furnace near but not on the bank of a mountain river, subject to rises of some twenty or twenty-five feet, I installed a plant designed to meet these conditions which has been very successful in operation, and of which the principle may be useful to others. This plant was described in the April 18, 1914, issue of the *Engineering and Mining Journal*, from which the illustration of Fig. 1 is taken.

A forebay of brick-work was built with its base about two feet below the lowest water level, very much as in ordinary construction, but instead of screening this with a straight stationary screen a circular revolving screen was used, which was supported on trunnions built into the masonry. The outlets for the screened water were through the ends of the screen wheel and

the side walls of the forebay into the pump pits on each side of it, these suction pits being covered over with iron plates laid in cement so as to be water-tight even when submerged. The screen wheel fitted snugly between the walls of the forebay and was perfectly open in front. At the bottom it passed with bare clearance over a wide sill of concrete running clear across the forebay. At the top it was covered over with a curved plate which fitted down over the top segment of the wheel with small but sufficient clearance. The arms of the wheel were solid plates running from side to side the full width of the wheel, reinforced by angles

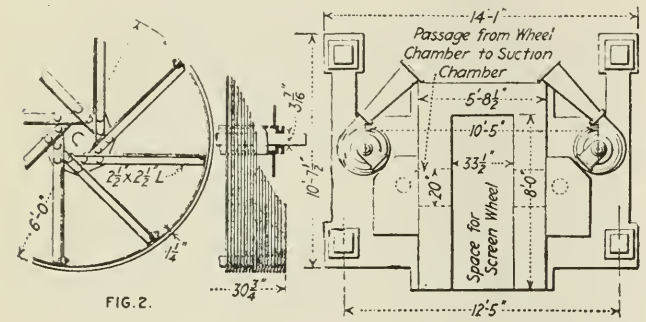

FIG. 2.

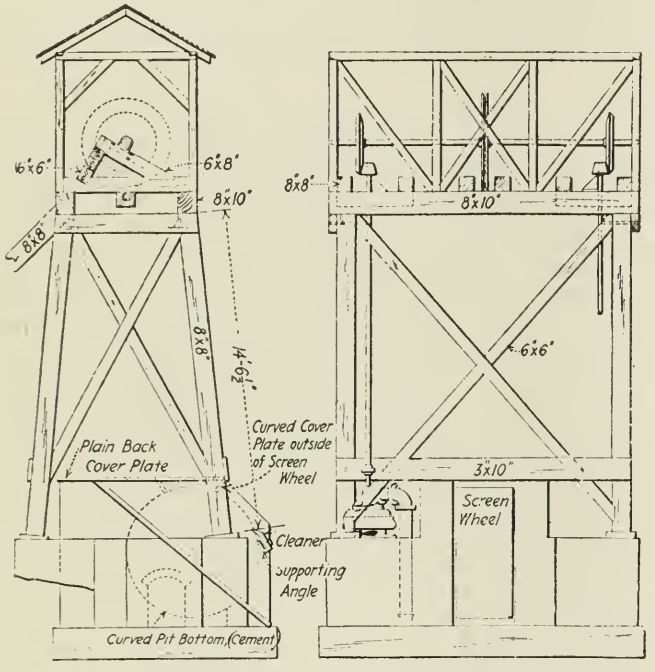

FIG. 1—SELF-CLEANING SCREEN FOR PUMP SUCTION

riveted to the hub as shown in the drawing. The sill and the curved cover plate at the top were a little wider than the space between two adjacent arms.

The wheel proper was made up of welded rings an inch and a half by a quarter, bent edgewise with half inch spaces between them. A stout angle across the front of the forebay carried cleaners which worked in the spaces between each pair of rings.

Supposing the pumps to be at work, and the water level somewhere about the center of the wheel, if the lower section of the screen through which the water is passing becomes obstructed by leaves, the pumps continuing to run, the level of the water inside the wheel is soon lowered well below that of the water outside, and this difference in level then works upon the arms of the wheel which thus virtually becomes an under-shot water wheel and rotates the obstructed section downward thus bringing a new clean section into play. When this becomes obstructed in turn the same action takes place and when the first section obstructed finally comes around to the cleaners, the leaves, etc., are thrown off by them and the wheel restored to a clean condition.

It will be noticed that centrifugal pumps with vertical shafts are used with their driving mechanism set on a platform many feet above the water level. The driving mechanism in this particular case was by wire rope and bevel gears, there being clutches to throw in or out either pump as desired. Now it would probably be preferable to use a vertical-shaft motor directly connected to the vertical pump shaft. A great advantage of the centrifugal pumps is that they have no valves to become obstructed, and can run submerged for an almost indefinite period. They are located about two feet above normal water level so as to make them easy of access for repairs, etc., under all ordinary conditions.

This plant had gone through several floods in which the screen wheel, pumps, and all were submerged for several feet, and has never failed, as far as I know, under those conditions.

A hand turning gear was provided to rotate the screen by hand if for any cause it should fail to work automatically, and of course it would be a very simple matter to arrange by a geared ratchet or some other mechanism to drive the screen wheel positively and continuously, which might be desirable in some cases.

This wheel was designed for a capacity of about one thousand gallons per minute, for which it was more than ample, and a plant of this kind with a capacity of many thousand gallons per minute could be built at a comparatively small expense. There is no patent on this design and any one is at liberty to use it who wishes to do so.

Pumping Machinery

Many different types of pumping machinery are used. For small plants and where steam economy is not important, and where the pump installation can receive attendance from the engine room force, direct acting steam pumps have often been used in the past, in fact, until quite recent years no other type of pumping apparatus was available except in the largest sizes. As a result different pumps were added from time to time and the number and variety of pumps to be found in the pumping station of some large blast furnace plants was remarkable.

The direct acting steam pump is moderately reliable, but not sufficiently so to run without attendance since the pumps may "stick on center," the valves may become blocked open, and various other contingencies may arise which necessitate inspection at frequent intervals. This type of pump is also extremely uneconomical. In the smaller sizes their steam consumption is probably always in excess of one hundred pounds of steam per horse power hour. In the larger sizes where compounding and triple expansion are used, and where more refinements can be included in the design, their steam consumption drops to the half of this and often to the quarter, the later figure being extremely rare except with what may be called pumping engines rather than steam pumps. In all the ordinary sizes steam consumption is probably never less than fifty to one hundred pounds per horse power hour.

For larger plants the vertical plunger pump with plungers directly connected to the cross-heads of a triple expansion engine, of the crank and fly-wheel type, with their cranks at one hundred and twenty degrees, are probably as economical as any type of pumping engine driven by steam machinery. They have the great advantage that being vertical the water cylinders can be placed near the normal water level, while the steam cylinders and driving mechanism are high enough

to be out of reach of any possible flood, and in case of a flood the pump cylinders may be submerged and continued to run indefinitely in that condition. These, of course, are necessarily large units and their speed of revolution is limited by the ability of the water to make its way through the valves and follow the plungers which, on account of the inertia of the water, is at a very slow rate. These pumps, therefore, seldom run at more than thirty revolutions, which makes their cost very high in proportion to their output.

In the last ten or twelve years the centrifugal pump with multiple stages has been developed to a high state of efficiency, and instead of being limited to thirty or forty feet lift as was the old single-stage centrifugal pump some twenty years ago, these pumps are now designed for lifts up to many hundred feet. Their efficiencies with good designs range from seventy per cent up to eighty in exceptional cases, and while this is considerably lower than the efficiency of a good plunger pump it is maintained through a long period of years.

The pumps are almost independent of leakage, operating solely by the velocity which their impellers impart to the water, and they are entirely valveless so that under any ordinary circumstances they will run without interruption for very long periods of time.

One word of caution may not be amiss here. The old centrifugal pumps were designed so that they would pass anything up to the size of cabbages, but the modern multiple stage pumps have what may be called a closed impeller with the outlets at its periphery rather narrow, so that sticks of moderately small sizes may lodge in these and cut off the water flow. For this reason screens must be provided with openings small enough to bar anything which could lodge in these discharge ports. The obstructions which will pass these ports are however larger than those which were likely to derange the valves of reciprocating pumps, and centrifugals have therefore the best of the argument in this very important respect. Owing to their extreme simplicity and to the fact that they have but one moving part, and to the entire absence of valves these pumps are relatively inexpensive, a result which is attained by virtue of the fact that they are run at very high speeds, and pass an enormous volume of water in proportion to their size.

I well remember that the master mechanic at the plant at which the pumping plant illustrated above, Fig. 1, was installed, assured me with great respect, but nevertheless with profound conviction, that those pumps would never deliver water enough to supply that furnace. When they were put into operation, however, one of them promptly ran away with the supply brought in by the race from the river, he had to bestir himself to increase the supply, and his doubts were overcome with a vengeance.

Centrifugal pumps on account of their extreme simplicity may be operated practically without supervision or at least only at several hour intervals, there being only a few oil cups to look after. These pumps may be driven by any type of motor desired but for large sizes there are practically only two to be considered. One is the electric motor, the other the steam turbine.

When the pumping plant is located at some distance from the main plant, electrical transmission is to be desired, as it will run for many hours without attention if properly installed and equipped, so that an occasional visit of an attendant is sufficient, whereas when steam machinery is employed it is virtually necessary to have an attendant on duty all the time though his work may be of the lightest 95 per cent of the time.

In small sizes the electric motor driven from an economical central station is probably more economical than the turbine, because the turbine economical in small sizes has not yet been developed, but in large sizes the directly connected turbine furnishes an ideal drive for these pumps. On account of the very high efficiency of the turbine, especially in view of the fact that a surface condenser may be installed in the water main and a very high vacuum attained without much expense, it is probable that the best type of unit of this kind is as economical in steam consumption as the vertical pumping engine earlier described because the greater efficiency of the turbine offsets the smaller efficiency of the pump, and the cost is only a fraction of that of the engine driven unit, so that where steam-driven plants are to be installed it may be expected that the turbine-driven centrifugal pump will play an increasingly important part.

In one plant of which I formerly had charge the pumping plant consisted of triplex plunger pumps belt driven from electric motors, and while the pumps were poorly designed and were too weak for the service for which they were furnished the combination formed (with this exception) a very satisfactory plant, and to my surprise the efficiency of the pumps was very high. A test was made of one of them using a large and accurate weir to measure the water, and although the pump was not tuned up for a test, but tested in its ordinary running condition, the efficiency of pump and motor figured out about 85 per cent, and undoubtedly a plant of triplex pumps properly designed and geared to their driving motors would be an effective and satisfactory type of pumping plant where electric drive was desirable, but of course this type of machine does not lend itself to satisfactory steam drive.

The details of these different types of pumping plants are no different from what they are in ordinary service and therefore need not be especially described and illustrated here.

Stand Pipes

The water supply is vital to the life of the furnace plant and must be continuous, since the failure of the water supply on the tuyeres for two seconds would almost certainly cause them to be burnt, and only a few seconds more would be necessary to burn the coolers and cooling plates as well. For this reason no amount of care expended to secure a reliable and constant water supply to the furnace is too great.

It is obvious that even with duplicate units in the pumping plant there must be an interruption of a few minutes from time to time in the supply, and it is therefore universal in good modern practice to have a stand-pipe with a capacity sufficient to take care of the furnace water supply for a limited period. What this period should be depends upon the judgment or, one might almost say, the individual caprice of the designer of the plant. I have seen some plants at which the stand-pipe looked hardly bigger than the smoke pipe of a domestic stove, while at many others it is of the size that would do credit to a large city.

It is probable that the stand-pipe should be sufficient to maintain a full supply of cooling water on all the furnaces for at least one hour. Then in case of a serious failure of the pumping plant the furnaces would be shut down and the water supply slacked to a very small percentage of its normal flow, and in this way they would be saved from injury for several hours. In case of necessity the tuyeres and even the coolers can be pulled if it is obvious that the water supply can not be restored before the stand-pipe gives out.

There are three types of stand-pipe in common use: first, the straight cylindrical pipe like a stack, second, the elevated tank (generally in modern practice having a spherical or parabolic bottom) supported on a steel

tower, and third, a flat tank of relatively small depth placed on top of some building for which it acts as a roof.

The first type is the poorest for the reason that only the upper third of it is useful for storage since when the water falls below that level the head is insufficient to maintain a proper supply. Or if the tank is built so high that a greater proportion is available then the water must be pumped much higher than is necessary to obtain the desired amount of storage, with consequent waste of power and high cost of equipment.

The second type is that which is commonly used as the stand-pipe for cities if no hills are available, and for large plants. The tank is elevated to such a level that its whole contents are available for a water supply, and the excess of the maximum over its minimum height of the water level in it is small so that not much excess pumping is required.

The third type is not so common now as it was a few years ago, but has much to recommend it, embodying as it does a very large storage with a very small fluctuation in height, and being supported on the walls of the building whose roof it forms, its expense is not excessive, although of course very heavy girders are required across the building to sustain its weight.

At some fortunate plants which receive their water supply by gravity little or no tank is used because of the slight probability of interruption to the regular water supply there being no machinery to fail.

Water Mains

The character of the water main, like that of many of the other auxiliaries, is determined primarily by the size of the plant. For small plants nothing but cast iron pipe is probably ever considered, but for larger plants riveted steel mains have sometimes been used, and it is possible that in the larger sizes they are cheaper for a given strength. One point should, however, always be kept in mind in designing mains, and that is that the water which is pumped through them varies from just above the freezing point to eighty or ninety degrees in some districts. The expansion therefore is considerable and means must be provided to take care of it. At one large furnace plant a large riveted steel main was pulled in two by contraction after being several years in service, and the job of making even a temporary repair was a very difficult one, while it could not be permanently repaired except by having the whole plant shut down, a condition which should not exist for many years at a stretch.

This illustrates a point which it is well to bear in mind in connection with auxiliaries, that while each furnace and its immediate accessories are shut down completely at periods ranging from one to three or four years the plant as a whole, even though it be not a very large one, is not likely to be shut down so completely as to permit stopping the auxiliaries for many years at a stretch. This fact should be borne in mind in laying out water mains, gas mains, electric lines, and sewer systems, particularly the first and last on account of their great size, their being buried underground, the great expense of doing anything with them, and the vast difficulty of rigging up temporaries to permit repairs to the regular ones.

Returning to the matter of the kind of pipe to be preferred, the cast iron has two very great advantages. The first is that cast iron is less subject to corrosive influences than any of the other ferrous metals, the extent to which it is eaten away being only a fraction of that at which steel is attacked under the same condition.

Second: A bell and socket cast iron pipe is laid with a lead joint every twelve feet, this lead being cast and calked to place on a backing of oakum in a way that makes it virtually an expansion joint, so that the expansion of each section is taken up at its ends. No heavy contraction stresses can arise in this kind of pipe, nor can any distortion due to cumulative expansion from one end.

Steel pipe, on the other hand, is rigidly fastened together in one piece, and if special precautions be not taken to prevent, the expansion or contraction is liable to be concentrated at one point and cause the failure of the pipe at that point. For this reason if steel pipe be used as a main water supply system, well-made expansion joints, preferably made on the principle of a huge stuffing box filled with oakum, hemp or other packing, and set up with a gland, should be inserted at such distances as to localize and limit the expansion and prevent its doing damage.

Where large plants are concerned, it is a matter for very serious consideration whether two mains should not be used instead of one, the two together being large enough to supply the whole plant, and one of them able to furnish an emergency or partial shut-down supply. By the introduction of a comparatively small number of duplicate valves permitting both mains to supply all parts of the plant, and at the same time enabling large sections of either to be cut out, provision can be made for repairs to these important accessories without much difficulty or expense, something virtually impossible when a single main is used.

Furnace Main Connections

The connections from the water main to the circulating system around the furnace are a matter of the greatest importance, and no amount of care, and no reasonable amount of money is too great to secure freedom from failure here.

It has been my misfortune to experience three partial failures of this kind, and while in every case we escaped without serious damage to the furnace, we were forced to desperate expedients, in one case being compelled to pull the tuyeres from the furnace as the emergency supply was insufficient to supply these as well as the coolers and cooling plates, the latter could not be removed without serious delay and so were left in and fed with the minimum quantity of water which would prevent boiling. In this way we managed to prevent the burning of any cooling member while we changed the fitting in the main supply line which had split but still remained in place, although its duration was evidently to be measured by minutes rather than hours.

It is my judgment that two independent supply lines should be used, equipped with the modern type of non-return valves close to the furnace main, these valves being bronze fitted throughout so as to prevent sticking in the hour of need. These supply lines should be of moderate size so that normally some water would flow through each and keep them both active, while in case of trouble with one the other would deliver an emergency supply. The non-return valves in case of breakage would prevent the water delivered by the unbroken main from flowing back out through the one which failed and is an indispensable feature of such a design.

Waste Water System

Until within recent years all the water used by the furnace was returned to the sewer supply so little polluted that it required no special treatment, the water having been used almost exclusively for cooling and condensing purposes, but this is no longer true since the introduction of the gas washer. The wet scrubbing of gas requires a large quantity of water both for cooling and cleaning purposes, and the water discharged from these systems is exceedingly foul, containing the dust from the gas, and also much of the fume which we

have been accustomed to consider separate from the dust. In most cases to return this foul water by way of the sewer system to the source of supply would be to invite legal action, and it must accordingly be settled so as to remove the greater proportion of its suspended matter. Even after giving it careful settlement it is still quite foul and should not be turned into the main sewer system without careful examination to see that it will not cause the filling up of the latter either by precipitation of suspended material, or by the formation of a deposit of dissolved matter upon the sewer walls.

Where very large quantities of waste water are to be handled brick or concrete sewers are used practically the same as in regular city sewer work, but the branches from these or the main sewer at smaller plants may be of different material. Generally terra cotta pipe is used from about two feet in diameter down, but in many cases square wooden boxes of heavy plank, strongly spiked together, are used very satisfactorily since they are relatively inexpensive and are very durable if located so that they stay wet all the time and are not liable to be broken by light shocks and heat, as are terra cotta sewers. It is probably safe to say that in nine cases out of ten the sewer system does not receive as much attention in the designing of plants as it probably should, and is put in as an afterthought, with the result of costing more, and not improbably being worse located than it might have been had it received earlier consideration. Above all, consideration should be given to design small sewers so they can be cleaned by punching without digging them up.

In many cases also where terra-cotta is used for secondary permanent sewers it is probable that the greater strength and durability of cast iron pipe of light section would more than justify its increased cost, since difficulties with a sewer, while they are not very frequent, are inconvenient and expensive to the last degree. Some miserable sewer buried under the ground and never thought of once a year, whose failure to carry off the waste water results in flooding everything, may necessitate the shutting down of the plant for hours in order to cut off or reduce the flow of water.

One point in the design of the sewer system relative to the plant as a whole is worthy of note. In plants located in northern climates much trouble is sometimes experienced from anchor ice forming on the screen below the water level and shutting off the supply of water. The main waste sewer is normally located to discharge below the pump intake, as is absolutely right and proper, but where this discharge consists of practically clean water which has been used only for cooling purposes the sewer may well be provided with an auxiliary discharge just above the main intake screen of the pumping plant, whereby some of the warm water returning may be discharged at the river bank so as to warm the entering water a little above the freezing point and so serve to cut off or prevent the formation of anchor ice with all its attendant annoyances. These are minor points in the consideration of the blast furnace plant as a whole, but they are apt to be extremely expensive ones unless given careful thought in advance.

Compressed Air Supply

In former times before electricity had reached its present state of development a supply of compressd air was one of the greatest conveniences that could be installed at a furnace plant. It was very frequently used for operating bell cylinders, for drilling the tapping hole, for operating pneumatic tools on repair jobs, and many simliar operations. For this purpose an air compressor of good design was installed in the power plant, and the air piped to the points of utilization. In good practice branches with valves were inserted in the main at different points so that air could be taken wherever it might be needed, with a short temporary line or hose.

The modern designs of air compressors are greatly improved over those of a few years ago, being more economical and more reliable, and air supplies a very desirable form of power, being absolutely safe and extremely convenient. Especially for repair and construction work no substitute for the compressed air riveter and other tools of that kind has as yet been discovered. Where compressed air plants are installed as a permanency an after cooler should always be provided to cool the air to or below the temperature of the atmosphere just outside the power house so that the moisture condensed out of the air by compression may be removed at that point and not go through the line as vapor to condense in some distant pocket where it can make trouble in Winter by freezing up.

Many types of compressors have been brought out, and one known as the straight line type, which is of the same general design as the long cross head blowing engine, but laid horizontally, has had considerable popularity, but compressors are very uneconomical unless they are compounded as to both steam and air. This means two cylinders for each, and therefore the straight line type must have four cylinders all in a line to embody these features. This makes a rather complicated and extremely inaccessible type of apparatus, and as this type of engine has two cranks and two connecting rods virtually no more machinery is involved to make a cross compound, two-stage tandem apparatus of it, with the advantage of vastly greater accessibility and generally a more economical design. The space required, and the foundation cost are greater with the cross compound type, but its operating advantages are well worth the difference.

Electric Supply

There are still a few furnace plants in existence which are without an electric supply, and are lit at night by oil torches, colloquially known by the descriptive name of "smoke pots," whose light is extremely poor and inconvenience very great, but within a few years the furnace which does not have an electric plant at least for lighting purposes will be a thing of the past. On practically all modern plants so much of the work is done by electricity that an electric plant of considerable size must be provided. In many cases the electric stock hoist is used, electric bell hoist, pumping plants, lights, and many other minor but necessary operations of the furnace are conducted by electricity.

Where the furnace plant is in conjunction with steel works the electric plant of the combined works becomes enormous. That at a steel works of two or three thousand tons daily capacity is probably as large as that of the average city of half a million people. The electric plant for the blast furnace does not differ essentially from electric plants for other uses and must be designed primarily with reference to its size and the service to be expected of it, never forgetting that on account of its convenience other duties will be hung on to it from time to time, and that the plant which does not start with a hundred per cent reserve capacity will probably soon be too small to do what is required of it.

Where very large electric plants are to be installed it is still a question as to whether the gas engine or the steam turbine is the more economical. The gas engine is undoubtedly the more economical by twenty-five to thirty-three per cent on the heat unit basis, but its operating cost is decidedly higher, and its fixed charges are very much greater than those of the steam turbine. It is therefore very largely a matter of local conditions.

If coal be high, intelligent labor plentiful, and capital not too dear, the gas engine is to be preferred. When these conditions are reversed undoubtedly the steam turbine is the best. The intermediate conditions must be decided on their merits after careful examination of all the factors.

The steam turbine has one great advantage in that it may be used as a low pressure machine exclusively, and in two of the most modern plants which combine both blast furnaces and steel works the blowing engines are steam driven, and exhaust their steam about at atmospheric pressure into turbines which drive the electric generators. The turbine is by far the most economical motor in existence for low pressures, while it is inferior to the piston engine at higher pressures. This arrangement places each type of machine under the conditions for which it is best adapted, and makes a type of plant which has everything to commend it when the electrical requirements are sufficient to use up the steam from the blowing engines.

In smaller sizes the electrical plant may be either steam engine or turbine driven, the steam engine probably being preferable in small sizes and the turbine having an increasing advantage as the size of the plant increases.

VOLTAGE AND KIND OF CURRENT TO BE SELECTED

The voltage and kind of current, direct or alternating to be preferred depends on the local conditions. For small plants two hundred and twenty volt direct current gives excellent satisfaction. This voltage is high enough to keep the cost of copper in transmission lines within reason, and is low enough to give good service with incandescent lamps, while for electrical machinery which requires much control, such as cranes, ore bridges, and the like, direct current still seems to have the advantage over the alternating on account of the ease of reversal, the possibilities of dynamic breaking, etc. At large plants where the power is transmitted in great quantities the direct current is out of the question except as an auxiliary. The alternating current must be used so that it may be stepped up to any voltage desired for transmission and stepped down at the point of utilization. If direct current be required for crane service or the like, it is produced by motor generator sets or rotary converters. When alternating current is used different voltages may be used in different services to suit the individual conditions. For mill motors and the like where men are likely to come in close contact with them four hundred and forty volts or less are used, whereas on large motors such as those which drive rolling mills direct, voltages from twenty-two hundred up to sixty-six hundred are used.

(To be concluded in July issue.)

Messrs. **Eimer & Amend**, Eighteenth Street and Third Avenue, New York City, have issued their catalog M on Apparatus for Metallography, describing the Wysor combined grinding and polishing machine and optical metallographic apparatus.

Ulcoloy is a new copper-lead alloy made by the United Lead Co., 111 Broadway, New York City. While ordinary copper-lead alloy under usual conditions cannot be cast without a crystallization of copper long before the lead hardens, ulcoloy is made by a patented process in such a way as to hold the copper uniformly distributed throughout the mass until it cools and hardens. The chief applications of ulcoloy are as a bearing metal, as a metallic packing and for bronzes and castings. As an acid-resisting alloy it is especially suitable for acid valves and pumps where polluted or acid waters come in contact with it.

The Chemical Industries of Germany[1]

BY PROF. PERCY F. FRANKLAND, F.R.S.

It is remarkable that the Royal House of Prussia has during many centuries been associated in one way or another with chemical enterprises of various kinds. Thus already the second ruler of the country, the Markgraf John (1608-1619) was actually surnamed "the Alchemist" in consequence of the zeal with which during many years he pursued his investigations on the transmutation of metals, whilst a number of his successors exhibited great interest in the same problem—the manufacture of gold—which has never failed to fascinate the needy princes—and what princes are *not* needy?—of all ages and all nations.

The Great Elector (1640-1688), who did so much to advance the power of Prussia, was a patron of chemistry, which was just then beginning to emerge, as an experimental science from the obscurantism of alchemy. He provided the celebrated Kunkel with a laboratory and glass furnaces on an island in his park at Potsdam, and it was there then in 1678 Kunkel made the discovery of ruby glass, produced by means of traces of gold, and which is still an unsurpassed method of coloring glass for ornamental purposes. Kunkel also rediscovered phosphorus, which has previously, in 1669, been obtained by the alchemist Brand of Hamburg, who had quite accidently produced it in the course of his attempts to extract the Philosopher's Stone out of urine.

But while the discovery of yellow phosphorus is thus of German origin, its production on an industrial scale was, until twenty years ago, only carried on in England and France. In 1892, the manufacture of phosphorus by electrothermic means was introduced into Germany by the Chem. Fab. Griesheim-Elektron at Frankfort.[2] Red phosphorus was discovered by Schrötter, an Austrian chemist, in 1848, and was adapted for safety-matches by the German Böttger in the same year. His invention was first taken up in Sweden, and was not adopted until ten years later in Germany.

The match industry has assumed its largest dimensions in Germany. Thus the German annual production in 1912 was $23,000,000.[3] The value of all matches (British and foreign) consumed in Great Britain in 1910 is estimated at $6,468,750—about nine matches per day per head. Messrs. Bryant and May's (by far the largest English concern) turned out 1,152,000,000 boxes in 1907. This represents about one-half the British output. In 1907 the total value of British production was $3,875,000, of which $380,000 worth was exported.[4] The British export of matches is diminishing. It is worthy of note that Japan in 1901 exported matches to the value of $6,000,000.

PORCELAIN

Another great German industry owes its origin to alchemistic studies made by Böttcher in the reign following that of the Great Elector, namely, that of Frederick III. (1688-1713), first King of Prussia. Having succeeded in making gold before witnesses, Böttcher was seized by order of the Elector of Saxony and was "interned" at Dresden, where, although he did not succeed in making the much-desired gold, he founded along with the physicist Tschirnhaus, the celebrated Dresden porcelain industry.

The astute Frederick the Great (1740-1786) was

[2] The author has much pleasure in acknowledging the assistance he has received from the valuable compilation by Professor Lepsius of Berlin, "Deutschlands Chem. Industrie 1888-1913," and from that by Dr. Duisberg, of Elberfeld, "Wissenchaft und Technik," 1911.

[3] Molinari, "General and Industrial Inorganic Chemistry," 1912.

[4] Clayton.

anxious to manufacture the Dresden ware at Berlin and to this end commissioned his court apothecary, Johann Heinrich Pott, to institute investigations. These attempts were, however, all unsuccessful.

The great Frederick placed much faith in secret agents and it was by means of spies that he succeeded in discovering the secrets of the Dresden porcelain manufacture, for at his instigation an enterprising merchant, bearing the name of Gotzkowski, with the assistance of a Saxon workman, brought the secrets of the Dresden process to Berlin and established a porcelain factory in the Leipziger Strasse, which still remains the warehouse for the Berlin porcelain goods. But Frederick later stopped the pecuniary assistance with which the factory had been subsidized, and Gotzkowski was forced to sell the concern of Frederick for about $150,000, and so was established the celebrated Berlin Royal Porcelain Factory, amongst the products of which are the well-known crucibles and evaporating basins. The flourishing state of the Germain porcelain and pottery manufacture is attested by the fact that during the past twenty-five years the number of works has increased from 228 to 359, and the number of workpeople employed from 37,000 to 66,000. In 1912 the German exports of china, earthen and stoneware were valued at upwards of $17,500,000.

GLASS

Even still more important is Germany's glass manufacture, for which she has long been pre-eminent. The annual export in recent years has been over $35,000,000.

CYANIDE INDUSTRY

In the early eighteenth century an accidental discovery was made by Diesbach, a Berlin color-maker, which has proved of great industrial importance. Diesbach was preparing what is known as Florentine lake, a red pigment obtained by precipitating a solution containing cochineal extract and an iron salt with caustic potash. It so happened, however, that the potash used by Diesbach had been in contact with bone-oil containing some cyanide, and the result was that, instead of the result he anticipated, a magnificent blue coloring matter was obtained. This substance, which is still known as Berlin or Prussian blue, was the first cyanogen compound to be discovered.

The cyanogen compounds have played a most conspicuous part in the development of organic chemistry, and every source of cyanogen has been exploited for obtaining them. In recent years the demand has increased enormously owing to the employment of sodium and potassium cyanides in the extraction of gold. To meet this demand a number of synthetical methods for their preparation have been super-added.

Germany's annual production of cyanides is estimated at 10,000 tons, valued at $3,250,000, or about half of the world's production.

BEET-SUGAR INDUSTRY

Another industry, also had its beginnings in the eighteenth century, during the reign of the Great Frederick, and was the outcome of the laborious researches of Marggraf (born in Berlin in 1700, and a pupil of Stahl) on the occurrence of sugar in the vegetable kingdom. Of the numerous plants investigated from this point of view he found that the beetroot (*Beta vulgaris*) contained the largest proportion of saccharine material and that the sweet-tasting substance was identical with that present in the tropical sugar cane (*Saccharum officinarum*).

It was not, however, until some fifty years later that the observations of Marggraf led to the first beet-sugar factory in the hands of Franz Karl Achard, who was subsidized in this venture by the Prussian King, Frederick William III (reign 1779-1840), who was also the founder of the University of Berlin.[5]

The beet-sugar industry had to contend with strenuous competition on the part of the cane-sugar manufacturers, who were chiefly English and who are said to have endeavored to corrupt Achard by heavy bribes. The industry was, however, greatly promoted when, in 1806, Napoleon issued his famous edict closing the European ports to British goods. The vast extent of this industry at the present time can be gathered from the following figures:

Total sugar crop for 1912-13: Cane sugar, 9,211,755 tons; beet sugar, European (one-third German), 8,310,000 tons; beet sugar, United States, 624,064 tons; total, 18,145,819 tons.

The sugar industry should give us food for serious reflection when we consider the following facts: United Kingdom spends annually $115,000,000 on 1,700,000 tons imported sugar. Germany produces $180,000,000 worth of beet sugar on 1,300,000 acres. France produces $65,000,000 on 570,000 acres; all continental countries together produce $580,000,000 on 6,000,000 acres.[6] In the United Kingdom there is only one small experimental beet-sugar factory in existence. The beet-sugar industry is of particular interest in connection with the present European crisis, inasmuch as it is a most notable example of an industry which largely owes its successful inception to a state of war which disturbed the previously established order of things in the matter of sugar supply.

In this country [Great Britain] agriculture is well known to be productive of a conservative frame of mind, but that it is not so in Germany is well illustrated by the extraordinary progress which has been made in the cultivation of the sugar beet under the guidance of systematic scientific research. Thus, in 1840, 100 kilograms of beet gave 5.9 kilograms of sugar; in 1850, 7.3; in 1870, 8.4; in 1890, 12.5, and in 1910, 15.8. In 1871 the mean production of beet per hectare[7] was 246 quintals,[8] and in 1910, 300 quintals. In 1867 the consumption of coal for 100 kilograms of beet was 35 kilograms; in 1877, 24; in 1890, 10, and in 1900, 7. Further economy in coal has been effected by means of the Kestner concentrator.[9]

SULPHURIC ACID, SODA AND BLEACHING POWDER INDUSTRIES

Sulphuric acid was discovered by the German alchemist Basil Valentine in the fifteenth century. The production of this fundamental acid, however, on any considerable scale took its origin in Birmingham, where Dr. Roebuck in 1746 introduced the classical leaden chamber process. At the beginning of the nineteenth century it became an industry of great importance, more especially in England, because of this acid being required for the manufacture of carbonate of soda by the Le Blanc process.

The manufacture of Le Blanc soda was taken up in England in 1814, especially in connection with soap-making, and it was in England that this manufacture assumed the largest proportions. The enormous ad-

[5]There was no University in Berlin until 1809, but the following figures will show how Prussia has made up for lost time in this respect. In 1913-14, there were 7613 male and 770 female matriculated students, and 4113 male and 89 female non-matriculated students. The annual income was $1,231,550, of which $1,023,250 came from the State, $204,500 from fees, etc., and $3,800 from other sources. The annual expenditure was $1,231,550, of which the teaching staff accounted for $523,950; departmental expenses, $500,700; building expenses, $53,050; reserve, $33,400; administration, bursaries, etc., $120,450. ("Minerva," 1914.)

[7]Hectare = 2.5 acres.

[8]Quintal = 100 kilograms.

[9]Molinari, "General and Industrial Org. Chem.," 1913.

vances made in this manufacture during the past century may be gathered from the fact that the price of carbonate of soda in 1818 was about $210 per ton, while to-day it is only about one-tenth of that amount. One of the determining factors which made England the principal home of soda manufacture was the great development of the English cotton industry during the nineteenth century.

During a large part of the last century England manufactured Le Blanc soda, sulphuric acid and bleaching powder[10] for most of the world. But during the latter half of the century the rival ammonia soda process made its appearance. The original discovery of the reaction on which it depends—it was first patented in England by Dyar and Hemming in 1838—is ascribed to several different persons, but the process was first made an industrial success in Belgium by M. Ernest Solvay. The Couillet works were founded with a capital of about $30,000 in 1863; the numerous affiliated works are now to be found in Belgium, England (Brunner, Mond and Company), Germany, France, Italy, Spain, Austria-Hungary, Russia and North America. They employ 35,000 persons. During the fifty years the price of soda has been reduced from $80 to $20 a ton. The displacement of Le Blanc soda by ammonia-soda involved the introduction of new methods of chlorine manufacture. After numerous abortive attempts in various directions, the successful production of electrolytic chlorine has been achieved, and about half of the bleaching powder in the world is now made by this means.

Electrolytic chlorine is now often converted into liquid chlorine (12 cents a kilogram), of which large quantities are used at Stassfurth for the annual preparation of 500,000 kilograms of bromine, and the Badische Anilin und Soda Fabrik used in 1900 more than 1,000,000 kilograms for the preparation of chloracetic acid employed in the manufacture of synthetic indigo.

In the manufacture of sulphuric acid, again, the old-fashioned English or leaden chamber process has not been allowed to remain unchallenged, for since the beginning of the present century it has had to meet the competition of the so-called contact process. This is based on a long known reaction,[11] which, however, remained almost unutilized until the meticulous industry of German chemists and the courageous enterprise of German manufacturers developed it into a commercially successful process, which was elaborated in the works of the Badische Anilin und Soda Fabrik at Ludwigshafen.

The ammonia-soda and the contact sulphuric acid[12] processes, although carried out in England, have been largely instrumental in making other countries, more especially Germany and the United States, independently of the English production of these all-important chemicals.

In 1882 the world's consumption of soda was 700,000 tons (160,000 ammonia-soda), and in 1902, 1,760,000 tons (250,000 Le Blanc). In England, in 1876, $35,000,000 was invested in the industry, which gave employment to 22,000 workpeople. In 1880 the British output was 430,000 tons, and in 1896 it was 800,000 tons. North America in 1886 produced 1100 tons, and 300,000 tons in 1898; and Germany in 1878 made 42,000 tons, 300,000 tons in 1901 and 400,000 tons in 1910.[13] The first soda works in Germany was only erected in 1843 by Hermann at Schönebeck, near Magdeburg, and the first leaden chamber by Kunheim in 1844 on the Tempelhof Plain near Berlin. (See also the statistics in Table I.)

[10] Discovered by Tennant in 1799.

[11] This reaction had for many years been used by Messel in England, but only for the manufacture of SO_3.

[12] The Clayton Aniline Co. and Nobel's Explosive Works have contact sulphuric acid plant.

[13] Molinari.

HYDROGEN INDUSTRY

The electrolytic production of soda and chlorine is, of course, attended with the evolution of enormous volumes of hydrogen. At first this gas was allowed to go to waste, but gradually interesting and important uses have been found for it.

1. Dirigible balloons have been rendered possible by taking advantage of the lightness of the internal combustion engine. One horse-power engines are but little heavier than 1 kilogram. Twenty-seven thousand cubic meters of hydrogen is required for a modern airship. The balloon sheds are often established near electrolytic soda works, or the gas may be transported in steel cylinders compressed to 150 atmospheres. Five hundred cylinders containing 2750 cu. m. of gas are placed on one railway wagon and more than eight such wagon loads are required for the filling of a single Zeppelin.

2. Autogenous welding with oxyhydrogen flame, a most important application of hydrogen, was introduced at the beginning of this century by the Chemische Fabrik Griesheim-Elektron. The oxy-acetylene flame is now more commonly used.

3. Artificial gems are made by means of oxy-hydrogen flame. Some thirty years ago C. V. Boys succeeded in fusing quartz with the oxyhydrogen flame and then drawing it out into incredibly thin fibers, which have proved of the highest value for certain physical experiments of extraordinary delicacy. The same source of heat was much later, in the nineties, employed by the French investigator, Michaud, to reconstruct rubies from small fragments of this gem. At the beginning of this century Verneuil and Paquier, in Paris, succeeded in making synthetic rubies. A little later Wild, Miethe and Lehmann in Germany elaborated methods for producing synthetic corundum, rubies, amethysts and sapphires, which are manufactured by the Elektrochemische Werke at Bitterfeld. These products are identical in chemical composition and physical properties with the natural gems, and the rarest varieties of these can be obtained at will. Fused alumina (very pure) gives corundum; fused alumina + 2½ per cent chromic oxide gives ruby; fused alumina + magnesia and titanium oxide and ferric oxide gives blue sapphire. These synthetic gems are now manufactured to the extent of about 6,000,000 carats annually (1 carat = 0.205 gram), or 1230 kilograms or more than 1 ton. Experienced connoisseurs can, however, distinguish between the natural and artificial gems, with the result that the former have not diminished in value. Natural rubies or sapphires of 2-4 carats cost $100 to $250, and larger stones up to $750, while the artificial would only cost 1/500 to 1/1000 of those amounts.

A still more recent and much more important application of hydrogen is for the hardening of fats, which depends on the transformation of unsaturated into saturated acids by means of hydrogen in the presence of a catalyst (nickel, palladium, etc.).

INDUSTRIES CONNECTED WITH ARTIFICIAL ILLUMINATION

The world is greatly indebted to Germany for inventions which have largely revolutionized artificial illumination, firstly, in connection with gas and more recently in respect of electric lighting.

Thus, one of the most remarkable discoveries in this domain was that of incandescent gas lighting, which was made by the Austrian Count, Dr. Carl Auer v. Welsbach of Rastersfeld in Styria, as the result of lengthy, laborious and ingenious researches. The now

TABLE I—PRODUCTION IN TONS, 1910*

	Germany	England	France	United States	Europe	World
Sulphuric acid (H_2SO_4)	1,250,000	1,000,000	500,000	1,200,000	3,700,000	5,000,000
(of this by contact process)	400,000	.....	.....	250,000	.....	.....
Soda	400,000	700,000	200,000	250,000	.....	2,000,000
(of this Le Blanc soda)	30,000	120,000	.....	.....	.....	150,000
Saltpetre consumption	786,000	93,000	337,000	523,000	1,740,000	2,360,000
(of this for nitric acid)	150,000	.....	.....	50,000	.....	.....
Hydrochloric acid (30 per cent)	450,000	**	.....	.....	.....	.....
Bleaching powder	100,000	....	.....	.....	.....	300,000
(of this electrolytic)	70,000	.....	.....	.....	.....	150,000

*Duisberg, "Wissenschaft und Technik," 1911.
**Already in 1895 the estimated production of hydrochloric acid in England was 1 million tons, and for the whole of Europe 2 million tons (Molinari).

so familiar gas-mantles are prepared by the ignition on the cotton frame of a mixture of 99 per cent of thorium nitrate and 1 per cent of cerium nitrate.

The source of these rare earths is monazite sand, the elaboration of which has become a very important industry depending on fractional crystallization, which already many years ago was brought to such a high pitch of perfection in the laboratory of Sir William Crookes. Out of this monazite sand Hahn in 1910 succeeded in extracting mesothorium and the process is carried out on a large scale at the works of Dr. O. Knöfler and Company at Plötzensee near Berlin. Radium bromide is worth about $85 a milligram, mesothorium about $37.50 a milligram. The mesothorium is only present in the monazite sand in extremely small proportion, about one part in 150,000,000 parts of the mineral.

I may also refer to Auer-metal, a preparation of iron (Fe 30 per cent) containing cerium, which sparks when scratched with hard steel, and which is familiar as a substitute for matches.

Another outlet for the use of hydrogen has been in reducing the rare metals osmium (melting point 2500 deg. C.), tantalum (melting point 2300 deg. C.) and tungsten (melting point 2850 deg. C.).

In 1903 the Auer Company showed that the carbon filament of electric incandescent lamps could be replaced by an osmium filament, with an economy of 50 to 60 per cent of current. In 1905, Siemens und Halske showed that a tantalum filament was cheaper and more advantageous, and in 1906 that the tungsten filament was even still better. Tungsten occurs in sufficient quantity in nature as wolframite (iron tungstate) and scheelite (calcium tungstate) to enable the metal to be now sold as filament-metal for $1.50 to $1.75 a kilogram.

Some idea of the enormous and increasing scale on which the incandescent lamp manufacture is carried on in Germany may be gathered from the figures in Table II.

TABLE II—PRODUCTION IN GERMANY

	1911	1912
Metallic-filament electric lamps	47,211,892 pieces	76,185,721 pieces
Carbon-filament electric lamps	24,791,196 pieces	20,975,348 pieces
Incandescent gas mantles	126,050,954 pieces	135,320,173 pieces
Arc-lamp carbons	10,740,025 kilos.	11,093,154 kilos.

According to V. B. Lewes, the consumption of gas-mantles in 1912 was: Germany, 100,000,000; America, 60,000,000; England, 38,000,000; France, 16,000,000; Belgium, 3,500,000; Italy, 3,000,000; Russia, 1,500,000.

The special tax imposed in Germany on lighting apparatus realized from the above sources in 1912 was $4,000,000.

AMMONIA

Of the commoner inorganic chemicals which are produced on the largest scale, one of the most important is ammonia, which has for so many years been obtained as a byproduct in the manufacture of coal gas.

So backward was this industry in Germany, that actually even as late as 1874 the ammoniacal liquor from their gas works was run to waste. All the more remarkable is the state of affairs to-day as betrayed by the following figures. The world production of ammonium sulphate was 210,000 tons in 1890, 500,000 tons in 1900, and 1,330,000 tons in 1912. Germany's production of ammonium sulphate in 1912 was about 370,000 tons.

The principal use of sulphate of ammonia is as a nitrogenous manure, as which it competes with Chili saltpeter; they may be taken as of equal money value per unit of nitrogen. In this connection Germany's manure bill, given in Table III., is interesting.

TABLE III—GERMANY'S MANURE CONSUMPTION

	1888 Tons	1912 Tons
Chili saltpeter*	225,000	650,000
Sulphate of ammonia	50,000	500,000
Superphosphate	250,000	1,800,000
Basic slag	250,000	2,200,000
Crude potash salts	160,000	3,000,000
Lime	500,000	800,000
Other manures		500,000
Total value		$150,000,000

*The total import of Chili saltpeter into Germany in 1912 was 800,000 tons, of which only 150,000 tons was used for manufacture of potassium nitrate and nitric acid.

It is the ambition of the Germans, firstly, to make themselves independent of the industrial products of other countries, and secondly, to produce in excess of their own needs and to impose this surplus on the rest of the world. Thus, they pride themselves on displacing more and more of the foreign Chili saltpeter by home-made sulphate of ammonia, and in 1911 they used in agriculture 75,000 tons of ammoniacal nitrogen against 70,400 tons of foreign saltpeter-nitrogen. This partial success they look forward to making complete and decisive by developing new methods of producing ammoniacal nitrogen and nitrates which can be carried out in Germany.

Of such methods there are already two in operation, and they are associated with that great problem which confronts mankind as a whole. How to supply the combined nitrogen, which will be necessary to build up the food-stuffs for the teeming millions of the future, after the deposits of Chili saltpeter are exhausted? This is the same problem as that of fixing the nitrogen of the air, which long ago, before anything was known of nitrogen at all, man had solved empirically by growing leguminous plants in the rotation of his crops, thereby increasing the fertility of the soil, although the mechanism of this time-honored procedure was only experimentally demonstrated in the last decades of the 19th century by the German investigators, Willfahrt, Hellriegel and Nobbe.

FIXATION OF ATMOSPHERIC NITROGEN BY INORGANIC MEANS

1. This has been successfully accomplished by the Birkeland and Eyde electric furnace, and the Schönherr electric furnace of the Badische Anilin und Soda Fabrik. These are simply realizations on the industrial scale of laboratory experiments made by Cavendish 130 years previously. This method is applicable only in Norway or other countries where abundance of water power renders the production of cheap electrical energy possible. It is being carried on by an international com-

pany at Notodden in Norway. They propose to use 300,000 horse-power capable of yielding 150,000 tons lime-saltpeter (15-20 per cent N) or about one-twelfth of the total amount of Chili saltpeter used by the world. Germany possesses but little water-power so that this process is of only indirect interest in connection with German chemical industry.

2. Nitrogen may also be fixed by calcium carbide at high temperatures. This discovery was made by the German chemists Frank and Caro. $25,000,000 capital is already embarked in this industry by various companies of Europe and America. About 120,000 tons is produced annually, about one-quarter of which in Germany. The crude calcium cyanamide (about 20 per cent N) may be used directly as a nitrogenous manure or may be made to yield ammonia. The production of calcium carbide involves the use of electric furnace and hence cannot be carried on economically on a very large scale in Germany owing to the limited water-power available.

3. Nitrogen and hydrogen may be combined at higher temperature and especially under high pressure. The long known fact that the reaction, $N_2 + 3H_2 = 2NH_3$ is realized to a very small extent at high temperatures has been investigated in recent years by Haber and Le Rossignol at Karlsruhe, and, guided by the principles of modern physical chemistry, Haber has elaborated, after overcoming extraordinary technical difficulties, an industrial process which promises to be of great importance in the future. The most advantageous conditions were found to be: Pressure, 200 atmospheres; temperature, 500 deg. C.; catalytic agent, osmium, uranium, etc.

Production of ammonia by the Haber process has been carried out on a commercial scale by the Badische Anilin Company since the summer of 1913, and a plant capable of yielding 130,000 tons of sulphate of ammonia per annum was to have been ready during the present year. Inasmuch as the German Color Syndicates have severed their connection with the Norwegian nitre undertaking, it would appear that they regard the Haber ammonia process as being more likely to be capable of capturing the inorganic nitrogen market of the world.

This synthetic production of ammonia obviously involves cheap hydrogen. I have already referred to electrolytic hydrogen, but there are cheaper sources. Thus water-gas contains theoretically equal volumes of hydrogen and carbon monoxide; the carbon monoxide (boiling point—192 deg. C.) can be removed by liquefaction from the hydrogen (boiling point—253 deg. C.). Similarly the nitrogen required for the process is obtainable from the fractional distillation of liquid air. The synthesis of ammonia thus dovetails with the possibilities of cheap low-temperature production for which the world is so largely indebted to the German engineer Carl von Linde of Munich.

The German ambition to make their combined nitrogen at home does not stop at the production of synthetic ammonia, for there are still large requirements in respect of nitrates (Germany produces upwards of $7,500,000 of nitric acid annually from Chili saltpeter) which have to be satisfied from foreign sources. They hope, however, to fill this gap in the home-production of combined nitrogen by utilizing a reaction discovered by Kuhlmann[14] as long ago as 1839, in which ammonia and air burn to nitric acid in the presence of platinum as a catalytic agent.

POTASH SALTS

Germany appears to be alone in possessing vast deposits of potash salts, whilst the enormous value of these to agriculture was first demonstrated by Liebig and made public by him in his "Application of Chemistry to Agriculture and Physiology" in 1840. This work may without question be regarded as the foundation stone on which agricultural chemistry has been raised.

The celebrated deposits of potash salts were accidentally discovered in 1857, when boring for rocksalt at Stassfurth, near Magdeburg, in Prussia. Their industrial exploitation on an ever increasing scale was begun in 1861 by Grüneberg and Adolf Frank. In 1861 the production of crude potash salts was 2000 tons; in 1912 it was 11,000,000 tons, worth $44,000,000. Ninety per cent is used as manure (about one-third in Germany itself), and 10 per cent in industries (about two-thirds being worked up in Germany for carbonate, caustic, nitrate, alum, chromate, and chlorate, etc.). America is now experimenting with a view to obtaining potassium chloride from feldspar by the method used in the laboratory for determining alkalis in insoluble silicates, and which consists in heating the silicate with a mixture of lime and calcium chloride. Whether it has any commercial future remains to be seen.

This is a matter of prime importance in the United States, as potash salts are there used on an enormous scale, especially for agriculture. Thus they consumed in 1900 Stassfurth potash salts worth $4,200,000; in 1910, $12,200,000, and in 1911, $15,200,000.[15]

EXPLOSIVES

I have already mentioned the importance of nitrates and of nitric acid, and have referred to the employment of the great part in agriculture; of the remainder the major part goes into the manufacture of explosives and into the coal tar color industry.

Black powder or gunpowder is said to have been discovered by the English monk Roger Bacon (1214-1294). Gun-cotton was discovered by Schönbein in Basle and Christian Böttger in Frankfurt in 1846.

Nitroglycerin was discovered by Sobrero in Pelouze's laboratory in Paris in 1847, and first manufactured on a large scale as an explosive by the Swede Alfred Nobel in 1862.

The disruptive properties of gun-cotton are greatly moderated by gelatinising by means of solvents (acetone, acetic ester, alcohol and ether, etc.), and by mixing with nitroglycerin ballistic materials like cordite. and other smokeless powders are obtained. There is another class of explosives which combine great safety in handling with enormous disruptive effect. Picric acid (discovered by Woulfe of London in 1771), but first used by the French under the name of Melinite for filling shells in 1881, and later by the English under the name of Lyddite. More recently this has been replaced by trinitrotoluene, first proposed by Haeussermann in 1891 for filling shells and used by the British Service under the mark "T. N. T." It is even less sensitive to shock than picric acid. "Ammonal," used by the Austrians for shell-filling, is a mixture of T. N. T. with ammonium nitrate, charcoal and aluminium powder. It is both very safe and very powerful. T. N. T. is much used for demolishing bridges. It is so sensitive to shock that it is not exploded on being struck by a rifle-bullet, and when in a shell it withstands the impact of the latter piercing an armor plate.[16]

Tetra-nitro-aniline, obtained by Flürscheim, enjoys the unique position among explosives of having been discovered in this country. It is said to be equally safe and even more powerful than trinitrotoluene.

According to the late Oscar Guttman, the production of nitroglycerin explosives in 1909 was as follows:

[14] Ann. Chem. und Pharm., 1839, 29, 280.

[15] Macnab. "Explosives," Inst. of Chem. Lecture, 1914.

[16] Molinari.

United States, 20,000; Germany, 10,300; England, 8100; Transvaal, 8000; Canada, 5000; Spain and Portugal, 3500; Austria-Hungary, 2300; France, 1500 tons; Switzerland, Austria, Norway and Sweden, 600 tons each; Russia, Italy, Holland, Belgium, 500 tons each; Greece, 175 tons.

Explosives are of enormous importance also in civil life—in mining and engineering modern explosives have greatly accelerated progress and have rendered possible such works as the Panama Canal. They are also being now employed with great advantage in afforestation for loosening the ground in which trees are to be planted. The manufacture of explosives in Germany is very highly developed. The total German production of 40,000,000 kilograms includes dynamite explosives, 10,000,000; ammonium nitrate explosives, 16,000,000 and black powder, etc., 14,000,000 kilograms. There were exported in 1908 explosives of a value of about $5,000,000, and in 1912, $15,000,000.

The world production of explosives is now about 400,000,000 kilograms, or 10 times the German total output. Great Britain has at Ardeer in Scotland, the largest explosives factory (Nobel's) in the world, covering 850 acres, employing 1800 men and 700 women, and producing annually about 16,000 tons of all kinds of high explosives.

ARTIFICIAL SILK

An eminently peaceful industry which is closely related to that of explosives is the production of artificial silk and celluloid. The manufacture of artificial silk has grown up during the past twenty-five years, for this product was first shown by Count Hilaire de Chardonnet at the Paris Exhibition of 1889; he discovered the method of its preparation while a student in the Ecole Polytechnique at Paris, and in 1891 formed a company at Besançon with a capital of $1,200,000 for its manufacture.

The chief kinds of artificial silk are: (1) Nitrated cellulose (soluable in alcohol-ether) silk (denitrated by ammonium sulphide) (Chardonnet silk). (2) Ammoniocupric oxide cellulose silk (Pauly, Fremery, or Urban silk, of the Vereinigte Glanzstoffabrik, Elberfeld, 1897). (3) Viscose-silk (CS_2 in presence of NaOH or Ca (OH_2) on cellulose) (Cross and Bevan). (4) Acetate-silk (acetic acid on cellulose) (Cross and Bevan).

Germany produces about 2,000,000 kilograms, value about $6,000,000, exports 600,000 kilograms, and imports 1,800,000 kilograms; the imported is principally "alcohol silk," due to disadvantageous alcohol tax in Germany. Germany is the principal user of artificial silk, although the fundamental discoveries upon which the manufacture is based are largely due to French and English chemists. The world production is estimated at about 7,000,000 kilograms.

The distribution of the industry may be gathered from the following: France, 7 factories; Germany, 8; Belgium, 3; England, 2; Spain, 1; Austria-Hungary, 4; Russia, 3; America, 3; Japan, 1.

Great profits have been made out of artificial silk (some of the companies paid 50 to 100 per cent dividends), and the price has greatly fallen since its introduction from $7 per kilogram in 1903 to $4 in 1906, and $3 (poorer qualities $1.50 to $2) in 1910.

The celluose industries furnish a particularly striking example of the manner in which chemical research and invention are able to enhance the value of the kindly gifts of the earth. Thus, 1 cubic meter of wood has value as fuel about $1.50; (after boiling with lime, soda and sulphite) as paper pulp, $8; ditto as paper, $14; and as pulp converted into artificial silk, $400 to $1200.

INDUSTRIES DEPENDENT ON SYNTHETIC ORGANIC CHEMISTRY

It is out of the profound study of synthetic organic chemistry which has been made during the past sixty years that the industries of artificial dyes, drugs, and perfumes have incidentally arisen. The earlier and pioneering achievements in synthetic organic chemistry are well distributed among the nations of Europe,[17] but during the major part of the sixty years the great bulk of the discoveries in this domain have been made in Germany. Organic chemistry is, perhaps, the branch of science which more perfectly suits the German mind and temperament. It involves the possession of those qualities in which Germans are so pre-eminent—the capacity for taking an infinitude of pains, the capacity to anticipate difficulties, and organize means to circumvent them. It is, moreover, only possible to make substantial advances in the problems of organic synthesis if the master has at his disposition a number of highly qualified and docile assistants and apprentices; in a word, the master must be at the head of a large and efficient school of research. It is in the possession of such schools of research, both in the universities and in the chemical factories, that Germany has by two generations the lead of all other countries in the world. While most of the professors of chemistry in British universities and colleges have under great difficulties and without any sort of encouragement been more or less successful in building up such schools of research, which are, however, by no means slavish imitations of the German model, the chemical manufacturers of England, have, with some notable exceptions, failed to establish anything worthy of the name of research laboratories in connection with their works.

It is in respect of the works research laboratory that there is the greatest contrast between the chemical industries of Germany, and those of other countries, and it is not surprising, therefore, that the present war should have served to emphasize the class of chemical products for which Great Britain is almost entirely dependent on Germany.[18] It is precisely those products —artificial dyestuffs, artificial drugs and artificial perfumes which are the outcome of the works research laboratories, that are now in many cases unobtainable in consequence of the cutting off of the German sources.

The seriousness of the situation is apparent from the following figures, relating to dyestuffs alone: The value of dyestuffs consumed in England annually is $10,000,000, and the value of trade in which these dyestuffs are employed is $1,000,000,000, whilst upwards of 1,500,000 workmen are dependent upon these industries. The total value of dyestuffs imported into the United Kingdom in 1913 was $9,460,275, of which Germany contributed $8,654,105.

Perhaps the most concise way of conveying a superficial idea of these industrial products of organic synthesis will be by means of the following classification.

I. *Artificial Products.*—Colors first obtained from aniline by Runge in 1834, by the action of bleaching powder. Aniline colors: Mauve was discovered by Perkin in 1856 and Magenta by Verguin in 1859. Azo-colors[19] were discovered by Griess in 1859, and introduced on an extended scale in 1878. The azo-colors have achieved an enormous importance and have practically banished cochineal and logwood from the dye-works. Some 2000 azo-colors in use. Congo-colors, substantive cotton dyes, were discovered by C. Böttiger in 1884.

[17] England and France were, however, more especially to the fore.

[18] Only about one-tenth of the annual value of dyestuffs consumed in England is produced in England.

[19] Both azo and eosin colors were kept as secret products, but the colors were investigated by Hofmann and their mode of production published, to the great consternation of the inventors.

It must not be supposed that British color manufacturers have been idle from the days of Perkin; thus in 1880 a very original departure was made by Messrs. Read, Holliday and Sons, who introduced the principle of developing azo-dyestuffs on the fiber with their so-called ingrain or ice colors. Some of these have achieved a great success, thus 2000 tons of p-nitraniline are now annually manufactured for the production of nitraniline-red and similar colors.[20] Again, the discovery of primulin and the colors which can be derived from it, by A. G. Green in 1887, is another very notable achievement.

Eosin colors were discovered by Caro in 1873.

II. *Artificially Produced Natural Products.*—This group contains substances occurring in nature and long valued by man. The chemical nature of these substances has been carefully ascertained by chemists who have then deliberately set to work to devise means for their artificial preparation at such a cost as to compete with and ultimately supplant the natural product. These campaigns against the commerce in the products of nature undoubtedly constitute one of the most remarkable phenomena in the history of the world. Bear in mind, it is the production and supply to man of the actual products of nature, but more cheaply than they can be produced and supplied by Nature herself. These endeavors have already been successful on a very large scale.

Alizarin (the essential principle of the madder root) was first synthesized by Graebe and Liebermann in 1869. At the time of this discovery, the world production of madder was 50,000,000 kilograms roots (1½ per cent alizarin), representing 500,000 to 750,000 kilograms alizarin, value $11,250,000. In 1870 France had 20,000 hectares (50,000 acres) under madder cultivation, which soon disappeared after the introduction of the artificial product.

The production of artificial alizarin was: 1873, 100,000; 1877, 750,000; 1884, 1,350,000; 1900, 2,000,000 kilograms (four-fifths of this was produced in Germany).

A great number of most valuable artificial dyestuffs, more or less closely related to alizarin, but not occuring in nature, have been prepared by chemists, and the total value of the alizarin-color exports of Germany at the present time is about $5,000,000.

Indigo.—This most highly prized blue dyestuff of both the ancient and the modern world was first artificially synthesized by Adolf Baeyer in 1880, but it required seventeen further years of unremitting and laborious investigation in the works of the Badische Anilin und Sodafabrik at Ludwigshafen, and the investment of nearly $5,000,000 before laboratory synthesis was translated into a commercially successful industry, for it was in 1897 that the artificial indigo was put on the market.[21]

In 1896 the world production of plantation indigo (100 per cent) was 6,000,000 kilograms, value $20,000,000; four-fifths of this was British, obtained from 1,500,000 acres in British India. In 1904 only 500,000 acres was under cultivation, and in 1913, only 300,000 acres (see Table IV.).

Table IV—Indigo

	British East Indies		Germany	
	Cwt. Exports,	Value	Imports	Exports
1896	188,337	$17,848,350	$5,180,000	$1,597,750
1899	135,187	9,901,595	2,077,250	1,961,250
1902	89,756	6,174,185	921,750	4,615,500
1905	49,252	2,782,025	300,500	6,430,250
1908	32,490	2,124,245	220,500	9,663,750
1911	16,939	1,125,000	111,500	10,457,500
1913-14		$300,000 to $350,000		

[20] G. T. Morgan, "Modern Dyes and Dyeing," Roy. Dublin Society, 1914. Cain and J. F. Thorpe, "The Synthetic Dyestuffs and Intermediate Products," 1913.

[21] Baeyer's first patent for the synthesis of indigo from o-nitrocinnamin acid was taken out in 1880, and by 1907 there had been no less than 316 patents obtained in Germany for processes connected with the preparation of indigo.

The price of indigo (100 per cent) in 1897 was $4 per kilogram and in 1913 $1.75 per kilogram.

By varying the ingredients in the indigo-synthesis, many very valuable dyes related to indigo have been obtained. Thus the chlorine and bromine substituted indigos are manufactured as ciba-blue, brilliant-indigo and bromo-indigo. Again with sulphur instead of oxygen, thio-indigo-red, and thio-indigo-scarlet are obtained. Moreover, by using the anthracene-grouping in the indigo-synthesis a number of most important colors have been obtained, *e. g.*, indanthrenes, of extraordinary fastness to light; alizarin-indigo; algol-colors (Rob. E. Schmidt), in all varieties of color, and of the greatest fastness to light. The discovery of these valuable dyestuffs provoked zealous emulation on the part of the azo-color chemists, who responded by placing some very excellent new products on the market under the name of benzolight colors.

Antique or Tyrian purple was perhaps the most highly prized of all colors in the ancient world. We know from Pliny that this dye was obtained from a rather rare snail living in the Mediterranean, and which he describes under the name of "purpurea." Paul Freidländer, of Darmstadt, succeeded in 1909 in extracting this color from certain glands of two different species of snail—*murex brandaris* and *murex trunculus*—which appeared to correspond to Pliny's description of "purpurea." He removed these glands from 12,000 individual snails, developed the color by a short exposure to sunlight, extracted it with suitable solvents and recrystallized it from quinoline. In this manner he obtained only 1½ gram of the coloring matter, so that its extreme costliness, which Freidländer estimates at about $10,000 a kilogram, is not surprising.

On investigating the chemical nature of this color he found that it was identical with the already known synthetical compound 6.6′-dibromindigo.

Drugs and Perfumes.—Not less remarkable are the achievements of organic synthesis in connection with pharmaceutical and perfumery products.

The production of artificial drugs and perfumes is in general only a branch of the artificial color industry, for in many cases the raw materials are the same, while the methods of investigation and synthesis are, of course, identical. But whereas the artificial color industry started in England, that of artificial drugs is entirely of German origin, and may be said to begin with the discovery by Liebig of chloroform in 1831, and of chloral hydrate in 1832. It was in 1869 that the chemical works of Schering, on the suggestion of A. Liebreich, produced chloral hydrate as a commercial article.

In 1887 began the discovery of artificial antipyretic drugs, the rivals of the natural quinine. The first of these was antifebrin, the properties of which were discovered accidently in consequence of a mistake. A specimen of acetanilide in a Strassburg pharmacy was erroneously supposed to be naphthalene, and was served out as such for some pharmacological experiments by Kahn and Hepp. On being taken, internally, its antifebrile effect was observed. Fortunately there was enough left for analysis, and it was found that the supposed naphthalene was the long known acetanilide, which soon acquired a great vogue for this purpose. About the same time antipyrin was discovered by Knorr, who erroneously thought that it was chemically related to quinine, and that it would, therefore, not improbably possess antifebrile properties. Direct experiment showed that it did actually possess these properties in a high degree, but subsequent research showed that it was in no way chemically related to

quinine. These and numerous other artificial antipyretics have been a great source of income to their inventors in consequence of the continued prevalence of influenza during the past quarter of a century.

During the period that antipyrin was protected by patent it was sold at $30 per kilogram, while on the expiration of the patent the price was reduced to $5 per kilogram, which still allows a good margin of profit.

These discoveries have led to the systematic study by direct experiment on animals and human beings of innumerable chemical compounds with a view of ascertaining their physiological properties. The enormous amount of most laborious work which has been carried out in connection with synthetic drugs may be gathered from the fact that up to 1912 about 5000 artificial products had been found to possess therapeutical value of one kind or another, but, of course, comparatively few of these have permanently established themselves in medical practice. Time does not permit me to do more than refer briefly to some of the simpler and better known synthetic drugs.

Thus of antipyretics, which have or have had some considerable vogue, are: Antipyrin; tolypyrin (dimethyltolylpyrazolone); salipyrin (antipyrin-salicylate); antipyrin mandelate (tussol, for whooping cough); neopyrin; pyramidon (three times as strong as antipyrin) (dimethylamino-antipyrin); antifebrin; phenacetin (cheapest antipyretic excepting antifebrin, about $1.50 per kilogram, and less poisonous than antifebrin); lactophenin, lactyl-p-phenetidine; aminophenacetin or phenocoll (also has an antiseptic action).

The above series derived from aniline affords a good illustration of the dependence of physiological properties on chemical constitution. Aniline itself is a powerful antipyretic, but is extremely poisonous, owing to its ready absorption and action on haemoglobin. By introducing the acetyl group the toxic properties are much reduced owing to its greater stability, although acetanilide is slowly hydrolyzed with liberation of analine, so that after a time the symptoms of aniline poisoning may supervene. The observation that acetanilide is partially oxidized in the system to *p*-aminophenol led to derivatives of the latter being tried. Thus phenacetin has been found to possess powerful antipyretics and greatly reduced toxic effects[22]

Hypnotics.—Sulphonal was accidentally discovered to possess hypnotic properties in connection with experiments on the transformations of sulphur compounds in the animal system. A dog, which had been dosed with the newly discovered sulphonal, in Baumann's laboratory at Freiburg, i.B., was found to fall into a deep sleep.

More powerful hypnotics were found to result from introducing further ethyl groups:

$(CH_3)_2C(SO_2.C_2H_5)_2$. Sulphonal

$(CH_3)(C_2H_5)C(SO_2.C_2H_5)_2$ Trional

$(C_2H_5)_2C(SO_2.C_2H_5)_2$ Tetronal.

In connection with the manufacture of sulphonal, I may refer to an interesting difficulty which was experienced by the Elberfeld Color Works owing to the appalling smell of the mercaptan from which it is prepared, and of which Emil Fischer and Penzoldt have shown that the human nose is still capable of appreciating 1/400,000,000 mgrm. In spite of this, German thoroughness has been successful in so perfecting the apparatus in which the manufacture is carried on that no nuisance is occasioned.

Veronal (diethylbarbituric acid) (E. Fischer and Mering, patented by Merck in 1903) is one of the most widely used hypnotics. Although it was formerly supposed to be practically free from toxic properties, in recent years cases of veronal poisoning have been known to occur.

Antineuralgics.—Salicylic acid, one of the first drugs to be artificially prepared (Kolbe, 1860), acetyl-salicylic acid (aspirin), and salol (phenylsalicylate), though extremely simple synthetic products, are almost exclusively made in Germany, with the result that their price has now greatly increased. Even synthetic phenol which is necessary for the above preparations, was exclusively made in Germany and kept down the price of coal-tar phenol. The price of phenol has now enormously increased from 7 cents per lb. to 33 cents per lb., and is likely to go higher. (Pharm. Journal, 1915.)

Anti-gout drugs (Uric acid solvents).—Piperazine (discovered by Hofmann in 1890), lysidine, urotropine (hexamethylene tetramine), atophane (*a*-phenylcinchonic acid).

Suprarenine.—This is of special interest. The active principle of the suprarenal glands known as adrenaline[23] had for some years been found to be of great value for increasing the blood-pressure, contracting the blood-vessels, and arresting haemorrhage. It requires the suprarenal glands of 40,000 oxen to prepare 1 kilogram of adrenaline, but this substance has been artificially synthesized by F. Stolz, and is put on the market as suprarenine by the Höchst Color Works. The synthesis of adrenaline may be presented thus:

Catechol $\xrightarrow{CH_2ClCOCl}$ Chloraceto-catechol $\xrightarrow{CH_3NH_2}$ Methyl-amino-aceto-catechol $\longrightarrow$ Adrenaline Al-amalgam

Natural adrenaline is laevo-rotatory; the synthetic can be resolved by tartrate; the laevo is 15 times as potent as the dextro.

The German color manufacturers are organized into two principal groups or trusts (Interessengemeinschaften). (1) Badische Company, of Ludwigshafen; Bayer Company, of Elberfeld; Berlin Aniline Company. (2) Cassella Company, of Frankfurt; Meister, Lucius, und Brüning, of Höchst.[24]

The share-capital of the above two groups in 1911 was $40,000,000 paying a dividend of 25.8 per cent, and probably now about $60,000,000 dividend, 28 per cent.

In 1860-70 Germany imported about $12,500,000 worth of dyes per year, while in 1912, Germany exported about $50,000,000 and produced about $62,500,000 of dyes.

The composition of the personnel who carry on these German color works is at the bottom of their success. Take the Works of Messrs. Meister, Lucius, und Brüning as an example. In 1913 the composition was as follows: Workmen, 7680; managers, 374; expert chemists, 307; technologists, 74; commercial staff, 611. Contrast with the above the fact that the six English factories now producing dyestuffs employ altogether only thirty-five chemists, while evidence of their relative activities is again furnished by the circumstance that between 1886 and 1900 the English firms took out only eighty-six patents, whereas the six principal German firms were responsible for 948 during the same period.

Having shown that these German coal-tar color manufacturers are without rivals from the commercial point of view, I feel it to be my duty to point out also that their industry is carried on under conditions of labor which are highly creditable to the management.

This vast and highly organized industry of dyestuffs and fine chemicals, which is certainly one of the most outstanding manifestations of the modern German spirit, were formerly very dependent on England for its chief raw material, coal-tar, and it is interesting to

[22]Chemistry of Synthetic Drugs, P, May, 1911.

[23]Discovered by Takamine in 1901.

[24]"German Coal Tar Companies," Textile Mercury, Jan. 9, 1915.

see in Table V how effectually Germany has emancipated herself from a control which might at any time become irksome or even paralyzing.

Table V—German Coal-Tar Production

	Coke Ovens, Tons	Gas Manufacture, Tons
1897	52,000	
1900	93,000	
1904	277,000	225,000
1908	632,400	300,000

In 1908, 40,000 tons was still imported from England, and in 1909, 18,000 tons, but 35,000 was also exported.

In 1900 the German production of coal-tar was only about one-half of that produced in England, while by 1912 it had equalled if not surpassed the English production. Again, in 1880, Germany used 1400 tons of pure anthracite of which only 200 tons was of German origin, while at the present time the 5000 tons now employed in Germany is all produced there.

The phenomenal increase in the German coal-tar production has depended on a similarly rapid development of the German iron and steel industry, which has entailed an enormous demand for metallurgical coke in the production of which the greatest attention has been devoted by Germany to the recovery of the byproducts—tar, gas, ammonia, etc.

In England the quantity of coal-tar treated was 175,000 tons in 1870, and 640,000 tons in 1880; at present over 750,000 tons is treated.

Synthetic Perfumes.—With regard to the synthetic perfume industry, the facts are in many respects essentially similar to those in connection with the artificial dyestuffs. The production of artificial perfumes, in many cases the identical substances which are produced by nature, has assumed very large proportions in Germany, the annual output being estimated at about $12,500,000. It is particularly noteworthy that one of the first steps in the realization of this remarkable achievement of artificially building up the natural perfumes was also made by William Henry Perkin, who in 1868 succeeded in synthesizing coumarin, the highly valued odoriferous principle of the woodruff (*asperula odorata*).

The effect of artificial synthesis on the price of natural perfumes may be gathered from Table VI.

Table VI

	Price of 1 Kilogram—Natural	Synthetic
Coumarin	$125	$6.25
Vanillin	250	7.50
Heliotropin	750	2.50

THE CHEMICAL SITUATION IN GREAT BRITAIN

The facts which I have brought forward speak for themselves and proclaim in the most convincing manner the stupendous progress which has been made by Germany in the chemical industries during the past 40 years. It is equally certain that England, once preeminent for chemical manufactures, has not progressed at the same rate and is at the present moment suffering much inconvenience through being so largely dependent on German chemical products of one kind and another. The country is now reaping the harvest of humiliation which it has sown for itself in spite of the warning repeated *ad nauseam* by the chemical profession during a whole generation. The systematic neglect of chemical science and the failure by manufacturers to utilize the services of highly qualified chemists, could only lead to the result that all the industries which are dependent on a profound knowledge of chemistry should tend to disappear from England's midst and pass into the hands of those who are prepared, not only to apply new chemical discoveries to industry, but even to prosecute the most varied chemical investigations in the hope of sooner or later making discoveries which shall be of advantage to their commercial undertakings.

The mischief caused through the neglect of chemistry by practical men in this country has been so subtle that to a large extent it has remained concealed from the average man of intelligence and from the governmental classes. During the past 40 years our country has been accumulating wealth in an altogether unprecedented fashion, so that the loss or restriction of some industries appeared a matter of unimportance to political observers taking only a broad and superficial survey of the national resources. The whole of our arrangements have evolved during the past half century on the assumption that this country would never again be engaged in a European war, while still more recently the new democracy has vainly boasted that it could prevent such a war by means of a general strike. The year 1914 has seen the dissolution of many fool's paradises and has given the *coup de grace* to all these vain imaginings, with the result that we find our vast textile industry in serious peril because the much smaller dyestuff industry has been complacently allowed to slide into the hands of our sagacious and more painstaking enemies. The same carelessness and want of foresight had even allowed us to become dependent on Germany for some of the most important materials used as explosives, *e.g.*, trinitrotoluene, and for many of the most valued drugs required alike by our army, navy and civil population.

The complete breakdown in our supply of fine chemicals, which is the direct outcome of the disregard of the constant warnings emitted by scores of British chemists, has led the Government of the day to intervene and attempt to remedy the intolerable state of affairs which has arisen in connection with the supply of coal-tar colors.

THE PROPOSED BRITISH COAL-TAR INDUSTRY

We devoutly hope that success will attend the endeavor to establish the coal-tar industry in these Islands on the largest possible scale. Whatever the ultimate scheme adopted may be, I would venture to point out that it must be based on a clear understanding of the following considerations:

1. That the provision of the required chemicals during the continuance of the war is one thing, and that their production on a commercial basis after the cessation of hostilities is quite another matter.

2. It appears to me that in order to provide the needful supply during the war, the only reasonable course is to assist in every possible way those firms which are already making similar or closely allied products so as to enable them to produce their present goods on a larger scale, and as far as practicable to undertake the manufacture of others which are urgently required. The immediate problem will be also greatly facilitated by utilizing supplies obtainable from neutral powers, and more especially from Switzerland, which is the only country, other than Germany, in which the manufacture of dyestuffs and similar chemical products has been vigorously prosecuted. As a matter of fact, Mr. Runciman admitted in the House a short time ago that the Government had granted licenses to trade with the enemy in the matter of dyestuffs.

3. As regards the prospects of the home industry after the war, it will require "nursing." I use the term advisedly in order to obviate the employment of another and much more familiar one which is so dear to some politicians and so hated by others; it will require nursing for a much longer period of time than has hitherto been mentioned. In this connection I would point out that the sum of $50,000 a year for ten years, which it has been proposed to guarantee for research purposes, is absurdly inadequate.

4. If the industry is to prosper it will not only have to manufacture materials already known. but also con-

tinually to be introducing new products of its own discovery, as well as constantly to be seeking to produce more economically a great number of auxiliary chemicals required in the manufacturing processes. It is also essential that the undertaking should branch out into the manufacture of other materials as occasion may arise for advantageously utilizing byproducts.

5. The competition which the industry will have to suffer from Germany is likely to be much more serious than is generally supposed, because it must be remembered that England only takes, as we have seen, about one-fifth of the total German exports of dyestuffs, so that it would be comparatively easy for German firms specially to reduce the price of the goods sent to England. They have already done this in America when attempts have been made to start an aniline industry there. It is particularly significant, and augurs ill for the prospects of this scheme, to rehabilitate the coal-tar color industry, that the latter has failed to flourish anywhere, excepting on German soil, and that countries with fiscal systems entirely different from our own have been no more successful in this respect than have we ourselves.

6. It will certainly be necessary that expert chemical knowledge should in the future be much more highly remunerated than it has been in the past, otherwise the supply of able and properly qualified men will not be forthcoming. The flow of men of high-grade intelligence into a profession is determined by the prizes which the profession has to offer, in the form of money and social position. Consider the great stream of able men who are attracted to the English Bar, in which profession the prizes, although limited in number, are of the most substantial kind, with the result that the successful leaders are selected by the fiercest competition in a very wide field.

If there is to be a large influx of high intelligence into the chemical profession, it will be necessary that there should be some very different prizes from the paltry bait which is offered at the present time, for the study of chemistry in this country now only draws those men who either have or think they have an overpowering zeal and passion for the science, to which they devote themselves against the advice of their friends, and in spite of the warnings of the professors of chemistry, by whom they are initiated.

Notwithstanding the absence of material inducements, I venture to say without fear of contradiction that there is more original investigation being prosecuted in this country by chemists than by any other body of British men of science, and this I attribute to the fact that such a large proportion of our number have either been at German universities or are the pupils of those who have been at these centers of research. Nor are any of us, I am sure, even during this unfortunate crisis, unmindful of the hospitality and the inspiration which we have received in the schools of the enemy.

7. If the proposed undertaking is to succeed, real chemists must be on the directorate, and in a sufficient proportion to give effect to their views. Many men of science are excellent business men. What does experience teach in the case of flourishing chemical industries which we fortunately still have among us? What does not the firm of Messrs. Brunner, Mond & Co., for example, owe to the late Dr. Ludwig Mond, F.R.S.?

8. In attempting to establish a commercially successful coal-tar company on a large scale in this country, I venture to think that the Government have undertaken a task which they will find to be surrounded with difficulties of quite a different order from those which they have had to encounter in some of their most striking previous legislative acts, such as the provision of salaries for members of Parliament, the granting of Old Age Pensions, and the establishment of a compulsory system of Insurance. These are matters in which if the Government dictate we are obliged to obey, but the commercial success of an industry which is based upon progressive scientific investigation depends upon factors so subtle and elusive that they cannot be coerced even by a majority of the House of Commons.

9. If the chemical industries are to be rehabilitated in England, there must be a complete change in the attitude of mind towards science in general, and towards chemical science in particular, among the influential classes of the population, and it will certainly not be effected by following the precept "business as usual." but by pursuing a policy which is the exact opposite of what is implied by that vulgar and undignified phrase.

Synopsis of Recent Chemical and Metallurgical Literature

Potash in the United States

In discussing the possible sources of potash in the United States before the New York section of the Mining & Metallurgical Society of America, Mr. A. H. ROGERS mentioned the work of the Government on the brines and deposits in desert basins, also the investigations on alunite in Utah, and the possible utilization of the giant kelps of the Pacific coast. Mention was made also of the potash-bearing silicates, feldspar and leucite. The former contains about 16 per cent and the latter 21 per cent potash. In speaking of the work of Cushman and Coggeshall on extracting potash from feldspar, Mr. Rogers said: "This includes fine grinding of feldspathic material and mixing with 20 per cent of burned lime. This mixture is deposited in a thin layer on a belt which travels under an arrangement which allows drops of a concentrated solution of calcium chloride to fall on it. The result is the formation of little balls having considerable hardness which, being screened out, are furnaced in an ordinary cement kiln; such of the powdered rock as has not been agglomerated is returned to the head of the belt. The heated agglomerates contain the potash of the feldspar as chloride, which is then leached out and recovered by evaporation. Messrs. Cushman and Coggeshall have experimented on a large scale with this process, and as the results of their work have estimated that potassium chloride can be produced for $31.32 per ton, or about 62 cents per unit K_2O."

Speaking of experimental work on leucite, Mr. Rogers continued: "We have tried both wet and dry treatment; the former has been possible because, in contrast with feldspar, leucite is very easily decomposed. Another curious feature about leucite is that, in distinction from most silicates, when decomposed by wet acids it yields its silica in granular form and not gelatinous. We found that by treating with sulphuric acid, to which a little hydrochloric acid was added, complete solution of the bases resulted, and we thought that this might solve our problem. However, it speedily developed that the mixture of sulphates was about as hard to separate into its constituents as the rock. Digestion of leucite with caustic lime under a high pressure was also tried, and this procedure was varied by using caustic soda, and even sodium chloride, the idea being that soda might replace the potash better than lime. From all of these tests some results were obtained, but not enough to be encouraging. Treatment of the rock with sulphurous acid gas at temperature ranging up to 1200 deg. C. was tried, and also the Hargreaves process, which is employed for making sodium sulphate out of salt by passing steam and SO_2 over the salt at a temperature of about 500 deg. C. These yielded a little soluble potash,

but results were not encouraging. We have, therefore, for some time abandoned this wet work.

"Of dry processes, I think we have tried almost all those which seemed to offer any possible chance of success. We speedily found that if you heat a mixture of leucite, lime and gypsum to the proper temperature, the potash could be quantitatively extracted as sulphate. Bearing in mind some of the experiences of cement manufacturers, that the small amounts of alkalis contained in their limes are volatilized, a good many experiments were made with this in view, but we were not altogether successful as sometimes a large percentage would be driven off, at other times but little. As previously stated, we tried heating the leucite with rock phosphate, without result. We also tried the Cowles process which, as perhaps you remember, was devised to extract alumina from clay. By the scheme proposed, a mixture of salt and clay was compressed into briquettes, and heated, whereby hydrochloric acid was given off and an alkali-silico-aluminate was formed. This compound was then to be decomposed by heating with limestone to form a lime silicate, leaving a soluble alkali-aluminate. Some briquettes were made up, and heated in Mr. Cowles' furnace, but very unsatisfactory results were obtained.

"We eventually concluded that unless alumina could be recovered also, the treatment of silicates was hopeless from a commercial point of view. This, I think, has been the conclusion of all investigators, as nearly all recent patents aim to produce something beside potash. As a great many others have learned, we found that when silicates are heated with limestone the potash is set free, but we also found that if the CaO is in the proper proportion, all the bases seem to be set free; at any rate, all except the magnesia. The alkali combined with alumina, and possibly also the ferric oxide and the alkali-aluminate, being soluble compounds, could be leached out. This is a point which has never been recorded by any other investigator, and the ability to recover alumina in such a simple way is, we believe, a solution of the problem. The process consists of grinding a mixture of leucite and limestone in proper proportions, just as in cement manufacture, and furnacing it in a cement kiln. The clinker produced is somewhat similar to cement clinker, and is simply ground and leached. Nothing but alkali and alumina go into solution, and those can be separated just as in bauxite refining. The resulting aluminas is just as good as that produced from bauxite. We have been doing this for about a year now in a small experimental kiln; and while, due to difficulty of temperature control, we do not always get high extraction, we consider it possible that, with the uniform conditions possible of maintenance in a large furnace, we can recover 75 to 80 per cent of these two substances."

Gold and Silver

Cyaniding at the Chiksan Mines, Korea.—In a paper presented to the American Institute of Mining Engineers for the meeting at San Francisco, September, 1915, Mr. Charles W. De Witt, of Seikwan, Korea, describes the metallurgical practice of the Chiksan Mining Company. A flow-sheet is shown in Fig. 1. The ore is quartz of medium hardness, and the average assay value in gold is $6.95 per ton. The mill originally contained two Nissen stamps; two more were added later. Subsequently two batteries of California stamps were installed, and gradually the Nissen stamps were replaced by ordinary gravity stamps. The only reason assigned for the removal of the Nissen stamps is the "wear and tear." Battery screens are thirty-mesh, and both inside and outside amalgamation are used. Pierce riffles follow the plates. After amalgamation the unclassified pulp is concentrated, the concentrates being shipped to the United States. Table middlings are reconcentrated on other tables without intermediate regrinding. Tailings are classified into sand and slime by an Akins classifier, and the sand is leached. Slime is settled in ponds, and may be cyanided later if found sufficiently valuable. The sand vats are filled and emptied by coolies carrying "jiggies." A treatment cycle, including loading and unloading, occupies four days. Precipitation is on zinc in boxes, and the precipitate is treated with acid, dried and melted in the usual manner.

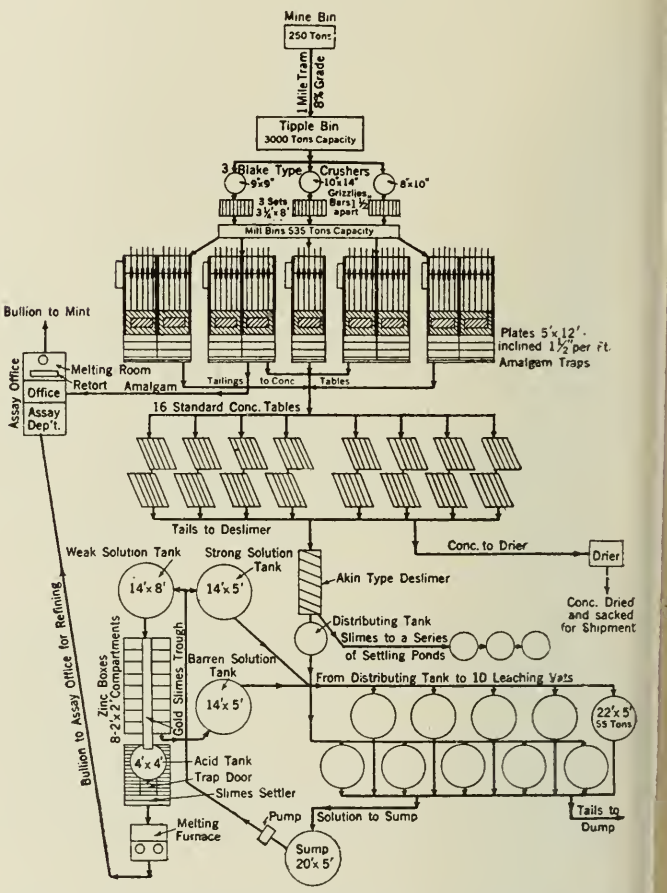

FIG. 1—FLOW SHEET OF THE REDUCTION PLANT OF THE CHIKSAN CO.

The performance of the stamp mill for the year ended Dec. 31, 1915, was:

Tons crushed	46,402
Average assay value	$6.956
Gross value (head assays)	$322,770
Bullion (21,872 oz.):	
Gold	$231,932
Silver	5,794
Concentrates (414.33 tons)	31,388
Total	$269,114
Milling cost, per ton crushed	$0.67
Average assay value of concentrates	$75.75
Stamp duty per 24 hr	4.12 tons

The costs and recovery at the cyanide plant for the year Jan. 1, 1914, to Jan. 1, 1915, were:

	Per Ton	Total
Recovery	$0.799	$29,426
Cyaniding costs	0.335	12,462
Profit	$0.464	$16,964

Total recovery from reduction plant was:

Bullion (28,105.6 oz.):	
Gold	$259,013
Silver	8,062
Concentrate	31,388
Total output	$298,463

Effect of Carbon in Contact with Auriferous Cyanide Solutions.—The subject of precipitation of gold in cyanide solutions by forms of carbon is again discussed in *Bulletin* No. 127, I. M. M., by Mr. W. R. FELDTMANN. He has had occasion to investigate the precipitating action of some "graphitic" ores, and has gathered other data on charcoal precipitation. The graphitic or carbonaceous schists of West Africa precipitate gold from cyanide solutions, and the low extractions obtained there are partly due to reprecipitation of gold by the schists. An analysis of the graphitic schist shows 10.80 per cent "graphite, etc." (by difference). The close analogy between the actions of West African graphitic schists and charcoal is shown in the following points:

1. Gold is precipitated (in the case of the schist in a measure roughly proportional to the amount of carbon present).

2. The gold thus precipitated is not soluble to any appreciable extent in fresh cyanide solution.

3. It is to a large extent soluble in alkaline sulphides.

4. After dissolving the gold in alkaline sulphides the precipitating capacity of both schist and charcoal is renewed practically in its entirety.

The author summarizes his conclusions as follows:

1. It has been demonstrated that the graphitic schists of West Africa precipitate gold from auriferous cyanide solution in a manner which is, in all important respects, analogous to the action of charcoal under like conditions.

2. The gold is precipitated on the charcoal (and on the schist) not as metal but as a compound—possibly a carbonyl aurocyanide.

3. The gold compound is decomposed and the gold dissolved to a considerable extent by alkaline sulphide solutions (judging by the results of a large number of tests, the re-solution is effected rather more easily from the schist than from charcoal).

Whether the discovery that alkaline sulphide solutions will dissolve gold which has been precipitated on the carbonaceous schist can be turned to practical utility in the cyanide treatment of ores containing such schist, is the subject of experiments at present being carried on. By post-treating, with sulphide solutions, sand residues from which a maximum possible extraction had previously been recovered by cyanide treatment, a further extraction has been obtained from a large number of samples, and there is some promise that an economical post-treatment may be evolved on these lines. The precipitation of the gold from the sulphide solutions (in which the gold is held as alkaline aurocyanide with hardly any free alkaline cyanide, but a large excess of alkaline sulphide) appears to be best effected by contact with metallic copper.

Effect of Mineralized Waters in Cyanide Mills.—At some of the cyanide plants in western Australia where good water cannot be obtained it is necessary to use water heavily charged with mineral sulphates, chlorides and carbonates. What is locally known as "fresh" water is obtained from shallow wells, while "salt" water comes from underground drainage. Both classes of water have to be used at the Sons of Gwalia. A description of their use and treatment is given by Messrs. THOMAS B. STEVENS and W. S. BRADLEY, in *Bulletin* No. 127, Inst. of Min. & Met. Analysis of the "fresh" water shows 1.6643 grams solids per liter, while the "salt" water contains 55.744 grams solids per liter. The principal salts are sodium chloride, magnesium chloride and sulphate and calcium carbonate and sulphate. From their experience the authors make the following recommendations for the use of mineralized waters:

1. If "salt water" is used it is not usually possible to obtain a protective alkalinity, but it is advantageous to add a small amount of lime in order to make use of the protective action of precipitated magnesium hydrate.

2. A mixture of "salt and fresh waters" is to be avoided, as dilution of the sodium chloride present causes precipitation of insoluble calcium and magnesium salts, but if they have to be used the addition of lime to produce a protective alkalinity is to be desired.

3. The use of all "fresh water" is by far the most satisfactory, but sufficient lime should be added to it to render it alkaline before it is introduced into the treatment plant.

4. Unless there be other adverse reasons against it, crushing in cyanide solution is to be favored when using mineralized water, as the quantity of "make-up water" required is kept at a minimum by doing so.

A great deal depends on knowing the exact composition of the water, and work done in finding out exactly how the positive radicals contained in the dissolved salts are combined with the negative radicals is time well spent.

Tube-Milling

Injector for Tube-Mill Feed.—In *Bulletin* No. 127, I. M. M., Mr. N. CARLESS describes a device used at the Waihi Grand Junction mill for feeding pulp to the tube-mills. The injector is shown in Fig. 2.

"In the smaller mills the feed nozzle is 1¼ in. inside diam. The nozzles discharge into a larger pipe which

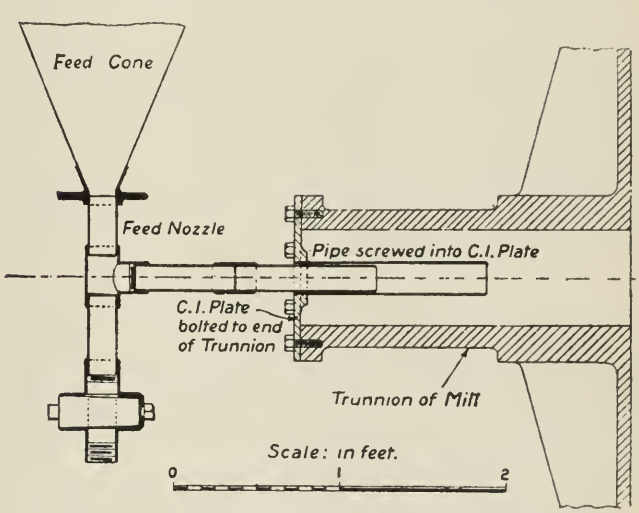

FIG. 2—INJECTOR FOR FEEDING PULP TO TUBE MILL

is bolted on to the end of the tube-mill. A clearance space of ⅛ in. is left around the feed-pipes, hence the pulp discharging into the mill causes a current of air to enter between the two pipes, thus preventing any chance of overflow of pulp at the inlet end.

"It has been found that the best results take place when the pulp passing into the tube-mill contains about 40 per cent of moisture. Experimental work is in hand, with a view of introducing thicker pulp into the mills."

Flotation

Testing Oils for Flotation Process.—An outline of methods for testing oils for the flotation process is published in *Australian Mining Standard* for April 8, 1915, by Mr. J. Coutts. Of the many tests required for this process, one of the most important is the testing of the active floating agent. Conditions of the test should follow as closely as possible the presumed actual conditions of operation. The following remarks pertain mainly to eucalyptus and resinous oils.

Certain standard materials are necessary. (1) Ore sample: A thoroughly representative sample of the material to be treated is dried, crushed to pass 60-

mesh screen, and weighed into 1-lb. lots ready for use. (2) Sulphuric acid: A solution containing 0.405 grams H_2SO_4 per liter, 1 cc. of which equals 2 lb. pure acid per ton, when working with 1 lb. of ore. (3) Oil: A standard oil sample is that oil which has been found to meet the requirements of the work, upon which all future calculations are based and comparisons made. It is stored for use in suitable bottles. (4) Hydrometer: one reading to 0.001.

"In all cases it is necessary to ascertain the sp. gr. of the oil with the view, at least, to future calculations; this may be carried out at any suitable temperature which has been fixed upon as standard; it has been found advisable to check the sp. gr. of the standard oil simultaneously, because of the gradual increase in sp. gr. which takes place owing to the loss of lighter oils by volatilization. A correction for temperature is made by allowing 0.00045 for each deg. Fahr.

"Oil Dropping.—A small burette is used for counting the number of drops in 1 cc. of the oil, also for admitting the oil to the machine during testing operations. The greater the number of drops per 1 cc. delivered by the burette, the greater the accuracy of the test; to obtain a suitable dropper, cut a burette about 8 in. above the cock, almost close to the discharge orifice by dumping up the glass with a blowpipe flame, then grind the outside back to a point so that a minimum surface is presented to the oil drop. The burette should at normal temperatures drop between 80 and 90 drops per 1 cc., when run at the rate of 1 drop per second. The temperature of the oil during dropping test should correspond with the temperature during flotation test.

"Calculations.—Having obtained the number of drops per 1 cc. and the sp. gr., it is easy to calculate the number of pounds of oil per ton of ore, when working on 1 lb. of sample.

Thus $\frac{2240 \times \text{sp. gr.}}{453.6 \times \text{No. drops per cc.}}$ = lb. of oil per ton of ore.

"Miscibility.—It is sometimes desired in practice to use a mixture of oils. When the oil under examination is to be used in conjunction with another, or other oils, they should be wholly miscible in the proportions in which they are to be used.

"The following classification and explanations will serve to convey to the reader a general idea of the methods employed when carrying out various tests:—(1) Flotation of lead, zinc and other sulphides, as a mixed concentrate; (2) differential separation or selective flotation of one sulphide in the presence of other sulphides. The term "differential separation" is usually applied to the selective flotation of lead sulphide from zinc and other sulphides; (3) flotation of copper and iron sulphides.

"General Outline of Scheme of Test.—The testing of oils in the laboratory is carried out by comparing measured quantities (from 3 to 6 drops) of a standard oil, with a similar quantity of the oil under examination; the values being arrived at by comparing the results obtained from each series of tests. Tests are usually made on 1 lb. of standard ore sample in 4 lb. of water at a standard temperature, acidulated with a definite quantity of sulphuric acid; the oil then being admitted; the mixture is agitated in a specially constructed agitating machine, the principle of which being dependent on the object of the test. The float produced is skimmed off, dried, weighed and assayed.

"Test 1.—The flotation of mixed sulphides. Almost any eucalyptol oil which produces a persistent froth, and leaves a gummy residue on evaporation, is suitable for this class of work, the test being carried out as described. An agitating machine may be constructed by cutting a winchester bottle about 10 in. above the neck (a bell jar of suitable dimensions can be obtained), fit four copper baffles 4 in. x 1½ in. wide to a copper band of the same width, push this arrangement hard down into the bottle (the band being first bent to fit the inside circumference of the bottle), the lower ends of the baffles will jam hard at a point where the concave glass begins; the band is then expanded hard against the glass, and held in position by soldering the separated ends. The mouth or discharge end is closed with a rubber stopper, through which is passed a glass or metal tube, fitted with a short rubber tube and clip. The bottle with the baffles in position is inverted and clamped centrally under two pairs of suitable bearings, which carry a ½-in. impeller shaft; at the upper end of the shaft is fitted a driving wheel, and at the lower end a four-bladed impeller, which just has clearance between the lower points of the baffles and the glass; the blades of the impeller have a lateral angle of about 45 deg., and should be driven at about 1200 revolutions per minute, in a lifting direction.

"Test 2.—Differential separation. For differential separation, an oil high in phellandrene is used, which leaves a gummy residue on evaporation. Phellandrene may be tested for by a polariscope. Differential separation is worked in acid and neutral, and in hot and cold liquors, and being still in its infancy, allows of many types of machines and schemes being applied; each different ore requires some modifications, but the principle in main is the addition of medium and aeration from below, which is effected by air jets or suction created by the impeller.

"Test 3.—Flotation of copper and iron sulphides. An oil which gives a deflection by the polariscope of 60 or over is considered sufficiently high in phellandrene for use in copper flotation. Tests are usually made with the apparatus described in Test 1, using cold circuit liquors made slightly acid. In practice the mine water usually contains sufficient acid for the purpose."

Iron and Steel

Automobile Gears.—Robert R. Abbot, metallurgist of the Peerless Motor Car Company, has contributed quite an interesting article on "an example of the development of heat treatment" to the *Sibley Journal of Engineering*. Gears form a very essential part of an automobile. Originally carbon steels were used and they were cyanided; but the hardened surface film was very thin and the gear teeth would fracture. Carbonizing was then employed as the hardened shell can be made as deep as desired. But there is a lack of toughness in a carbonized gear tooth and this led to the use of alloy steels and their heat treatment. Many gears were made of chrome, nickel, and silicon steels containing about 0.5 per cent carbon and were oil-quenched and drawn without carbonizing. The carbon was low enough so that no cementite was present. The alloy gave an extremely strong tooth; the cost of machining was higher than for a low-carbon steel. Such a surface would not wear as well as one containing a higher percentage of carbon. A marked step in advance was then made in the development of the so-called double treatment of carbonized parts; this is applied to either a plain or an alloy steel. When a piece of carbonized steel is hardened at the ordinary hardening temperature, there are three different zones. But if a temperature higher than the hardening temperature is used, the excess substance in the inner and outer zones, namely iron and cementite, becomes less in amount while the martensite becomes greater; briefly the martensite absorbs both the iron and ce-

mentite. As the temperature is raised still further this absorption continued until finally all three zones contain martensite alone. The temperature at which the last of the cementite is absorbed will usually be different from that at which the last iron goes into solution; also the time element for the absorption of the cementite is much greater than for the iron. The temperature of final absorption of the iron increases as the amount of iron originally present in the core decreases. Also the temperature of final absorption of the cementite is higher as the temperature at which the original carbonizing took place is higher. This temperature can also be changed by suitable selection of the material with which the carbonizing is done. In general, all the above factors are adjusted so that the temperature of final absorption of the iron shall be higher than that for the cementite. If the steel is now quenched from above this temperature, there is martensite throughout, but there is a difference in the physical characteristics of the martensite in the three original zones; that in the center zone will be fine grained, while that in the middle and outer will be very coarse. Steel treated in this way will be less brittle than when at the lower hardening temperature, but it will not wear so well because the cementite is no longer present and this is the hardest constituent formed in steel. If the steel is now reheated to the regular hardening temperature, i.e. 1375 deg. to 1400 deg., and then quenched, there is an enormous increase in toughness and also in hardness and wear resisting ability. Microphotographs show that both zones contain the same constituents and in the same relative proportions. However, the structure is entirely different, the cementite in the outer zone no longer exists as brittle sheets, needles or nets, it is uniformly distributed in minute globules which have a maximum durability of wearing surface with a total lack of the former extreme brittleness. The core is very fine-grained and the martensite instead of occurring in a comparatively few large crystals which would tend to promote brittleness now occur as fine crystals embedded uniformly in a matrix of soft iron.

Electrolysis in Concrete Structures

Paints to prevent electrolysis in concrete structures have been investigated by Mr. HENRY A. GARDNER, who presents the results of his tests in the March, 1915, *Journal* of the Franklin Institute. The author concludes that the use of properly made paints on metal embedded in concrete is a safeguard that should not be neglected by the engineer. In the preparation of such paints the vehicle should contain: Boiled or bodied oils or products which dry to a fairly saturated film; oils which dry by semi-polymerization rather than oxidation; oils which dry to a flat rather than a glossy surface. The solid portion of the paint should contain a percentage of pigments which are coarse and tend to form films having rough surfaces; which are inert and do not act as electric conductors; which are either basic or of the chromate type. The painted metal should be coated with sand before drying in order to afford a good bonding surface for the concrete.

Hydraulic Forcing and Miscellaneous Presses is the title of Sectional Catalog No. 92, issued by the Watson-Stillman Co., 50 Church Street, New York. It is an illustrated book of 128 pages, describing the many special types of hydraulic presses made by this company, such as wheel presses, crank pin presses, armature presses, broaching presses, forcing presses, die presses, projectile capping and banding presses, baling presses, briquetting presses, smokeless powder presses, carbon squirting presses, lead presses, crayon presses, etc.

Recent Chemical and Metallurgical Patents

Iron and Steel

Steel Refining.—Mr. W. R. WALKER of the U. S. Steel Corporation, patents the following combination process for steel refining. He introduces molten pig metal into a Bessemer converter and blows it until the silicon and incidentally a large proportion of any manganese which may be in it has been eliminated and the carbon reduced to a definite percentage, preferably to about 0.05 per cent, which percentage can be gaged with accuracy because it is about the percentage contained in the metal at the time when the flame "drops." He then adds to the desiliconized and decarburized metal sufficient carbon to raise its carbon content to a definite percentage, preferably 0.3 per cent. The metal is now enriched in carbon to the same percentage as steel is; it is also deoxidized. It is, in fact, steel but containing an excess of phosphorus, sulphur, etc.

This phosphorus and sulphur is then removed by treating the metal in an electric furnace or an open-hearth furnace. (13,861, Jan. 5, 1915.)

Steel Alloys.—A method of producing silicon-steel, vanadium-steel and other steel alloys is patented by Mr. ARCHIE SMITH, of Leetonia, O., and assigned to the Youngstown Iron and Steel Co. In the ordinary method of making such alloys, the steel is tapped directly into a ladle containing the alloying metal. According to the improved patented process, the steel is tapped first into an intermediate ladle from which, in turn it is tapped into the ladle containing the alloying ingredient. The advantages claimed are the exclusion of slag from the alloy, and the possibility of making use of refining furnaces of any size, so that a large quantity of steel can be refined, charged into an intermediate ladle and then alloyed in smaller charges in the mixing ladles. (1,131,799, Mar. 16, 1915.)

Treating Mill Scale.—A method of reducing the mill scale formed in the manufacture of high-speed steel, is the subject of a patent granted to Mr. FREDERICK M. BECKET, of Niagara Falls, N. Y. By smelting such scale with silicon as a reducing agent, in an electric furnace and in accordance with certain methods disclosed in prior patents, it may be reduced to an alloy having approximately the same composition as that of the steel from which it was derived. Analyses of a mill scale and the alloy obtained therefrom by silicon reduction, are as follows:

	Mill Scale	Reduced Alloy
Tungsten	11.90	15.60
Chromium	2.90	3.40
Vanadium	0.49	0.43

The resulting alloys, however, contain an unusually high percentage of phosphorus, and the product of direct reduction of the scale is low in tungsten. These conditions can be obviated by a preliminary acid treatment, where the major portion of the iron and practically all of the phosphorus are removed. Thus the scale is ground to 8-mesh and treated with sulphuric acid of 1.2 to 1.4 sp. gr., either at normal temperature or at from 50° to 70° C. The residue is washed and smelted with silicon. Up to 75 per cent of the iron can be removed by the acid without material loss of tungsten, and the resulting alloy will contain from 25 per cent to 45 per cent tungsten and be practically free from phosphorus. According to a modification of the invention, the mill scale is subjected to a reducing operation with carbon before acid treatment. The mixture of scale and carbon is heated to about 1000° C. in a retort, and then treated as above described. (1,127,162-3, Feb. 2, 1915.)

Gold and Silver

Agitator.—Fig. 1 illustrates the features of an agitator, patented by Mr. John V. N. Dorr, of Denver, Colo. The apparatus is designed to treat ores by cyanidation, or for the thorough mixture and treatment of finely divided solids in a liquid capable of dissolving a constituent of the solids. The device embodies both air and mechanical agitation, and effectually prevents the accumulation of banks or beds of settled solids within the tank. It consists of a circular tank in which is suspended an upright, hollow, rotatable conduit 3, carrying from its lower extremity two or more radial arms 10, provided with blades or plows 12. Near the upper end of the central conduit are arranged two or more distributing launders 16. The central conduit and attached arms and launders are rotated by means of a worm 8 and wheel 7 above the tank. Compressed air is admitted at the bottom of the conduit through a pipe 24 extending downwardly within the conduit from above, or it may be applied through the bottom of the tank.

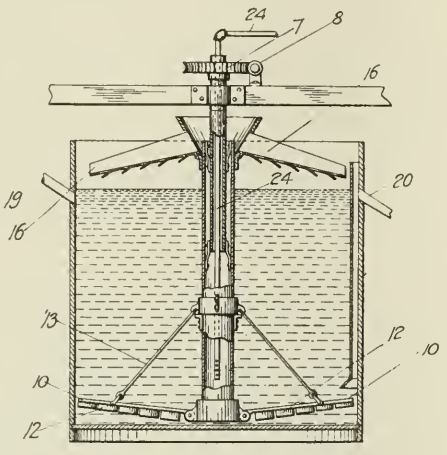

FIG. 1—AGITATOR

In operation the radial arms and plows convey the settled pulp to the central conduit where it is raised by the air-lift to the launders and distributed over the surface of the pulp in the tank. Operation may be continuous through a succession of agitators, the pulp being fed in at one side of the tank, as at 19, and removed at the other side, as at 20. By adjusting the means of discharge, the density of the pulp can be controlled. (1,131,222, March 9, 1915.)

Copper

Use of Sulphur Dioxide in Electrolytic Copper Process. — It has been previously proposed to make use of sulphur dioxide to prevent the harmful action of ferric salts in the electrolysis of impure copper solutions. According to a patent granted to Marcel Perreur-Lloyd, of Boulogne-sur-Seine, France, the method of application has hitherto been defective, and it is the object of his invention to make effective use of this substance as a depolarizer. This he claims to accomplish by bringing about an agitation of the electrolyte. Such agitation can be done either by moving the electrolyte by means of compressed air or by moving the anodes in the electrolyte. The former method has the objection of driving sulphur dioxide out of solution, hence the latter method is preferred. As shown in Fig. 2, one method of moving the anodes is to cause them to rotate in the electrolyte, being moved about a shaft to which they are attached. The cathodes C are stationary. The anodes, which are composed of two parts, A and B, are partly stationary and partly rotatable, A being attached in a stationary manner and B attached to the rotating shaft O. With sufficient agitation of the electrolyte, keeping the sulphur dioxide in solution, it is possible to employ a current of 100 amperes or more per square meter of cathode area and to extract copper from the most impure solutions up to 0.1 per cent and obtain good deposits of copper. It is claimed further that with this apparatus the required electric energy can be reduced to less than one kilowatt hour per kilogram of copper deposited. Sulphuric acid is generated in the course of the process from the sulphur dioxide which, in turn, is cheaply generated from the process of roasting ores. (1,133,059, Mar. 23, 1915.)

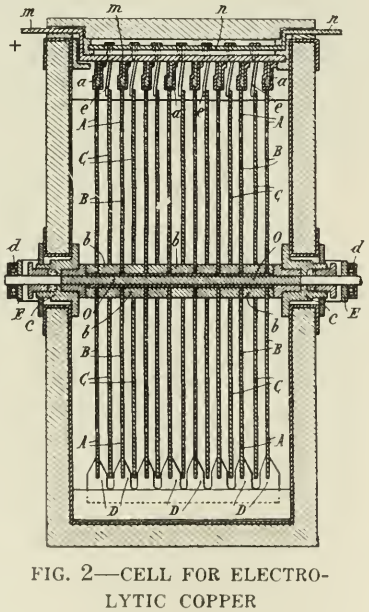

FIG. 2—CELL FOR ELECTROLYTIC COPPER

Notes

Air-Lift Pumping is the title of a bulletin recently issued by the Sullivan Machinery Co. It contains valuable data and information on the subject.

The **Dorr Cyanide Machinery Co.** announce that after May 1, 1915, the address of their New York office will be Room 2843, Whitehall Building, New York City, instead of 30 Church Street, as heretofore.

The Kelly Filter Press Co., Salt Lake City, Utah, has issued a new pamphlet illustrating and describing the Kelly filter press. The company maintains a large testing plant where products can be tested to determine capacity, filtering medium, operating cost and other data.

The **Association of Iron and Steel Electrical Engineers** held a meeting on April 10 at the Seventh Avenue Hotel in Pittsburgh, Pa., a paper by Mr. A. W. Soderberg, of the Carnegie Steel Company, on "Apprenticeship and Educational Work in the Iron and Steel Industry" being on the program. Another meeting was held on May 1, when Mr. R. S. Wile, president of the Wile Electric Furnace Company, presented a paper on the electric furnace and the melting of alloys in the electric furnace.

The Liberty Bell mine, Telluride, held its first annual "Safety First Dinner" on April 8, "to celebrate a year without a fatal accident and with fewer serious accidents; to pledge ourselves to better care in future." This is a new and effective method of bringing the "safety first" idea prominently before the employes of a company. The dinner was followed by five-minute talks by General Manager Charles A. Chase, Mill Superintendent W. E. Tracy and others. The evening was enlivened by "safety first" verses sung to the tune "Tipperary."

Water Meter.—The Yarnall-Waring Co., Chestnut Hill, Philadelphia, has just received orders for four Lea V-notch recording liquid meters in combination with Webster feed-water heaters aggregating 1,125,000 lb. per hour capacity, from the E. I. duPont De-Nemours Powder Co., Wilmington, Del., following the original installation of the Lea system by them two years ago. They also report an order for a 275,000-lb. per hour capacity Lea V-notch recording liquid meter for the new power plant of the Victor Talking Machine Co., Camden, N. J.

Fuel-Supply Contracts and the Progress of More Scientific Methods of Purchase and Control in America and Europe

BY JOHN B. C. KERSHAW

That the application of scientific methods for determining the sale and purchase value of fuel is advancing in favor, is proved by the growing literature of the subject, and by the increasing tendency of power engineers in the leading industrial countries, to demand guarantees from the colliery companies, or from the coal dealers and "middlemen," that the fuel shall yield on test a minimum number of calories, or shall contain less than a definite maximum percentage of sulphur and ash.

These newer methods of purchase and control have obtained their widest application in America, a result due partly to the fact that the American Government has taken up vigorously the system of purchasing fuel on a heat-unit basis, and partly to the greater readiness of American business men to give science its proper place in the control of industrial and manufacturing operations.

In Europe the necessary incentive to adopt more scientific methods has been supplied by the advanced labor legislation of recent years, and by the striking rise in the cost of coal mining in the leading industrial countries. The additional financial burdens placed upon the colliery owners have, in fact, rendered the use of scientific methods for checking the quality and price of fuel imperative, for not only has the price of fuel been increased by 20 per cent to 30 per cent within the last few years, but the quality has at the same time deteriorated, and every large fuel-user knows only too well that he is *now paying more for a worse fuel than ten years ago.*

The (British) Eight-Hours-Day Act has been the chief factor in causing this deterioration in the quality of the fuel mined, a deterioration which is most marked in the case of the slack and small coal sold in large quantities for steam-raising purposes. In order that the miner may produce his daily quota of output he has to work with less care than formerly, and a much larger proportion of shale and dirt is now brought to the surface with the coal than was the case ten years ago.

The proportion of smalls in every 100 tons of coal raised has also increased enormously since the Mines Eight-Hours Act came into force. The writer of this article has tested quite recently a large delivery of slack sold by a well-known Lancashire colliery company for steam-raising purposes which gave the following results when graded in the laboratory:

Slack left on ¼-in. mesh sieve..... 48 per cent.
Fine slack which passed through ¼-in. mesh sieve ..... 52 per cent.

The latter portion of the slack was again graded into two portions by use of a 1/12-in. mesh sieve and it was found that nearly one-half of this portion, or 24.3 per cent of the original weight of slack, was composed of fine dust that passed easily through a 1/12-in. mesh sieve. Separate ash tests of these three grades of slack were then made and the test results are sufficiently interesting to be given here:

Slack left on ¼-in. mesh sieve.... 11.15 per cent ash.
Fine slack, between ¼-in. and 1/12-in. mesh ..... 19.20 per cent ash.
Dust under 1/12-in. mesh..... 29.60 per cent ash.

Nearly 25 tons of every 100 tons of this slack as delivered was therefore practically valueless as a fuel in any ordinary boiler furnace, and in this particular case it only served to clog up the air passages of the firebars and to prevent proper combustion of the remaining 75 per cent of the fuel. To charge $3.25 per ton for such a slack was a gross imposition upon the fuel-user. Instances of a similar kind could be given in large numbers, but enough has been said to prove that during the past ten years the quality of fuel has deteriorated enormously while the price has increased, and that the need for the application of scientific methods of controlling the quality and price of fuel was never more urgent than at the present time.

In this article details will be given of the methods in use in Germany, Switzerland, the United Kingdom and America for sampling and testing fuel in transit, or when discharging at the consumer's works. Some examples of forms of contracts, in which the price paid for the fuel is made dependent either upon the calorific value, or upon the percentage of ash will also be given.

Germany.—The information relating to German methods has been obtained from Dr. Aufhäuser, head of the Thermochemische Prüfungs-und Versuchs-Anstalt in Hamburg. The fuel testing for the members of the *Hamburg Verein fur Feuerungsbetrieb und Rauchbekämpfung* is carried out at this laboratory, and the last annual report of the above society contains the results of many hundreds of tests of samples of English and German coals, which have been made in Dr. Aufhäuser's fuel-testing laboratory. A large number of members of the *Verein für Feuerungsbetrieb* are now having their supplies of fuel sampled and tested regularly, the usual plan being to take separate samples of each 50 tons of coal as delivered, and to have these samples tested for moisture and ash, and also for calorific value, in a Berthelot-Mahler bomb-form of calorimeter. In some cases the purchasers of the fuel have been able to arrange for contracts with the "middlemen," or colliery agents, in which the price paid varies with the monthly average of these calorimetric tests, the basis of the contract being a fixed price for 100,000 calories. In other words heat units and not coal are bought and sold.

In the majority of instances at Hamburg, however, only two limits are inserted in the contract, namely, a *minimum calorific value* and a *maximum percentage of ash.* The seller of the fuel then contracts to deliver a fuel which shall not fall below a certain stated calorific value, or contain above a certain stated percentage of ash, and if any delivery of fuel is found which does not fulfil these conditions of sale it is either returned to the seller or an allowance is made on the price.

Average tests of the monthly deliveries are taken in deciding upon the value of the fuel and slight variations up to 1 or 2 per cent are generally overlooked. Very bad or dirty samples are quickly detected by the wide deviation of the test results from the average of the deliveries, and the tests of such camples *are not included in the average*, unless the sampler is convinced they represent fairly the deliveries on the particular occasion when they were taken.

Although the colliery companies and "middlemen" prefer this form of contract to the former one, it is really the more rigorous of the two, for it contains no possibility of the price being increased, when the fuel actually supplied is rather better than that contracted for. The simpler form of contract is, however, preferred; and not only in Hamburg but also in many other industrial centers of Germany the supplies of fuel are now being purchased under what is practically a chemical guarantee of quality. Over 1000 samples of fuel were tested at Hamburg in 1909 and the work of Dr. Aufhäuser's laboratory has increased greatly in the four years that have elapsed since that return was published.

Switzerland.—The facts and figures relating to the progress of fuel sampling and testing in Switzerland have been obtained from Prof. E. J. Constam, director of the federal fuel-testing laboratory at Zürich. The erection and equipment of this laboratory was one result of the purchase of the Swiss railways by the state in 1902 and of the fact that all the fuel required for working the railways was purchased in France or Germany, generally in the form of briquettes.

The laboratory is an annex of the Zürich Polytechnic and is really an extension of the old thermo-chemical laboratory, the extensions and equipment costing about $10,000 and having been completed in 1907. In the year 1908 (the first of its existence) over 3300 samples of fuel-briquettes and coal were tested in this laboratory, and the latest available figures show that this has been increased to 5860 in 1912. The laboratory examines fuel for private firms and indivduals, as well as for the state railways, and from time to time the results of its investigations are published in the form of a report.

As the value of briquettes depends largely upon their ability to stand handling without falling to pieces, an important test at this federal laboratory is that for "cohesion." This test is carried out as follows: Fifty kilograms of the briquettes are put into the drum of the cohesion testing machine in ½ kg lumps. The machine is set in motion and, after making fifty turns in two minutes, the contents is emptied onto the gridiron and shaken. What remains behind is weighed. This is expressed as a percentage of the weight used and gives the cohesion value, which in the case of good briquettes should not be less than 55 per cent.

The large number of tests carried out at this state-aided laboratory has had good results in Switzerland for it has tended to enlighten the consumers as to the relative economic values of the fuels they have been importing from the various countries, and has assisted in their classification according to heating power.

The director of the federal fuel-testing laboratory, Dr. Constam, is a firm believer in the use of the thermal value of a fuel as the basis of the fuel-contract, and he is doing all he can to get this system of purchase adopted in Switzerland.

Both the coal producers and the consumers are stated to be satisfied with the methods of fuel sampling and testing adopted at the Zürich laboratory. The results of the tests are compiled monthly and are communicated to both the sellers and buyers of the fuel. In the case of briquetted fuel the settlement is effected by adding to or deducting from the price a proportionate sum for every 90 B.t.u. by which the average monthly calorific value of the fuel actually delivered differs from the standard calorific value inserted in the contract.

The United Kingdom.—Although a very large amount of fuel-testing is being carried on in the United Kingdom at the present time in the laboratories of technical colleges and universities, of independent experts, and of works and factories, it is not easy to give an exact record of what is being done since the English manufacturer and works-manager is extremely unready to make his methods of control and management known, even when these contain little that is novel or of patentable value. It is certain, however, that in a large number of works and factories where fuel is an important item in the costs of production the deliveries of fuel are regularly and systematically sampled, and that these samples are tested either in the laboratory attached to the works or are sent to some independent institution or analyst for examination.

With regard to the form of the fuel-contracts used in the United Kingdom little progress has been made yet in persuading the colliery companies or the coal dealers to sell coal on a sliding scale basis, *i. e.*, to sell calories or heat-units in place of tons of coal.

The majority of fuel contracts are based, however, on the system of guaranteeing a certain definite standard of quality expressed in British thermal units and in percentages of moisture and ash. Should the coal actually supplied not come up to this standard of quality the delivery may be rejected. This form of contract suffers from the grave defect that in nine cases out of ten the fuel is discharged and is partly or wholly used before the deficiency in heat units or high percentages of moisture and ash are discovered. The rejection of the fuel is, therefore, a course which can rarely be adopted, and as the colliery company is protected in this manner from the operation of the clause, the adjustment of price, which ought to follow the delivery of bad fuel, seldom occurs.

The systematic sampling and testing of the fuel which is going on, however, has some effect in keeping up the quality of the fuel delivered. A contract with a clause defining the quality of the fuel purchased in B.t.u. and setting limits to the allowable percentages of moisture and ash, is certainly an advance upon the form of contract in use fifteen or even ten years ago, when only the mine and seam of coal were named in the clause specifying the quality.

Some practical examples of the forms of contract that have been tried or are now in force in the United Kingdom are given below. These are drawn chiefly from the electrical supply companies, since the engineers of these undertakings are quite ready to answer inquiries, and the writer is most in touch with what is being done in this branch of the engineering industry.

A. A Large Municipal Electrical Supply Undertaking in Scotland.—The chief engineer reports that samples are taken daily of all the coal, a small scoopful of coal being taken by the check weighman from each ton-load delivered. These small samples are stored in a clean receptable until the barge or wagon is empty. The sample is then reduced by crushing and quartering to one of 3 lb. and this is forwarded in a sealed tin to the testing laboratory of the electricity department. The contents of the tin are there crushed and still further reduced in bulk in the usual manner and the calorific value of the sample is finally determined in the bomb type of calorimeter.

If the tests show that the fuel being delivered is below the standard set for the particular pit from which it is shipped complaint is immediately made and the cause of the deterioration in quality is usually found to be *careless mining and picking of the coal.* By this means the engineer of this works reports that they have obtained a thorough working knowledge of the relative values of all the fuels mined within a practical distance of the generating station and when offers of coal are made they can bring all prices down to a common calorific basis by use of their past test records for each pit. Although the contract is not based on heat units they are able to bring the contract price into close agreement with the real calorific value of the fuel.

B. A Large Municipal Electrical Supply Undertaking in the Midlands.—The chief engineer and general manager reports that the fuel is sampled and tested daily. Samples are taken from the rotary filler supplying a conveyor at intervals during the unloading of each boat, the coal in this case being delivered by canal. Each day's samples are mixed and are quartered down into two lots of convenient size. One of these is tested for calorific value, ash and moisture daily, the other portion is put with the previous day's sample in order to make up the weekly average sample of fuel.

The Contract stipulates for a certain calorific value

and ash percentage but the price is not dependent upon the quality. This latter must, however, be maintained or the fuel can be rejected, and if not rejected a claim can be made for a reduction in price based on the average figures of tests taken over the period in question.

C. A Large Municipal Electrical Supply Works in the North of England.—The borough electrical engineer reports that tenders are invited for fuel to a specification which records the minimum calorific value of the fuel and also the maximum percentage of ash. When the tenders are received certain fuels are picked out for testing purposes. A sample lot of 100 tons is asked for (this is equal to one day's supply) and the whole of the works is then run on this sample lot, the weight and cost of fuel per unit generated and the percentage of ash made being carefully noted. In addition to this practical test a laboratory test is made from a sample sent to an analytical chemist. The contract is placed with the firm whose sample of fuel shows the best practical results per unit generated, but regular analytical tests of the fuel are made during the period for which the contract runs and a clause is inserted in it giving power of cancelling the contract in the event of the fuel not coming up to the guaranteed calorific value. The laboratory tests are therefore used in this case solely to check the quality of the fuel delivered.

D. A Large Cotton-Spinning Company with a Mill in the Manchester District.—This company managed to obtain in 1908 a contract with a Lancashire colliery company on the sliding-scale basis but after a two years' trial the contract was not renewed. This non-renewal was due to the objection of the colliery company to the terms of the contract and to their refusal to be bound by them, even when the fuel supplied was better than that contracted for and the price variation was in their own favor.

While this contract was running two carefully prepared average samples were tested per month by an independent analyst. These samples showed a striking uniformity in ash contents and calorific value, the variation from the calorific value of the sample upon which the contract was based being well within 5 per cent for the whole of the period. This uniformity in the heat-value of the coal actually delivered was, no doubt, largely due to the knowledge that the coal was being regularly sampled and tested at the consumer's works. The consumers recognized this fact themselves, and stated in a letter to the author that "we are greatly in favor of the system of purchase upon calorific units. Since our contract of December, 1908, when we began the new system, we have had a much more uniform fuel supplied to us, which is all we aimed at."

E. A Flour-Milling Company with Several Mills in Southwest Lancashire.—This company, like that cited above, found a firm of colliery proprietors willing to close a contract on the sliding-scale basis.

The experience of the second firm, however, has been rather different from that of the first, since marked variations occurred in the quality of the fuel supplied, and in consequence there were considerable reductions made in the price paid for the fuel. It is noteworthy that the largest increases in ash and corresponding decline in calorific value occurred during the second half of the year 1909, although the coal merchants declared they were supplying exactly the same fuel as in the earlier months. This falling-off in the quality of the fuel contracted for lends support to the assertion that the operation of the mines eight-hour act is affecting the quality of the small coal raised and sold in certain mining districts.

In this case, also, the sliding-scale arrangement ceased at the end of 1910 owing to a change of management at the mill and the appointment of a manager who did not believe in the value of fuel-testing.

In concluding this account of the progress of the movement for the more scientific control of fuel supplies in England, reference may be made to a standard coal specification for the purchase of coal by electricity works. This specification was drawn up by a committee representing the principal London firms of coal contractors on the one hand and the Associated Municipal Electrical Engineers of Greater London on the other.

There are two model specifications, the first being for a coal of a particular description or "named" coal; while the second is for a coal guaranteed to possess certain definite physical qualities.

The principal feature of this latter specification for "guaranteed coal" are as follows:

The tenderer shall set out in his details the classes of coal for which he is tendering corresponding with the classes referred to in the table of standards.

Testing—(*a.*) A representative sample shall be taken on delivery from each or any consignment and shall be divided and sealed in three air-tight vessels. The contractor shall be at liberty to be represented when the sample is taken, and shall be entitled to one portion thereof; but he shall have no opportunity at a later date of objecting to the manner in which the coal has been sampled.

(*b.*) Samples taken in the manner defined shall be taken from each consignment and tested by the purchaser, or in the event of a dispute by a competent expert, who shall be approved from time to time by the purchases and whose fees shall be paid by the contractor if the purchaser's test is confirmed. The tenderer is invited to set out in the tender's details, the names of three experts either of whom he is agreeable shall be employed. A table of standards is then given for application in connection with guaranteed coals. As regards the methods of testing the fuel the following conditions are laid down:

British thermal units shall be ascertained on coal dried at 220 deg. Fahr. for an hour by means of a Mahler-bomb calorimeter. Moisture shall be represented by the total loss in weight of the coal delivered after air-drying and exposing to a temperature of 220 deg. Fahr. for one hour. The percentage of sulphur shall be based on the analysis of the coal "as received" and must not exceed 2 per cent. The sieves used for determining the percentages of "small" shall be of square mesh with openings in the clear to the sizes given.

America.—As already stated earlier in this article the United States Government has given a strong lead in America to the scientific control of fuel supplies by purchasing a large proportion of the coal required for the navy and other state departments on a B.t.u. or strictly specified basis. As regards the naval requirements the fuel is purchased on a B.t.u. basis, a premium being paid for all coal showing more than 15,000 B.t.u. in the dry state, and no wet coal being accepted. The balance of the government's annual coal purchases is bought on a pro rata as received B.t.u. basis and the seller is also penalized to the extent of from two cents to thirty-five cents per ton for variation in ash rising from 3 per cent to 9 per cent above the guaranteed amount, 2 per cent above the guarantee being allowed to pass without fine. The method of sampling and of calculating the heat-value is as follows:

In all cases where practicable the coal is sampled during its discharge into the building where used. The sample selected in no case is less than 100 lb. and it must be reduced by repeated crushings and quarterings to the small amount required for testing by the treas-

ury department. The method of analysis and of calorific valuation is that drawn up by the American Chemical Society.

Payment is made upon the basis of the price named in the proposal for the coal specified by the seller, correction being made for the variation in ash and heating value. For example, if the coal contains 2 per cent more or less B.t.u. than the standard named in the specification the price is increased or decreased in the same proportion.

The price is also corrected for the percentage of ash, and for all coal which contains less ash than the standard named in the specification a premium of 1 cent per ton is paid for each 1 per cent of ash. An increase of 2 per cent of ash over the standard named in the specification, on the other hand, is not weighted with a penalty, but above this limit a deduction is made from the price paid for the coal. The coal is to be weighed as delivered, and as payment is made upon this delivery weight the calorific test is made upon the coal containing whatever moisture may be present at the time.

With regard to other methods or systems of purchase in use in America, the Fuel Engineering Company, of Chicago, was founded in 1908 as an independent sampling and testing organization with a large number of clients who purchased fuel on a B.t.u. basis and handed over all the scientific work required in connection with this method of purchase to the officers of the company. The company published a monthly test sheet for circulation among its clients giving details of all the tests made during the previous month. Much valuable information concerning the comparative value and price of the fuels marketed in Chicago thus became the common property of all who were having regular tests made by this organization of their fuel deliveries, and each consumer found out quickly if he was obtaining a good return for his expenditure upon fuel. The specification and method of regulating the price by the quality used by the Fuel Engineering Company, of Chicago, was more complicated than that used by the United States Government departments and was based upon what was called the "contract guarantee," or number of B.t.u. which was obtainable for 1d. (2 cents) from the trial sample of the fuel.

The Interborough Rapid Transit Company is an electric tramway company which consumes annually 360,000 tons of a bituminous "run of the mine" coal. This is purchased upon a B.t.u. basis—with limiting values of 9 per cent for ash and of 1.5 per cent for sulphur. Variations above or below these figures are subjected to deductions or premiums as the case demands.

The coal for the Panama Canal constructional works, which amounted to 650,000 tons per annum, was also purchased on a B.t.u. basis of 14,600 as received, with deductions for variations below this limit.

The Department of Water, Gas and Electricity Supply for New York City uses a very large quantity of coal per annum and the system of fuel control employed is considered by its officers to be an improvement upon the system used by the United States Government departments. According to the description of the system given in *Power* by F. R. Hutton and J. L. Pulz, before drawing up definite specifications a careful investigation is first made of the character of the various coals furnished in the buyer's area, and from these results a diagram is plotted representing the variations in moisture, ash, volatile matter, sulphur and combustible matter. Any coal falling within the limits considered desirable are put on the list of eligibles as to quality. Coals lying outside these limits and below them are penalized with respect to weight, but not as to price, so that the buyer should not buy water or incombustible mineral matter and pay for them at the rate agreed on for good coal. The research carried out on these lines by the company's staff developed the relation that each percentage of ash in the coal besides displacing 1 per cent of combustible matter has a retarding effect (varying with the quality of the coal) equivalent to the withdrawal of between 145 and 155 B.t.u. or an average of 150 B.t.u. With this as a basis, a formula was evolved applicable both to anthracite and bituminous coal in the following form:

$$\text{Corrected tonnage} = \text{tonnage delivered} \times \frac{\text{B.t.u. per lb. as delivered} - 150 \text{ B.t.u.} \times \text{excess percentage of ash}}{\text{B.t.u. per lb. as specified in standard analysis}}$$

For practical purposes the formula can be simplified by using a direct percentage relation whereby 1 per cent in weight shall be deducted for each 100 B.t.u. and an additional 1 per cent for each percentage of ash. This can be equally well applied when it is desired to give a bonus.

The weight of the coal after correction for moisture is then reduced at the rate of 1 per cent for each percentage of ash in excess of that permitted by the standard and the gross dry weight after correction for moisture is reduced at the rate of 1 per cent for each 100 B.t.u. below the standard heating value. The gross dry weight is also corrected at the rate of 5 per cent for each 1 per cent. of volatile sulphur in excess of the standard. These corrections are then aggregated and deducted as a whole, payment being made only for the balance of the gross weight at the price bid per unit furnished, delivered and stored and trimmed (if so specified in the schedule).

These examples will show that purchases on a B.t.u. basis is the rule rather than the exception with large fuel users in the United States and that there are many different ways of carrying this out.

As proof of the interest taken in the subject of fuel sampling and testing in America, the publications of the Bureau of Mines at Washington may be referred to. The following list of bulletins is by no means complete, but it shows how well the subject has been covered.

1908. Bulletin 339.—The Purchase of Coal under Government and Commercial Specifications, on the Basis of its Heating Value.
Bulletin 362.—Mine Sampling, and Chemical Analysis of Coals Tested at the U. S. Fuel-Testing Plant, Norfolk, Va.

Is Duplexing Slated for Assassination?

BY JOSEPH I. PEYTON

Duplexing of late years has been the subject of much criticism, especially in regard to the quality of the product, by various engineers and users of rail steel.

It has only recently been brought to light that one of the main causes of duplex steel not comparing favorably with that of the straight open-hearth practice was due to the fact that in the converting department, where the molten metal is blown, the manganese originally in the blast furnace or mixer metal was nearly all eliminated, *i.e.*, most of the manganese went into the slag as manganese sulphide and manganese oxide, while some volatilized, passing out of the converter as a gaseous product. Then when the blown metal was transferred to the open-hearth furnace for further refining, there was naturally a shortage in manganese content, which is so necessary in the open-hearth furnace, to assist in reducing sulphur from the steel, and at the same time preventing the occurrence of overoxidation of the metal.

To obtain a good quality of steel, a good quality of slag is absolutely essential as well, and to obtain this a sufficient amount of manganese should be present. In duplexing, formerly, there was no addition to the manganese content of the blown metal, other than the amount contained in the direct mixer metal, which is charged into the open-hearth furnace for the purpose of raising the carbon content of the bath, until just before tapping or directly afterwards, thus the benefit of having a sufficient amount of manganese present throughout the operation was lost. The present practice, however, of adding manganese to the blown metal differs in different plants, largely due to conditions.

Some use a high-manganese mixer metal and add a small quantity to each ladle of blown metal before it is transferred to the open-hearth furnace. Another method is to use sufficient steel scrap containing enough manganese to give the bath the desired content. Others use an ore with a high manganese content as a part of the open-hearth furnace charge or in the working of the heat, and where conditions are not so favorable ferromanganese or spiegeleisen is charged, preferably after part of the molten charge has been made in the open-hearth furnace. Since the adoption of this practice duplex steel has rolled as well as the straight open-hearth steel, proving that duplex steel has the quality.

Another improvement in duplexing of vast importance, not so much in improving the quality of steel, but in saving time in working the heats, is the elimination of the Bessemer slag from the open-hearth furnace. Bessemer slag is most variable in volume, due entirely to conditions, and contains considerable quantities of silicon dioxide, which when entering the open-hearth furnace changes the constituency of the slag of the furnace, making it necessary for additional lime to flux the silicon dioxide of the Bessemer slag and on account of the fluctuating volume of highly silicious slag from the Bessemer, it renders it difficult for metallurgical calculation to take care of it in the initial charging of the furnace. However, the recent methods of straining blown metal through either a stoppered ladle or one of the cupola-tap type, leaving the slag in the ladle, has helped the situation to a marked degree, both as to the time and ease on the furnace linings.

No doubt many consumers of steel have had the impression that duplex steel on account of its being made much faster and with fewer units involved than in straight open-hearth practice was a moneymaker for the manufacturer, but as a matter of fact, it costs the manufacturer more to make duplex steel than it does to make straight open-hearth steel, except when the price of scrap is excessive. The metallic loss in the Bessemer converter department is very high as compared to the metallic loss in the straight open-hearth process, and the metallic loss in a duplex basic Bessemer is about double the metallic loss in the duplex acid Bessemer. It is this huge metallic loss in the Bessemer department that makes the cost greater to the manufacturer.

To duplex economically the units must be large and in close proximity, which means a minimum waste and a minimum labor cost. So many of the plants engaged in duplexing work under distressing conditions as to cost and metallic loss, which is due to the size of the units and their arrangement principally. The most efficient duplex mill in existence is located at Steelton, Pennsylvania, and it should produce results on duplexing well worth knowing.

Several prominent metallurgical men who know that duplex steel possesses quality, have said that if the discard in the ingot could be reduced to 5 per cent, duplexing would be absolutely necessary on account of the high price that scrap would then assume.

INGOT MOLD WITH HEAT-INSULATING VACUUM CHAMBER

It is a fact well known to all metallurgists that something to prevent the enormous waste in shearing to obtain sound steel, i.e., steel free from piping and segregation, would be most welcome to the steel industry. For that reason many men have come forth with suggestions, methods, processes and inventions for the producing of sound ingots. Most of them, however, are impractical and a few cost too much per ton of steel produced to ever be of any commercial value to the manufacturers of the cheaper grades of steel.

The few methods in use find a market only where high-grade, high-priced steels are manufactured, which steel can afford a considerable tariff for the betterment of the product. Three methods in use are the Harmet or pressure process, which is very expensive, and is only used on high-grade steels, such as high-grade marine shafting, etc., the a[illegible]-piping thermit method, which costs 35 cents per ton of steel produced, and the Hadfield method, with a refractory sand ring in the molds head, using charcoal to cover the ingot top just after the teeming of the molten metal into the ingot mold with a forced gas flame playing thereon, which method costs 25 cents per ton of steel produced for the sand ring and claims to cut the discard to as low as 8 per cent. Even this method is hardly to be considered in connection with the cheap steels, for aside from the cost, it must require considerable labor and time to equip the molds each time before the teeming of the molten metal into them.

For that reason there has been developed a new type of ingot mold, upon which patents have been issued, which is cheap, practical and economical. It is cheap from the standpoint that there is practically only one cost (the initial cost) and when considering the average life of an ingot mold, it cuts the cost to a matter of only a few cents per ton of steel produced. It is practical because these molds are as ever ready as the molds in common use to-day. It is economical from the standpoint of a sounder ingot, which should offset the cost thereof many times. It has within the mold itself the most efficient heat insulator known, that is, *a vacuum* chamber, as shown in the accompanying figure. It is known as "Peyton-Hitt vacuum chamber ingot mold."

Instrument Exhibit at San Francisco

The Bristol Company, Waterbury, Conn., have a large exhibit of their extensive lines of recording instruments for pressure, vacuum, liquid level, differential pressure, temperature, electricity, time, motion, speed humidity, etc. at the Panama-Pacific International Exposition, at San Francisco. This exhibit (Fig. 1) is located in the

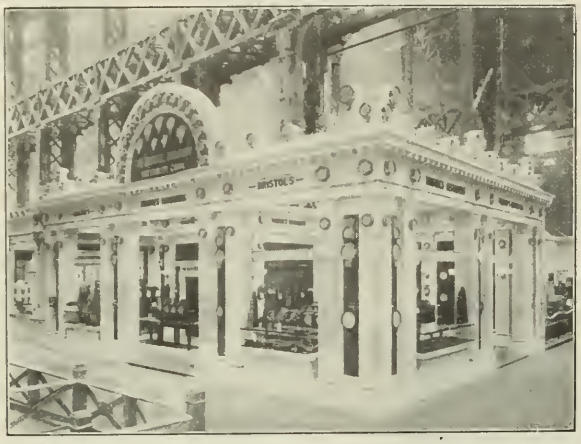

FIG. 1—INSTRUMENT EXHIBIT

Palace of Machinery in section 22. The decoration of the superstructure of the booth are actual models of Bristol recording instruments.

On the lower part of the outside columns of the booth actual working models of Bristol Instruments are exhibited in operation, producing records of atmospheric temperature, the level of the tide in the bay, over a distance of several hundred feet, electrically, also records of conditions on the electrical circuits of the Palace of Machinery, including volts and cycles, or frequency,

FIG. 2—INSTRUMENT EXHIBIT

record of the water pressure in the mains of the Palace of Machinery, and records of the operation of a series of signal switches provided for the visitor to manipulate at will.

Inside the booth, an interior view of which is shown in Fig. 2, more than 100 complete working models of the Bristol recording instruments are mounted on walls and tables, and of these instruments quite a number are arranged in the form of demonstration outfits which can be operated by hand by the visitor.

For instance, a hand-operated generator is provided for lighting a series of lamps and mounted with it is a Bristol recording voltmeter, an ammeter, and a wattmeter, recording simultaneously the voltage and the amperage as well as the wattage on these lamp circuits.

Another interesting demonstration outfit is a pair of the new Bristol long-distance electric thermometers by means of which the visitor is shown how the temperature of his own hand could be indicated automatically on an instrument 50 miles away from the point at which the temperature is measured.

The instruments in many demonstration outfits are shown with glass fronts, or without covers, making it possible for the visitor to see the simple internal construction, and to study the principles of operation.

Electric Steel in Germany and Austria

The following latest figures on the use of the electric furnace for steel refining and reduction and production in Germany and Austria during 1914 should be of considerable interest.

The total production of electric steel in **Germany** in 1914 was 89,336 tons. Of these 44,080 tons or 49.34 per cent were produced in furnaces of the three types controlled by Siemens & Halske, as follows: 34,393 tons or 38.50 per cent in induction furnaces, 7437 tons or 8.32 per cent in Girod furnaces, and 2250 tons or 2.52 per cent in radiation furnaces.

In 1914 there were twenty electric steel plants in operation in Germany, not including electric furnaces for melting ferromanganese. Of these twenty plants ten used furnaces controlled by Siemens & Halske, as follows: Six plants have only induction furnaces, two have induction furnaces and Girod furnaces, one is equipped with only Girod furnaces, and one with radiation furnaces only.

The other ten electric steel plants used furnaces not controlled by Siemens & Halske, as follows: Seven use Heroult furnaces, two Nathusins furnaces, and one Keller furnaces.

Plants which contemplate building new electric furnaces are not included in the above figures.

Of all the above-mentioned twenty electric-furnace plants eight use the electric furnace for making high-grade electric steel to supplant crucible steel. Of these plants four use only induction furnaces, two induction furnaces and Girod furnaces, and two Heroult furnaces.

The total amount of crucible steel and electric steel produced in Germany in 1914 was 184,432 tons, of which 95,096 tons or 51.6 per cent were crucible steel and 89,336 tons or 48.4 per cent electric steel. *Electric steel has therefore now reached practically the same commercial importance as crucible steel in Germany.*

Twelve plants using electric furnaces for melting *ferromanganese* were in operation in Germany in 1914. Six of these plants used Siemens & Halske furnaces namely, induction furnaces (four plants), Rombach furnaces (one plant), and Girod furnaces (one plant). In the other six plants Heroult furnaces are used in three plants, the Nathusins furnace in one plant and the Keller furnace in two plants.

The production of electric steel in **Austria-Hungary** in 1914 was 19,844 tons. Of this amount 9037 tons, or 45.54 per cent, were produced in induction furnaces. The production of electric steel made in Girod furnaces cannot be specified as these furnaces are also used in plants operated by the Government. The production of electric steel made in Siemens & Halske furnaces is, however, over 50 per cent of the total production.

The total amount of crucible steel and electric steel made in Austria-Hungary in 1914 was 37,401 tons, of which 19,844 tons or 53.1 per cent were electric steel and 17,557 tons or 46.9 per cent were crucible steel. That is, *Austria-Hungary now produces more electric steel than crucible steel.*

An Important Advance in Gas Producer Efficiency

The "Producer-Gas Machine," built by the Morgan Construction Company of Worcester, Mass., represents a radically new departure in gas producer design, and the results obtained thereby mean a very important

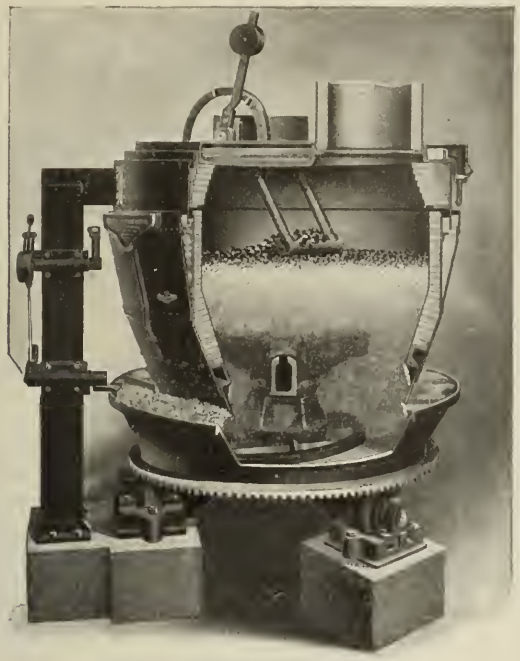

FIG. 1—GAS PRODUCER MACHINE

advance in efficiency of operation. Heretofore it has been an axiom of gas producer design that it is necessary to poke or otherwise break up the fuel bed. The Morgan producer-gas machine is based upon the opposite principle—namely, that the fire must not be disturbed, that it is far better to leave it alone, provided certain essential conditions are fulfilled. These conditions are that the coal be properly spread and the surface be properly leveled, that the ash be removed without producing an uneven fuel bed, that small quantities of coal be regularly and continuously fed to the producer, and that all these functions be performed by continuous mechanical means without hand labor.

The reason for the effectiveness of leaving the fire alone is that every disturbance of the body of the fuel causes variations of density which create local hot places and, in consequence, poor gas and clinkers. To have a uniform, even, quiet fuel bed, two conditions must be fulfilled. First, the top surface must be continually levelled; this is done, as shown in the illustrations, by the leveller which floats on the fuel, permits any practicable variation in height, and is quickly and easily replaced through the top. Second, the removal of the ash must be carried out in such a way as not to make the fuel bed uneven. For this reason, it is a mistake to rely upon sweeping the ash off the edge of the ash support. In the Morgan producer-gas machine the entire bottom of the ash pan is swept by a spiral-shaped bar or plow, the result being a uniform settling of the ash over the entire area. The plow is simply held stationary by the setting of a lever, while the machine makes one complete revolution, which requires fifteen minutes, and is usually sufficient to discharge the ash made in twelve hours. The release is automatic.

Regular continuous feeding of small quantities of coal requires the abolition of manual charging. The feeding device receives the coal from the bin and charges it in small and uniform quantities at frequent intervals *without manual action*. A result of the development of this feeder, acting together with the coal leveler and ash plow, is that one man can tend a battery of six machines gasifying four times as much coal as is possible for one man in any previous construction.

While practically all known types of mechanical gas producers, having a gas-making surface of 10 feet diameter, operate at an average rate of not over 1600 to 1700 lbs. of coal per hour while yielding gas averaging about 145 B.T.U. per cubic foot from Pittsburgh coal, the 10-foot Morgan producer-gas machine converts 3000 lbs. of the same coal per hour, into gas yielding 178 B.T.U. per cubic foot. This is an advantage of over 50 per cent in capacity, combined with 20 per cent advantage in quality.

Before giving further results from actual practice, a few words should be said concerning some minor, though important details of design. The even distribution of the blast over the entire gas-making area would

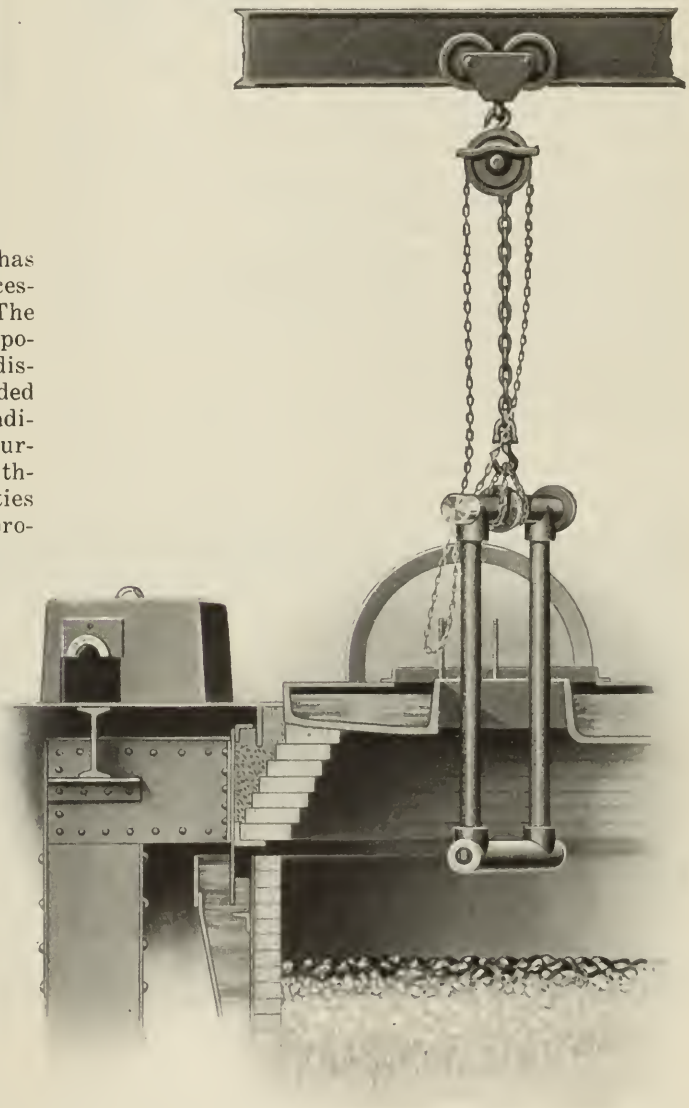

FIG. 2—REMOVING THE FUEL LEVELLER

(Under normal conditions the water-cooled bar lasts about one year unless the water is shut off for several hours. It can be changed in twenty minutes.)

be impossible with a central blast hood for a gas producer of such high capacity. In the Morgan machine the blast is delivered from three hollow radial arms and around the whole circumference of the hollow ring or mantel shown in the illustration. The result is a gentle sustained pressure evenly distributed over the whole surface.

The question of fire-brick lining has also been given unusual attention. To prevent the inner surface of the bricks from fusing with the ash from the coal so that large clinkers would attach themselves to the wall, the thickness of the fire-brick is reduced and it is surrounded with a water-jacket which keeps it cool enough on the inner surface to prevent any slagging action with the ash, but without appreciably reducing the temperature of the burning fuel adjacent to the wall.

As to the composition and the calorific value of the gas produced, the results obtained with one of the first Morgan producer-gas machines by a large steel company are interesting. Twelve-hour samples of the gas were taken day and night for several weeks. They show the great uniformity of the gas. For instance, the CO_2 content in the 11 analyses made during one week, had the values 3.0, 3.2, 2.8, 3.0, 2.5, 2.7, 2.7, 3.0, 2.5, 2.9, 3.0 (average 2.8). The CO content 26.3, 25.4, 28.7, 27.8, 29.2, 26.7, 26.9, 27.5, 27.2, 28.6, 26.7 (average 27.4).

The average values of the analyses for one week were as follows, the corresponding values for the following week being given for comparison in parentheses: CO_2, 2.8 (2.8); C_2H_4, 0.6 (0.6); CO, 27.4 (27.3); H_2, 11.4 (11.1); CH_4 3.6 (3.4); B.T.U. at 32 deg. F., 182.5 (179.0). During part of the time these analyses were made an accurate account of the quantity of coal gasified was kept. The average was 2766 lbs. coal per hour for 120 hours with gas of 178 B.T.U.

At another plant operating open-hearth furnaces eight-hour continuous samples of the gas were analyzed practically every day. The records, covering a period of five months, average 3.5 per cent CO_2, 28.8 CO, and 182 B.T.U. (at 32 deg. F.).

Recently the same plant desired to determine on what gasifying capacity they could safely count as a guide for their future requirements. After increasing the rate to 3260 lbs. coal per hour with every indication that it could be further increased, they decided that they could safely rely on a working capacity of 3000 lbs. per hour, without the quality of the gas suffering at the higher capacity.

The above figures are of significance if compared with best present practice, as a gas averaging 25 per cent CO and a calorific value of 160 B.T.U. per cu. ft. (total at 32 deg. F.) are considered the very best results at present attainable.

Further details of extensive service tests with illustrations of details of design and construction may be found in a new catalog which the Morgan Construction Company of Worcester, Mass., is publishing.

Drop Forged Parts as a Substitute for Brass Castings

The development of a new alloy, placed on the market under the name of "titan bronze," makes it possible to manufacture drop forged bronze parts in place of brass castings. The Titan Metal Company, 1124 Real Estate Trust Building, Philadelphia, control the process of manufacturing the metal, and have granted an exclusive license for the manufacture of finished castings and casting ingots to the Alpha Metals Company, Bellefonte, Pa.

Titan bronze has a high tensile strength, ranging from 75,000 to 85,000 lbs.; an elastic limit of 40,000 to 48,000 lbs.; reduction of area, 45 per cent to 50 per cent, and elongation 22 per cent to 30 per cent, making it possible to use it in many places where steels have been used and where bronze would have been preferable, with the added advantage of its non-corrosive qualities. This point is of particular interest to the chemical and metallurgical industries.

Titan bronze can be worked hot and is valuable for making drop forgings to supersede certain forms of castings and on account of the ease with which it is worked its introduction into practice is expected to have a great effect on hot press work from bars or sheets, hot rolled thread bolts, cap-screws, wood screws, gears, pinions, ship and bolt fittings, and a large number of uses where steel has been utilized with expensive machine operations to produce the finished article.

A valuable application of titan bronze is in form of bronze-covered iron and steel sheets suitable for a wide variety of uses to resist corrosion in various lines of manufacture.

The Preparation of Metal Specimens for Metallographic Tests

To the inexperienced, the tedium of preparing the specimens has often been a barrier to the acquirement of a working knowledge of metallography. Any scientific work may be made difficult and unattractive by the use of crude or cumbersome appliances. While polishing metallographic specimens is a delicate operation, it is not difficult if a few simple precautions are observed. The procedure must, of course, differ somewhat with the character of the metal.

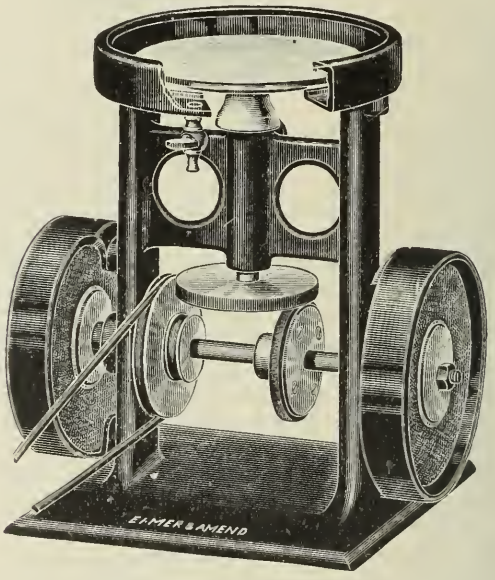

FIG. 1—GRINDING AND POLISHING MACHINE

Messrs. Eimer & Amend, 18th Street and Third Avenue, New York City, have recently placed on the market the Wysor combined grinding and polishing machine which facilitates greatly the preparation of the metal specimens. It is suitable for hard metals and alloys in general, but it is designed especially for the treatment of iron and steel.

It comprises two machines in one, though quite simple in construction. As shown in Fig. 1, a one-piece casting forms the base and frame upon which all the parts are mounted. The grinding wheels are of carborundum, and are carried on the horizontal or driving shaft, the roughing wheel being on one end and the medium and finishing wheels on the other end. The

polishing discs are of brass with cloth coverings, and are easily replaceable on the head of the vertical spindle. This is driven by contact with a friction wheel on the horizontal shaft. It is disengaged when not in use, or when discs are to be exchanged, by means of a cam attached to the frame. The speed at which the polishing discs are revolved may be varied by shifting the friction wheel on the shaft. The disc upon which the specimen is first polished after the grinding is covered with canvas, and the powder used is emery flour. The second disc is covered with broadcloth and tripoli powder is used. The third disc, on which the specimen is finished, is covered with broadcloth, jewelers' rouge being used with this. Separate cases are provided for holding the tripoli and rouge discs when not in use. This insures freedom from grit. Ample protection against flying particles from the wheels is afforded by the cast iron shields.

FIG. 2—BULBS IN TRAY

The polishing powders are mixed with water to the consistency of flowing paste, and may be kept in glass bottles from which they are conveniently poured into the glass bulb holders, which are used for applying them to the discs. When filling or shaking, the small opening of the bulb is closed by pressure of the finger, and when filled the large opening is closed with a tightly fitting rubber stopper. The three bulbs for the pastes and a fourth for clear water are held conveniently on a wooden tray as shown in Fig. 2.

Sprays for Cooling Water

The Spray Engineering Company, 93 Federal Street, Boston, Mass., has placed on the market a new spray nozzle, the design of which is shown in Fig. 1. It is provided with a removable turbine center which has large passageways. The center is held stationary in the nozzle so that there are no moving parts to wear out. The water, in passing through, is given a rapid rotating motion. A central driving jet, which impinges on the rotating water at the orifice, causes the water to be ejected as a fine, dense, uniform spray.

These nozzles are operated at a low pressure. The central driving jet, which is a particular feature of this design, fills in the center of the spray, thus giving it a solid (instead of hollow) conical formation.

One of the principal applications is for **spray cooling ponds,** and for this purpose the arrangement of the sprays is next in importance to the design of the nozzle. As seen in Fig. 2, which shows the spray cooling pond of the Erlanger Cotton Mills, of Lexington, N. C., the nozzles are arranged in groups and are so inclined toward opposing nozzles that when the sprays are operating they are made to collide with each other. By reason of this collision the drops of water are broken into much finer particles than could be effected by the action of the nozzles alone. For it is evident that the finer the spray the greater will be the cooling effect.

Natural ponds without sprays require about fifty times more area than the spray cooling system and in the summer seldom cool the water sufficiently. When water is scarce or insufficient for fire protection a spray pond offers a good source of supply. It is customary to connect the fire pumps direct with the pond.

The cooling of the water is effected in three ways: by evaporation, by radiation, and by convection. That is, heat is abstracted from the water equal to the latent heat of evaporation of the amount of water which evaporates; secondly, heat is radiated from the sprays to the cooler surroundings; and thirdly, heat is carried away by the surrounding air currents by convection.

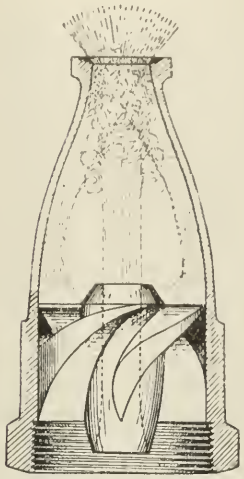

FIG. 1—SPRAY NOZZLE

Those spray cooling ponds are of great usefulness wherever water has to be cooled for condensers, transformers, or water jackets. With the introduction of steam turbines better vacuum and, therefore, colder condensing water have become a necessity. A 26-in. vacuum requires condensing water not over 103 deg. F., a 28-in. vacuum not over 80 deg. F. By the use of the spray system it is possible to obtain an average vacuum of 28 in. the year round in almost all parts of the United States.

A second application of the spray system is for **washing and cooling air,** for instance, for turbo-alternators. The design and construction of the spray turbo air washer are such that every particle of air passing through the machine is forced into intimate contact with fine particles of water from spray nozzles. To insure the complete removal of any dust particles which may have passed through the first set of sprays in the air washer the air is again subjected to the action of cross-scrubbing sprays placed beyond the first set of sprays. The air is next passed through a screen, which removes a large part of the entrained water and prevents any large stratum of air from passing through the washer without coming in contact with wet surfaces. All free moisture in the air is then removed by eliminator plates, the air leaving the washer clean and dry, but with a relative humidity of 100 per cent.

FIG. 2—SPRAY COOLING POND AT ERLANGER COTTON MILLS, LEXINGTON, N. C.

Personal

Mr. **H. G. S. Anderson**, formerly with the Buffalo Company, at Cobalt, and more recently in Mexico, stopped in Denver on his way to Nevada on professional business.

Mr. **Will H. Coghill** has removed to El Paso, where he will continue his work as consulting metallurgical engineer.

Mr. **J. C. Daley**, electrical and designing engineer for the Thordarson Electric Mfg. Company, Chicago, has severed his connections with that company and joined with Mr. J. A. Bennan and Mr. A. R. Johnson in the incorporation of the Jefferson Electric Mfg. Company. The new company is already located and doing business at 847-851 W. Harrison Street, Chicago, manufacturing a complete line of toy, bell ringing, sign lighting and welding transformers, battery switches, steel battery box outfits, make and break and jump spark igniton coils, and a line of high-tension transformers for testing, laboratory and research work.

Mr. **J. V. N. Dorr** spent part of the month of May at the Denver office of the Dorr Cyanide Machinery Co., having previously been farther West on professional business.

Mr. **A. E. Guy**, chief engineer of the pump department of the Providence Engineering Works, lectured in Denver recently on the History and Development of Centrifugal Pumps. Mr. Guy has been in charge of the pumping installation on the Penrose shaft in the downtown district of Leadville.

Mr. **H. W. Hardinge** has left New York for a six weeks' trip to the West and Alaska.

Mr. **James M. Hyde**, of San Francisco, has gone to New York on professional business.

Mr. **Bradley Stoughton**, secretary of the American Institute of Mining Engineers, is visiting western mining centers and has been the guest of honor at luncheons and dinners given by various sections of the Institute.

Mr. **Pope Yeatman** is in Chile inspecting the copper leaching plant at Chuquicamata, which is expected to be put in operation this month. He is expected to return to New York about the end of June.

The following changes in the technical staff of the International Smelting & Refining Co., at Tooele, Utah, were made effective May 1. **A. B. Young**, formerly in charge of the testing plant, is superintendent of blast furnaces. He is succeeded in the testing plant by **B. L. Sackett**, formerly chief chemist. **Carlos Bardwell** is the successor of Mr. Sackett.

Notes

The German Potash Syndicate has authorized the following deliveries of potash for domestic and foreign consumption during 1915 when the embargo is removed. This will enable consumers to know the amount available. Plans for denaturizing potash salts, so that the embargo can be raised, have not as yet materialized.

Kinds of potash	Metric tons of pure potash, K_2O Domestic	Foreign
Carnallite with at least 9 and less than 12 per cent K_2O	4,800	300
Raw salts with 12 to 15 per cent K_2O	266,600	82,200
Fertilizer salts with 20 to 22 per cent K_2O	2,000	33,400
Fertilizer salts with 30 to 32 per cent K_2O	3,600	11,500
Fertilizer salts with 40 to 42 per cent K_2O, including potash fertilizer with 38 per cent K_2O	229,200	68,700
Potassium chloride	54,500	138,300
Potassium sulphate with more than 42 per cent K_2O	1,200	37,600
Potassium-magnesium sulphate	200	14,700
Total	562,100	386,700

New Gas Works.—Under the title "Interesting Installations, Philadelphia," the Improved Equipment Company of New York City has issued a profusely illustrated little pamphlet describing the improvements made by the United Gas Improvement Company at its Point Breeze works in Philadelphia. They included the installation of five benches of mines. These are the Improved Equipment Company's No. 8 benches of mines—21′-0″ thrus—equipped with the Doherty bench fuel economizer and having sectional silica retorts and settings. The illustrations in the pamphlet show the construction in the course of progress.

An electric steel furnace installation of considerable interest is being made in Detroit, Mich., by the John A. Crowley Co. While the details are not as yet given out it will be a six-ton unit of the Grönwall type, which has been used successfully by Sheffield, England, mills for producing high-grade steels and difficult castings. This will be the first installation of this type of electric furnace in this country and it was expected to be put into operation during May. The furnace operates on a two-phase circuit, with two electrodes, each phase being connected to one of the electrodes, the circuit being completed through a neutral pole embedded under the lining of the hearth. This method carries the current through the bath and causes sufficient motion of the molten metal to effect uniform heating and complete distribution of any alloys that may be added, which together with the characteristic non-oxidizing atmosphere insures the production of sound castings of the exact compositions. The design of the Grönwall furnace was described in some detail in an article in our vol. IX, page 573 (November, 1911).

An antimony smelter is in course of erection in the city of San Luis Potosi, Mexico, according to Consul Wilbert L. Bonney. It will be ready for operation when mining and transportation conditions permit ore to be produced and the product shipped. The machinery, which is American, is now ready for installation. It is expected that the plant will employ 150 men and the capacity is to be 3000 tons per annum of refined star antimony. The product will be shipped to the United States. This will be the first and only smelter in Mexico producing refined antimony for the market. It is owned by American capital and will draw ores from its own properties in San Luis Potosi and Queretaro.

The only antimony smelter heretofore operating in Mexico is located at Wadley, a small station on the National Railway, 102 miles north of San Luis Potosi. The Wadley smelter is not equipped for finishing the product, and has exported its product to England for further refining. The Wadley plant was erected about 14 years ago, and has drawn a large part of its ore from the Catorce district.

Chilean nitrate statistics reported by Consul D. J. Myers show a marked decrease in production. In November, 1914, the output was 2,659,875 quintals (of 101.6 lb.) compared with 4,885,869 quintals in November, 1913. Fifty-four plants were working in November, 1914, compared with 127 in the same month of 1913. Government loans to nitrate companies up to November 30, 1914, amounted to 25,836,207 paper pesos (value from 15 to 20 cents per peso). Exports from July 1 to November 30 showed a decrease of 13,000,000 quintals under the corresponding period of 1913.

Tin exports from Bolivia in 1914 were seriously restricted by the war, particularly during the last three months of the year, when the decrease amounted to 36 per cent of the average monthly shipments. The rise in price has partly compensated the loss in tonnage. The shipments for the year are estimated at **34,624 metric tons.**

Tin output of the Federated Malay States in 1914 fell short of that for 1913, being only 109,854,533 lb., a decrease of 2,429,333 lb. The decrease in value was $2,048,620 U. S. gold. The offer of the local government to buy the total tin output at a price of $34.05 per picul (133 1-3 lb.), averted a crisis in the community, as the European war had effectually restricted the market.

Analysis of Brazilian monazite sand by F. H. Lee, of the Geological Service of the Brazilian Government, shows 29.28 per cent P_2O; 31.28 per cent Ce_2O_3; 30.88 per cent La_2O_3 and Di_2O_3; 1.40 per cent SiO_2; 6.49 per cent ThO_2; 0.20 per cent loss on ignition; total 99.53 per cent. The average thorium oxide content of the marketed product ranges from 6.2 to 6.4 per cent. The following table shows the exports of monazite sand from Brazil from 1905 to 1913.

Years and countries	Metric tons	Value
1905	....	$485,184
1906	....	480,843
1908	....	157,475
1909	....	708,092
1910	5437	631,251
To United States	1100	130,650
To Germany	2636	303,953
To France	1691	195,466
1911	3686	539,299
To United States	700	101,352
To Germany	1890	280,996
To France	1096	156,961
1912	3397	527,268
To United States	600	93,197
To Germany	1852	291,467
To France	945	142,604
1913	1437	186,478
To United States	400	51,905
To Germany	256	33,181
To France	778	101,003

The Anaconda Copper Mining Co. expects to have its new copper refinery at Great Falls ready for operation by January, 1916. The capacity will be 10,000,000 pounds of copper per month. The work of construction will be in charge of J. H. Klepinger, superintendent, and Peter Thill, master mechanic. The company recently announced that it would ship copper from Montana via Tacoma, Wash., and the Panama Canal to New York. The routing shows economy over present all-rail shipment to the Atlantic seaboard, and the experiment will be tried to see what the actual result will be.

According to the annual report of the **Portland Gold Mining Co.**, Colorado, for 1914, the net earnings were $590,595. The mine produced 62,997 tons of ore which was shipped to the high-grade mill at Colorado City. The average grade was $23.42 per ton. The low-grade mill at Victor treated 210,132 tons of ore, of which 18,934 tons came from the mine and 191,198 tons from the dump. Dividends paid during the year amounted to $360,000. No statement is made regarding milling costs or recoveries.

The iron industry of Brazil is comprised in one furnace with a capacity of about 15 tons per day, situated at Esperanca. The plant has been operated for about 10 years, and has recently been rebuilt and enlarged.

Branch laboratories of the Bureau of Standards are maintained at Northampton, Pa., and Pittsburgh. The former is devoted to the sampling, testing and certification of cement, and the latter to investigations and tests of structural engineering and miscellaneous materials.

The prospectors' short course offered this spring by the Mackay School of Mines, Reno, Nev., and the Colorado School of Mines, Golden, Colo., was very successful. The attendance at Nevada was 25 and at Colorado 49. The courses evidently meet a need among men engaged in prospecting but who are without much technical education.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath, Anodes

82,877, October 6, 1868, William H. Remington, of Boston, Massachusetts, assignor to himself, Sarah A. T. Peabody and George D. Allen.

Relates to anodes for electroplating, and describes suspending nickel particles in a platinum basket or woven-wire receptacle; also lining a vat with carbon, connected to the anode, and covering the carbon bottom with nickel particles; also inserting a carbon shelf, or shelf of other suitable conductor not acted on by the solution through a side of the vat and placing the nickel particles on the shelf; also electroplating carbon or other conductor with nickel, and using the composite conductor as an anode. The electrolyte preferred is made as follows: Nitric acid, to which is added about one-twentieth part water, is saturated with nickel, the latter is then precipitated by the addition of carbonate of potash. The precipitate is then washed with pure water and then dissolved in a strong solution of sal-ammoniac, and filtered. It is then ready for use.

129,881, July 30, 1872, George W. Beardslee, of Brooklyn, New York.

Relates to an electrode for electrodepositing metals, and consists of a plate of carbon, platinum, or other conductor that is insoluble in the electrolyte, inclosed in a cover of mosquito-netting or similar very loosely-woven fabric, the fabric holding a layer of granular or fractured metal to be electrolytically dissolved and deposited upon the article to be plated, against each side of the carbon electrode, the whole being supported in a frame of wood or other like material.

155,884, October 13, 1874, Pierre Adolphe Normandeau, of Brooklyn, E. D., New York.

Relates to receptacles for holding granules or fragments of metal to serve as anode, the receptacle being rigid in form and consisting of a flat casing with perforated walls and an open upper end, and preferably made of gutta-percha, or similar material. It is suspended by hooks of insulating material. A conductor of platinum or silver is secured to the inside of the receptacle and contacts with the metal to be dissolved.

166,367, August 3, 1875, August Hermann and Warren H. Taylor, of Stamford, Connecticut.

Relates to anodes for electroplating, and consists preferably of a carbon plate having imbedded in its surface, while the carbon mass is still plastic, a number of nickel granules, or fragments of nickel anodes. If a platinum plate is used the granules are secured to the platinum by shellac, glue, or other suitable adhesive substance. See the reissue of this patent, No. 7,489, dated February 6, 1877.

166,433, August 3, 1875, Edward Weston, of New York, N. Y., assignor to Stevens, Roberts and Havell, of Newark, New Jersey.

Relates to an anode in which particles of metal or an oxid, carbonate, or other compound thereof, or metallic dust, is mixed with a cement such as powdered carbon and molasses, or some other substance capable of forming a coherent paste. The mass thus obtained is placed in molds and subjected to pressure, dried, and then baked out of contact with air until the mass is thoroughly carbonized, and a solid, compact, coherent mass is obtained. When nearly exhausted of metal by use, the residue may be ground up and mixed with a fresh mass for a new anode.

Reissue 7,489, February 6, 1877 (original 166,367), August Hermann and Warren H. Taylor, of Stamford, Connecticut, assignors, by mesne assignments, to the Yale Lock Manufacturing Company, of same place.

Relates to anodes for electroplating, and consists preferably of a carbon plate having imbedded in its surface, while the carbon mass is still plastic, a number of nickel granules or fragments of nickel anodes. If a platinum plate is used the granules are secured to the platinum by shellac, glue, or other suitable adhesive substance.

208,003, September 10, 1878, Adolph C. Wenzel, of Brooklyn, New York.

Relates to a receptacle for holding grain nickel or other metal for use as an anode in electroplating. The receptacle consists of two carbon or graphite plates, perforated with many fine holes, and separated by a U-shaped carbon or graphite separator, the plates and separator being united by hard-rubber bolts. The receptacle is supported by a clamp carrying a hook by which it is suspended from a conductor above the plating tank. The grain nickel is placed in the receptacle, and makes contact through the carbon sides thereof.

223,265, January 6, 1880, Joseph Wharton, of Philadelphia, Pennsylvania.

Relates to nickel anodes for electroplating and consists of a wrought, rolled, or hammered cast plate of nickel, the physical condition of the malleable metal effecting a greater economy in use than that obtained with the granulated metal.

226,576, April 13, 1880, Abraham Van Winkle, of Newark, New Jersey.

Relates to anodes for electroplating and consists in a frame surrounding the side and bottom edges of a rolled or plate anode, for the purpose of preventing pieces that may be dissolved loose from falling to the bottom of the tank.

Book Reviews

Industrial Chemistry. By **Rogers** and **Aubert.** Second Edition. Edited by Allen Rogers in collaboration with many specialists. 1005 pages, 305 illustrations. Price $5.00 net. New York: D. Van Nostrand Company.

The publication of this second thoroughly revised and enlarged edition is timely. No such opportunity as that presented to-day has come before the chemists of this country for a fuller development of our natural resources. The work deals with American practice, and from the fact that the present edition has the imprint "fifth thousand" we learn that it has been appreciated.

The range of subjects is wide. The topics are treated of by men having experience in more fields than those they write of, and so a broader view of each subject is given. Ten new chapters have been added, recognizing the newest features in chemical progress. One cannot but be impressed with the constructive work now being done by the professional chemists in comparison with the older type of analysts. As the work widens better conditions will obtain and young men will be attracted to chemistry as a life work. This volume will undoubtedly be the means, in many instances, of creating interest among students and manufacturers in chemical problems. Heretofore their interest has been largely in mechanical devices and methods. Abundant references to special treatises are given at the end of each chapter. Particular pains have been taken to make the principles involved in each manufacture clear. Often several different methods of carrying out a chemical reaction are given. There are diagrams illustrating the flow of material from the raw state to the various finished products, and schematic plans of apparatus give clear conceptions of what the several processes are intended to accomplish. There are also abundant illustrations of plants and of apparatus.

The practical part of the book is excellent and most creditable to the publishers.

* * *

The Cyanide Handbook. By **J. F. Clennell.** Second edition, octavo, 602 pages, illustrated; price $5.00. New York: McGraw-Hill Book Company.

This is a *vade mecum* for assayers, chemists, foremen and managers of cyanide plants, giving all the details of chemical and physical principles and practice utilized in the operation of such plants. It is an eminently practical book, written in the true scientific spirit by a scientifically practical man.

* * *

How to Build Up Furnace Efficiency. A handbook of fuel economy. By **Jos. W. Hays.** 126 pages, illustrated. Seventh edition. Price $1. Chicago: Jos. W. Hays.

This a popularly written little treatise discussing in five chapters why fuel is wasted, how it is wasted, how to "spot" fuel waste, how to stop it, and how to keep the waste stopped.

The book is intentionally written in a popular style and anecdotes are liberally used for purposes of illustration, for the author's thesis is that the men to stop the fuel waste are the men who are doing the wasting —the practical firemen. Their interest must be aroused and kept. The author emphasizes that just as all practical men know how to use thermometers and scales, so they can be shown how to use draft gages and gas analyzers, even if they don't understand the theory.

The book is well written for the purpose for which it is intended and should do much good.

* * *

Analysis of Alloy Steels. Methods of the Chemists' Committee of the United States Steel Corporation. 70 pages. Price $1. Copyrighted by **J. M. Camp,** Carnegie Steel Company, Pittsburgh, Pa.

This pamphlet prepared under the direction of the Chemists' Committee of the United States Steel Corporation (J. M. Camp, chairman) on the Sampling and Analysis of Alloy Steels, is now being distributed to its various chemical laboratories. This makes the fifth pamphlet so distributed, whose purpose is to unify and simplify methods of analysis. The other four pamphlets, with their date of issue, cover the Sampling and Analysis of Cases, 1911: Pig Iron, 1912: Ores, 1914 (second edition) and Plain Steel, 1914. To curtail the numerous requests for these pamphlets a charge is now made of $1 each to persons and firms outside the corporation.

The pamphlet covers both sampling and analysis of alloy steels. Methods for the determination of carbon, manganese, phosphorus, sulphur, silicon, tungsten, cromium, vanadium, nickel, cobalt, copper, molybdenum, aluminium and titanium are given.

* * *

Joplin News Herald's 1915 Zinc and Lead Handbook. By **L. L. Wittich.** 60 pages. Price 25 cents. Joplin, Mo.: Joplin News Herald.

This is the first edition of a little statistical handbook which is intended to be published annually. To those interested in zinc and lead statistics it should prove interesting and useful. Besides data on zinc and lead production in the world and in the United States, on imports and exports, on consumption, on weekly prices of zinc and lead ores during 1914, etc., it contains very full information on the activity of the Missouri-Kansas-Oklahoma district.

Patent Suit Procedure

This issue contains an unusual amount of news on important patent suits: a sketch of the present status of the flotation suit, an account of the District Court decision in the bakelite suit, and an account of the Court of Appeals decision in the nickel-chromium resistor suit. The flotation suit is probably the most momentous patent suit now awaiting decision, as flotation will ultimately become one of the greatest agents in the conservation of our mineral resources—but not until the patent situation is settled. To accelerate the slow pace of patent law procedure is one of the greatest industrial problems of the day.

In this respect the bakelite suit is of interest, as it was one of the very first suits tried under the new open-court system. The final argument was made on Feb. 20 and 21, 1914. The decision was rendered on June 12, 1915. While the interval seems long, it is safe to assume that under the old rules the trial would still be going on for years to come.

Nevertheless our methods of court procedure could be made considerably less complicated. Reforms could be introduced whereby the presiding judge would not be compelled to study in every case every detail of highly specialized scientific or technical testimony, which requires not only intelligence, but long technical training. Matters would be still further simplified if the question of validity or non-validity of a patent could be referred to a technical court, where simple, relatively inexpensive, and direct proceedings could be instituted, similar to the nullification proceedings in Germany. The decision of such a technical court would be a direct guide for the judge so as to decide on the question of infringement. Some reform along such lines would be eminently desirable.

Steel Shape and Rod Production

Statistics of production of shapes, rods and nails in the United States in 1914 have just been presented by the Bureau of Statistics of the American Iron and Steel Association.

Measured by the basic material, pig iron, 1914 was a decidedly poor year, for the pig iron production, 23,332,-244 gross tons, was almost 25 per cent less than the record output made in the preceding year. The production of structural shapes suffered slightly more than the average, as the 1914 production, 2,031,124 gross tons, showed a decrease of 32 per cent from 1913. That was quite natural, for as the total demand for iron and steel rises and falls from year to year, the fluctuations are made more largely by the materials which enter into more or less permanent structures, or are involved in

the investment of capital, while the articles of everyday consumption show much smaller fluctuations. The production of structural shapes has shown more conspicuous illustrations of this fact than the illustration afforded by the 1914 statistics, for in 1908 the production of shapes was less than half the production in 1906, whereas the production of pig iron suffered a decrease of only a trifle more than one-third.

For an article representing common everyday consumption, no better commodity could be selected than wire rods, and it is a happy chance that brought the rod statistics for 1914 to light at the same time as the shape statistics. We find that the production of rods in 1914, 2,431,714 gross tons, was only 33,000 tons less than the production in 1913, and we also find, interestingly enough, that 1913 was not the banner year for rods, 1912 retaining that honor with 2,653,553 tons. There have indeed, been nothing like violent fluctuations in the production of rods since the early days of the industry, when the production was increasing rapidly because the wire nail was supplanting the cut nail. The production of nails, cut and wire, has been quite steady; of the past 11 years the best was 1912, with 15,638,115 kegs, and the poorest year 1908, with 11,619,154 kegs. No other important steel commodity has shown such slight variation.

A rather interesting statistical event occurred in 1914, the production of rods for the first time exceeding the production of rails. This was an event long predicted. In fact, it was predicted altogether too soon, at a time when the production of rods was experiencing a temporarily rapid growth on account of the supplanting of the wire nail by the cut nail, already referred to. There is not the least reason to suppose that rods have permanently passed rails in tonnage. The passing in 1914 was due simply to the fact that in an "off" year rail production suffered severely while rod production suffered scarcely at all. In 1914 the rod production was 2,431,714 tons and the rail production 1,945,095 tons, but in 1906, eight years earlier, the rail production was 3,977,887 tons, and it will probably be easier, in future years, for the rail tonnage to regain that height than for the rod production to attain it. Given still more time, however, the rod tonnage may permanently pass the rail tonnage.

Effect of Zinc Prices on Cyanidation

With spelter at 25 cents per pound, zinc sheets at 30, and zinc dust at 28 to 32, a decided dislocation has resulted in the cost of precipitating cyanide solutions. The sudden prosperity of the producer of zinc is reacting unfavorably on the producer of gold and silver by the cyanide process, raising the cost of precipitation to a point where substitute methods are being considered. In spite of technical improvements in precipitating practice, the irreducible minimum cost has assumed abnormal proportions. Six months ago spelter was quoted at 5.5 to 6 cents per pound, zinc sheets at 8.5 to 9, and zinc dust at 10. Current prices are three to five times as great.

In the reports of those companies that give annually a detailed cost of milling operations, we find the following data on precipitation: At Goldfield Consolidated, using zinc dust, the cost of precipitation in 1914 was 6.2 cents per ton of ore milled, out of a total milling cost of $1.606. At the Hollinger, where zinc dust also is used, the precipitation cost of 6.3 cents per ton of ore milled, out of a total cost of $1.237. For similar precipitation at the Commonwealth, in Arizona, the cost was 11.6 cents, out of a total of $1.879. These precipitation costs range from 3.86 per cent to 6.17 per cent of the total cost of milling, ranking with the costs of crushing and conveying, settling, filtering and concentration, where the last is practised. Excepting stamping, tube-milling, and agitation, which show the highest itemized costs, precipitation is quite as important an item as any other in the total cost of cyaniding.

It is not surprising, therefore, that managers are giving careful thought to the present conditions. Precipitation by aluminium dust for Western cyanide mills has long since been investigated by some companies, but as far as we are aware none has adopted it. Other changes have been contemplated in general methods of operation. In one instance, where cyanidation had superseded amalgamation and concentration, the advisability of temporarily reverting the former practice was investigated, but found unprofitable even at the present high cost of zinc for precipitation. While this is a strong endorsement for cyanidation, the company's action shows the influence of current conditions.

One of the most striking effects of the high price of zinc is a renewed interest in electrolytic precipitation of cyanide solutions. Experiments of this sort are under way at one mill, and the early results appear encouraging. The work is in competent hands and the outcome will be awaited with interest. Regardless of the ultimate effects of the present zinc market on cyanide metallurgy, all the investigations under way indicate a healthy condition in the management of our metallurgical concerns.

The Field for Engineers

With the recurrence of the annual graduating season, new accessions have been made to the ranks of the engineering professions, and one hears again the old familiar question, "What becomes of all the engineers?" The same query may well be put regarding lawyers, physicians and others who have pursued a course of special training. The inference is that all of these specialists cannot find lucrative employment in their chosen lines; that the professions are overcrowded and opportunity for success is consequently limited.

It is a fact that there is a growing tendency for engineering graduates to assume vocations apparently unrelated to the particular branch of engineering in which they were graduated. This, however, is not an argument against the pursuit of an engineering education, for the fundamental qualities of such training are adaptable to success in a wide variety of commercial operations. The engineering graduate, of whatever brand, should be well fitted to observe keenly, analyze with precision, draw correct conclusions, discriminate

between essentials and non-essentials, and attain his ends by the most direct and economic route. Such qualities as these are appropriate in the administration of any branch of business, and should enable their possessor to rise rapidly and prove himself invaluable. It makes little difference what particular label is placed on the engineering graduate. If he is well grounded in the fundamental qualities of an engineer, he is fitted to become a most useful member of society.

There is ample evidence that the ramifications of engineering are extending into many branches of business. National, state and municipal affairs require engineering direction. Imagine the beneficent results flowing from a legislature composed of fewer lawyers and more engineers; not that lawyers are unnecessary, but that they deal unintelligently with matters foreign to their knowledge. Salesmanship of the highest type is open to engineers in fields where the "drummer" is inefficient. The field of insurance also is open, with the adoption of workmen's compensation laws in the mining states. Recently we were asked to recommend to an insurance compay an engineer capable of inspecting mining and milling properties for purposes of setting the premium rates for liability insurance. Such an engineer might never mine or mill a pound of ore, but he could develop a field for special talents. The uses of an engineering training are not confined to actual field work. Society has many benefits to gain from a wider spread of such training among young men.

Steel Corporation Allowed to Live

Practically everybody but the plaintiff appears to have been pleased by the decision handed down June 3 in the United States Steel Corporation dissolution suit in the United States District Court of New Jersey. As a matter of fact, it would not be necessary to await expressions of opinion after the decision, for the witnesses the corporation brought to the hearings represented the majority of its competitors and customers, and there was favorable testimony also as to the corporation's treatment of its employees. Naturally the interests thus arrayed on the corporation's side are pleased with the verdict.

Comment that has been passed upon the case since the decision was rendered has run so largely to the expression of gratification upon the result that some interesting long-range observations have not been emphasized as they should be, if we as thinking individuals are to profit by the experience. How strange it would seem to the conventional inhabitant of Mars if he were given but the skeleton, that the Sherman law was passed in 1890, that combinations in restraint of trade were formed in 1898, 1899 and 1900, that these combinations were themselves united in 1901, that they entered into illegal arrangements with outside interests at various times as late as 1908, that in 1911 the government brought suit under the Sherman law and that in 1915 the corporation was given a clean bill of health as a result of that prosecution! The Martian would probably at once inquire why the suit was not brought earlier, when a conviction, apparently, could easily have been secured, and if nobody desired a convinction at that time, why the law had ever been enacted.

Reply might be made that the Knight Sugar Trust decision of 1904 had apparently interpreted the law so that it could not be made to apply to the Steel Corporation or the prior consolidations, while subsequent decisions suggested that possibly the Steel Corporation might be found guilty, thus encouraging the Government eventually to bring the suit. At the time of the Knight decision, however, the Sherman law was already fourteen years old, and it was only seven years older when the steel suit was brought.

One can scarcely avoid the conclusion that public thought has had much to do with molding the course of events. The Sherman law was not taken very seriously in its early years. It put some inconvenient restraints of secrecy upon those who entered into trade restraint combinations, but enough was known to have formed the basis for many prosecutions if the people had been ready for them. Later there was a great awakening on the part of the people as to their commercial rights, but at first their desires were inadequately expressed for they had not the knowledge and experience. The revolution in public thought was one thing and the clamor of the "muckrakers," as we now know, was another. While condemning the muckrakers, the leaders in industry and finance recognized the rightness of the revolution in public thought, and reforms were instituted. Judge Gary, himself, the chairman of the Steel Corporation, has frequently and strongly expressed the view that business needed to be reformed and that it had reformed. The decision in the steel suit, including both the opinion rendered by Judge Buffington and the separate opinion by Judge Woolley, reaching the same conclusion but by a separate process of reasoning, condemns much in the Steel Corporation that has passed into history, while entirely vindicating the corporation as it stands to-day, or as it stood on the day upon which the suit was brought.

Thus we have a gradual changing and molding of public opinion whereby the rights of the public are declared, and a changing in the conduct of business whereby those rights are recognized.

What is particularly gratifying is that sufficient time chanced to be allowed for "big business" to be judged by its performance and not by academic theory. It was an economical necessity that "big business" should come. Given time it would show its right to exist by benefiting the public. Fortunately that time was furnished. Instead of regarding the corporation as a menace because it was big, the court observes in substance that the bigness was desirable for economic reasons, and gives the readily comprehended dictum that it is not the size of the corporation, but the importance of the power that was not acquired, that should govern the decision in the case. The extent of the power that was not acquired was shown clearly by the testimony, that nine important competitors of the corporation had grown in capacity at much greater percentage rates than had the corporation, and that the corporation's proportion of the country's total output had steadily diminished.

Readers' Views and Comments

The Neutrality of Science

To the Editor of Metallurgical & Chemical Engineering

SIR:—Many, many lamentable things have happened in the "World War" which is desolating Europe, but one of the most unexpected, to scientific men, has been the regrettable action taken by the British Iron and Steel Institute, in London, on May 14th last. At the meeting on that date the Council of the Institute put the following resolution before the members present, which was "carried unanimously":

"That the names of all alien enemies be struck off the list of members of the institute, and that steps be taken to amend the by-laws so that they provide for the future that, in the event of war existing between this and other countries, citizens or subjects of which are honorary members or members of this Institute, such honorary members or members shall *ipso facto* cease their membership."

Being a born Englishman, the undersigned may not lightly be charged with anti-British sympathies; being also a member of the Iron and Steel Institute, he may be granted the right to express publicly his disapproval of the above action. But speaking from the broader standpoint of a believer in the international character of science and the salutary saneness of the scientific spirit, he wishes to voice his deep regret that such a dignified Institute, such an honored and honorable society, should stain its annals by an act of such lamentable folly.

In this pandemonium of strife, collapsing of the safeguards of civilization, reversion towards primitive barbarism, where shall the seeds of future peace and harmony be found if the fraternity of scientific brotherhood and mutuality is also swept into the abyss? There must and there will come an "after the war," when reconstruction of the desolated earth will be the common task. Then conquerors and conquered must and will work towards a common end, and then will come the need of mutual co-operation and re-established goodwill. And where could a better starting point be found than in the fraternal bonds of international scientific co-operation?

Alas, our ideals are being shattered and our hopes falter when we contemplate the short-sighted action of the venerable Iron and Steel Institute. All honor to Professor Turner, who raised a protesting voice in the discussion, telling them that they would live to sorely regret their hasty action.

The writer believes that he voices the sentiments of the majority of members of the Iron and Steel Institute in America, in deploring this ill-advised, short-sighted, and altogether regrettable action. He believes, further, that this would be the nearly unanimous view of American scientists in general. The escutcheon has been blotched. Members of the Iron and Steel Institute in Great Britain repent your haste, rescind the action, and wipe out the blot.

Lehigh University.

JOSEPH W. RICHARDS.

Flotation Results

To the Editor of Metallurgical & Chemical Engineering

SIR:—May I call your attention to an error in the editorial on "flotation as a conservation measure" in your June issue?

You say that the recovery from sulphide ore in the Inspiration Company's experimental mill last February was 90.3 per cent, or from 20 per cent to 25 per cent greater than at five other porphyry copper mines. This is evidently a misunderstanding of a statement in Mr. Mills' yearly report, which was to the effect that 90.3 per cent of the copper occurring in sulphide form was being recovered. It is known, of course, that all these porphyry ores are partly oxidized and that to get a fair comparison between the work done at different reduction plants it is necessary to discriminate between recovery made on the sulphide copper contents and on the oxide copper contents, as Mr. Mills has done in the report in question.

I think it will be found that the other porphyry copper mines also make a fairly good sulphide recovery, although there is no doubt that the flotation process will assist materially in raising it. But improvements of from 20 to 25 per cent with which you credit us are out of the question, as long as the oxide recovery is not raised materially. The prospects are bright that this will be done in the near future.

Inspiration Consolidated Copper Co.,
Miami, Arizona.

RUDOLF GAHL.

An Interesting Application of Colloidal Chemistry

To the Editor of Metallurgical & Chemical Engineering

SIR:—It is fairly evident from the progress already made that colloidal chemistry will within a short time place many industries under heavy obligations to this rapidly advancing branch of science. Some suggestion as to this is contained in the chapters on the applications of colloidal chemistry in tanning, dyeing, soil improvement, sewage purification and biology in a volume on this subject by W. W. Taylor of the University of Edinburgh ("Chemistry of Colloids and Some Technical Applications"; Longmans, Green & Co., New York, 1915). A striking example of the aid this department of chemistry may afford in explaining hitherto unaccounted for industrial results, and in providing a line along which rational improvement may be sought, is found in the investigations of Clifford Richardson in connection with the collodial nature of Trinidad asphalt and the results of these investigations as applied to the asphalt paving industry.

Mr. Richardson's work in this connection is also a good example of the value of the chemist's services. A lecture on colloids delivered by Wolfgang Ostwald, the great authority on this subject, at the laboratory of the College of the City of New York, early in 1914, supplied the first suggestion that colloidal chemistry could aid the asphalt industry, although Dr. Ostwald made no special reference to bitumens in his review of the past ten years' study of colloids. In a memorandum dictated the day after the lecture, however, Mr. Richardson said: "It is evident that a portion of the clay in Trinidad asphalt is in this condition, and this throws a great light on the character of this substance and explains why it differs in some respects from all other bitumens with which we are acquainted. It has very probably acted as a catalyzer in producing a peculiar form of bitumen, and by its presence in the bitumen, as used, confers upon it properties which are unique. The field this affords for investigation is interesting and worthy of study."

Since the date of this memorandum Mr. Richardson has spent a year of study and laboratory investigation with results that should mean more to the asphalt paving industry than any discovery that has been made

in many years. The conclusions from this study clear up many conceptions that have heretofore been held merely as theories, or which have been applied in a rather haphazard manner; they point the way toward rational rather than empirical methods in the preparation of paving formulas.

Every since Mr. Richardson's standard work, "The Modern Asphalt Pavement," appeared in 1905, the fact has been generally realized that the perfection of a sheet asphalt paving mixture will depend very largely on the surface area of the particles composing the mineral aggregate of sand or filler entering into the mixture. In the minds of most of those—even the experts—who are engaged in the industry, the grading and the fineness of the mineral aggregate is supposed to have little importance outside of the extent to which a fine grading will "carry" the bitumen. Any paving man knows that a fine aggregate will carry more bitumen than a coarse aggregate, but that is about as far as he has gone.

Mr. Richardson's investigations have now shown that the extent of surface area presented in any mineral aggregate, especially if it embodies colloidal material, has a great importance in addition to the carrying of the bitumen.

A pound of coarse sand such as might be used in a paving mixture is found to contain 129,030,065 particles with 44,378 square feet of surface. A finer sand of the type used in some of the most successful pavements laid in New York in the 90's contains 232,075,324 particles to the pound, these particles having 60,503 square feet of surface. Going a step further in these investigations it is found that the number of square feet of surface in a pound of dust or filler used in a paving mixture is 527,821. Dust or filler of the latter characteristics, that is, of from 0.08 to 0.0025 mm., is estimated to run 192,715,000,000 particles to the pound, and has been considered the ultimate of fineness in paving mixtures.

These figures are given for the purpose of permitting a comparison between ordinary conceptions as to how fine the aggregate of a paving mixture may be and the degrees of fineness we encounter in the field of colloids. For the purpose of comparison with the above it is pointed out by Mr. Richardson that if the amount of material represented by a cube having a dimension of 1 cm. is reduced to the coarsest colloidal size (ten-thousandths of a millimeter in diameter) the surface area of the material in the 1 cm. cube would be increased 100,000 times.

It had already been demonstrated that a large surface area was a necessary feature of the mineral aggregate of an ideal paving mixture; hence the addition of the finest dust that could be obtained. Service tests had shown that pavements such as those laid on Fifth Avenue, New York, the Victoria Embankment in London, and Vermont Avenue, Washington, D. C.—the latter being in use for 35 years—containing the largest amount of the finest obtainable material, are the most durable. The reasons for this, however, were not entirely clear, except in the particular already pointed out; namely, that the finer the aggregate the more bitumen it would carry without excess.

All of these pavements were constructed with asphalt containing colloidal clay, and it is now appreciated as a result of Mr. Richardson's studies, why the results in the cases cited were obtained. The power of selective adsorption possessed by colloids is shown to be of prime importance in the sheet asphalt paving industry, because the surface of the mineral aggregate adsorbs selectively and holds with great power the bitumen which is used as the binding material or cement. In Trinidad asphalt there is a considerable amount of mineral matter present in a dispersed solid colloid form which shows great capacity for adsorption, selecting the denser portions of the bitumen and forming a combination which gives great body and density to this binding material.

The bitumen under these conditions has a further influence, in that it serves as a protective film to the highly dispersed particles. Various bitumens differ in the degree in which they exercise protective properties, this difference being apparently in proportion to their viscosity or density; and there is a close relation between this property and the success achieved with them in the making of a sheet asphalt paving mixture. The more viscous the bitumen and the larger the amount of colloid material it contains, the thicker will be the film which adheres to or is adsorbed by the mineral aggregate, and, consequently, the greater cementing power of the bitumen which forms the thicker film.*

Barber Asphalt Paving Co.,
Philadelphia, Pa.

DANIEL T. PIERCE.

Flotation Suit

On May 27, 1915, the hearings in the case of Minerals Separation, Ltd., vs. Miami Copper Company were concluded after a nine weeks' contest in the United States Court for the District of Delaware at Wilmington, presided over by the Hon. Judge Bradford. In view of the enormous industrial importance of this case, the following summary of the present status should be of very considerable interest:

When suit was first brought by Minerals Separation, the Miami Copper Company was merely technically liable to an infringement suit, owing to its use in an experimental plant, of a 60-ton Minerals Separation type of flotation machine. This first proceeding, in form of two separate suits, was based upon two of Minerals Separation patents—patent 835,120, for the use of "less than one per cent of oil," and patent 962,678, covering the use of soluble frothing agents.

About the first of August, 1914, the Miami company commenced experimenting upon a 300-ton plant with what is generally known as the Callow type of cell—a flotation device in which air bubbles are *not* introduced by agitation, as was done by mechanical beaters in the Minerals Separation machine, upon the use of which the original suit was brought.

The first suits were then withdrawn and a new suit in equity was instituted, alleging infringement of three of the Minerals Separation patents, the two above mentioned and a new one which had just been issued, 1,099,699. The claims of the latter cover the use specifically of aromatic hydroxyl compounds as frothing agents *in the cold* and *without acid*. The bill of complaint urged that the Miami Copper Company had infringed in the use of these three patents conjointly.

Interrogatories were filed by the complainant and were most frankly answered by the defendant.

It will be seen that the Miami suit introduces several features which were not present in the Hyde case.† This case was decided in favor of Minerals Separation in the lower court of Butte, but the decision was reversed in the Superior Court of San Francisco, and the case is now awaiting a hearing in the United States Supreme

*Those who are interested in pursuing further the result of Mr. Richardson's investigations may be referred to the following articles: "A Unique Geophysical Phenomenon," *Journal of Physical Chemistry*, Vol. 19, No. 3. "Colloids in Their Relation to Bituminous Road Construction, the Asphalt Paving and Other Industries," *Technology Monthly* and *Harvard Engineering Journal*, Vol. II, No. 2. "The Theory of a Perfect Sheet Asphalt Surface," *Journal of Eng. and Ind. Chemistry*, June, 1915

†See METALLURGICAL & CHEMICAL ENGINEERING, Vol. XII, p. 362 (June, 1914).

Court. In the Hyde case only patent 835,120 was at issue, and since the operations in that case had been carried on in a machine, employing agitation with mechanical beaters, the defense had largely to depend upon breaking down the validity of the patent for less than 1 per cent of oil (patent 835,120). The Superior Court in San Francisco decided that this patent was invalid in that the reduction of oil to a point less than 1 per cent had shown nothing new besides an economy in oil. In the Miami case it became, therefore, now incumbent upon the complainant to demonstrate to the court that some new effect, some new result other than mere economy, is produced when the oil is reduced to this extremely minute quantity, while the defendants had to show that in the use of less than 1 per cent of oil no effect that was not also attained by the prior-art processes, except mere economy, is produced in the operation of patent 835,120.

The pneumatic cells of the Miami process having no mechanical beaters or agitators, but having the finely divided air admitted through a porous bottom from blowers or fans, left open more of a question as to infringement, since the defendant company maintained that its mode of operation did not infringe any of the claims of the patents in suit. Upon the other hand, the witnesses of Minerals Separation, who had visited the Miami plant, testified that all of the agitation necessary to produce their agitation froth was found in certain centrifugal pumps, Pachuca tanks, etc., which formed adjuncts to the pneumatic cells, and that the cells themselves were in fact agitators.

The defendants, on the other hand, maintained that if some agitation froth were produced through the agency of such accessory apparatus it was negligible in quantity and was not utilized in the subsequent separation in the cells. To sustain this claim they introduced figures and assays in evidence tending to show that in the present operating plant the results were identically the same, when two sections of the mill were operated side by side, one section having the Pachuca in operation and the other section having the oil merely fed into the launders in which the feed to the flotation plant was flowing with no mechanical handling other than a bucket elevator.

In the demonstrations to establish the non-validity of the less than 1 per cent of oil patent the defendants exhibited to the court models of various prior-art machines, such as those of Carrie Everson, Froment, Kirby, etc., in which experiments were made in court, and concentrates produced with quantities of oil varying from ½ per cent up to 25 per cent of oil. On the other hand, the experts of Minerals Separation contended that the defendants' apparatus has no foundation whatever in the prior art, and that all such results were obtained by defendants through their availing themselves of present-day knowledge, and not of the engineering knowledge at the time of the patents or processes in question, and the complainants (Minerals Separation) exhibited their conception of the prior art, endeavoring to illustrate to the court how utterly these prior-art processes had failed to produce any commercial results except upon a laboratory scale. They maintained that not one of these so-called prior-art processes had actually been in successful commercial operation.

The display of models in the court room at the close of court was most interesting, when all these exhibits were seen together as the various deposits of complainant and defendant. Possibly the most interesting of the prior-art disclosures was the description of froth-producing experiments as described by three students of the University of California in *California Journal of Technology* of November, 1903, in which they clearly set forth the distinction between the "lake effect" of the bulk oil (Elmore) process and the "foam effect" due to the "beating in" of air as in the Minerals Separation practice, describing the demonstration corresponding to the "bottle test" used as a field test as to the suitability of ores for treatment by the Minerals Separation engineers.

Possibly the most novel feature of the demonstrations was the use of a moving-picture film to illustrate certain laboratory experiments which had been made at a laboratory in New York. This, among other things, was to illustrate the action of air bubbles in their attraction for oiled and non-oiled mineral particles, and essentially to show that when particles were oiled with less than the Cattermole proportion, that is with less oil than is necessary to make them adhere, their affinity or attraction for the froth-producing air bubbles became effective, whereas it was stated to be a general law that particles oiled with sufficient oil to cause them to adhere had little or no attraction for air bubbles. The Miami experts showed by a similar set of experiments that the broad statements of the picture film were not sustained, and that there did not exist any actual difference in behavior of oiled and non-oiled particles as supposed by the Minerals Separation.

This discussion of the film constituted an important feature of the proceedings of the trial. The ingenious manner of observing and illustrating the action of air bubbles in a moving picture was devised by Dr. Wm. M. Grosvenor of New York.

The experimental demonstrations before the court were mostly in connection with patent 835,120, which covers the use of less than 1 per cent of frothing agent.

With reference to patent 926,678 the defense in argument contended that soluble frothing agents had been disclosed in previous patents, and with respect to patent 1,099,699 (covering flotation without acid and without heat) that the use of both acid and heat had been disclosed as optional in various prior patents, though the use of both acid and heat had become general in the application of flotation.

Mr. Henry D. Williams of New York, who had handled the case of Minerals Separation, made the principal argument for the plaintiff. He was followed by Mr. William Houston Kenyon, also of New York, in an able review of the case, with the legal citations.

Mr. Walter A. Scott of Chicago, who had the case for the Miami company, made the principal argument for the defense. He was followed by his law partner, Mr. Thomas F. Sheridan, who took up the legal citations. Mr. Scott had also handled the defense in the Hyde case, above referred to. He showed his wonderful grasp of the subject matter by the readiness with which he referred to the records of the previous, as well as the present case, in replying to Judge Bradford's numerous questions.

Dr. Adolph Liebman of London was chief expert for Minerals Separation, and Dr. Samuel P. Sadtler of Philadelphia for the Miami company. Upon each side were also some eight or ten engineers and metallurgists, many of whom had taken part in the Hyde case.

Mr. John Ballot, head of Minerals Separation, Ltd., who had come to America some time previous to the trial, was unfortunately unable to be present, owing to serious illness. Dr. S. Gregory, managing director of the American Minerals Separation Syndicate, represented the plaintiff by his presence.

Mr. R. C. Canby, consulting metallurgist, who had introduced flotation at the Miami plant, was present throughout the suit in the interest of the Miami company, and Mr. J. Park Channing, vice-president of the Miami Copper Company, was in almost constant attend-

ance, spending the larger part of each week in Wilmington.

The arguments upon both sides were good and very interesting. As Judge Bradford said in his closing remarks, he could see from the arguments that he was not going to be able to render a decision which would please both sides.

The decision will probably not be handed down until some time in the fall.

Bakelite Suit Decision

The U. S. District Court, Eastern District of New York, has just rendered its decision in the case of General Bakelite Company versus George J. Nikolas. The decision is in favor of the General Bakelite Company, the bakelite patents in question being held valid and infringed. The case is not only of commercial importance, but very instructive in various of its legal and chemical aspects. A full review should therefore prove of considerable interest.

An infringement suit was started by the General Bakelite Company, plaintiff, against George J. Nikolas of Chicago, defendant, trading as George J. Nikolas & Company, varnish and lacquer manufacturers.

The counsels for the General Bakelite Company were Mr. Charles Neave of Fish, Richardson, Herrick & Neave, and Mr. C. P. Townsend, of Byrnes, Townsend & Brickenstein. Dr. Baekeland testified in his own behalf and also as chemical expert. Dr. Parker McIlhiney and Dr. A. H. Gotthelf testified for the plaintiff in relation to analytical work.

Judge Willard M. McEwen and Mr. William R. Rummler of Chicago acted as counsel for the defendant in conjunction with Pennie, Davis & Goldsborough of New York. Mr. K. P. McElroy of Washington acted as chemist and patent expert for the defendant in conjunction with Dr. Ludwig Saarbach of New York, and Mr. E. B. Stuart of Chicago.

The trial was conducted before Judge Thomas I. Chatfield, of the United States District Court, Eastern District of New York. The trial was held in open court and was begun on December 9, 1913. The testimony filled 1396 typewritten pages. The whole trial took about 23 days. The final argument for plaintiff was presented on February 20 to February 21, 1914. The decision was given on June 12, 1915.

The suit was started on the following United States patents:

Baekeland, "Varnish," No. 954,666, patented April 12, 1910; original application filed October 15, 1907, divided and this application filed November 22, 1909. The claims of this patent are as follows:

"1. A varnish containing a volatile organic solvent and a condensation product of a phenolic body and formaldehyde, said condensation product characterized by its capability of transformation under the action of heat into an insoluble and infusible body, and by the presence therein of a base condensing agent.

2. A varnish containing a volatile organic solvent and a condensation product of a phenolic body and formaldehyde, said condensation product characterized by its capability of transformation under the action of heat into an insoluble and infusing body, and by the presense therein of a base condensing agent in proportions not exceeding one-fifth of the equimolecular proportion of phenolic body employed."

Baekeland, "Varnish," No. 1,018,385, patented February 20, 1912, application filed March 14, 1911. The claims of this patent are as follows:

"1. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde substantially free from uncombined phenols and a solvent therefor, said solvent containing a readily volatile organic liquid, and another organic liquid which is immiscible with water but miscible with said solvent and of which the boiling point exceeds that of water.

2. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde and a solvent therefor, said solvent containing amyl alcohol and a readily volatile organic liquid.

3. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde substantially free from uncombined phenols and a solvent therefor, said solvent containing acetone and an organic liquid of which the boiling point exceeds that of water.

4. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde and a solvent therefor, said solvent containing acetone and amyl alcohol.

5. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde and a solvent therefor, said solvent containing a readily volatile organic liquid, and another organic liquid which is immiscible with water but miscible with said solvent, which is volatilizable without decomposition when heated at atmospheric pressures, and of which the boiling point exceeds that of water.

6. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde and a solvent therefor, said solvent containing acetone and an organic liquid which is volatilizable without decomposition when heated at atmospheric pressures, and of which the boiling point exceeds that of water."

Baekeland, "Varnish," No. 1,037,719, patented September 3, 1912, application filed March 14, 1911. The claims of this patent are as follows:

"1. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde, transformable by heat into an infusible body and a solvent therefor, said solvent containing a liquid oxygen-compound of the aliphatic series, and a hydrocarbon.

2. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde, transformable by heat into an infusible body and a solvent therefor, said solvent containing a liquid oxygen-compound of the aliphatic series, and a cyclic hydrocarbon.

3. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde, transformable by heat into an infusible body and a solvent therefor, said solvent containing a liquid oxygen-compound of the aliphatic series, and a hydrocarbon of the benzol series.

4. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde, transformable by heat into an infusible body and a solvent therefor, containing a liquid oxygen-compound of the aliphatic series and a hydrocarbon, and another organic body soluble in said solvent or miscible therewith.

5. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde, transformable by heat into an infusible body and a solvent therefor, said solvent containing acetone and a hydrocarbon.

6. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde, transformable by heat into an infusible body and a solvent therefor, said solvent containing acetone and a cyclic hydrocarbon.

7. As a new composition of matter, a varnish comprising a condensation product of phenols and formaldehyde, transformable by heat into an infusible body and a solvent therefor containing an oxygen-compound of the aliphatic series and a hydrocarbon, and Chinese oil or tung oil."

The counsel for the defendant presented no less than 47 prior patents, aside from many literature references, each one of which was alleged by the defense to contain prior disclosures; but the decision rejected all these allegations and held that the three Baekeland patents in suit are valid and infringed. The decree covers about sixty pages; it reviews carefully the details of the testimony as well as all the arguments of the defense.

From Judge Chatfield's decision we quote the following:

The testimony shows commercially successful accomplishments, as well as scientific investigation by the patentee in this country, and his appearance and testimony upon the witness stand have plainly shown mental capacity, scientific knowledge and deductive ability which would accord with and be expected as the necessary foundation for such investigations and experimental operations as those involved in practicing or advancing the art and processes set forth in the patents as to which the present litigation has arisen.

The defendant is a practical manufacturer of varnishes in the City of Chicago, who disclaims knowledge of chemistry as a science, and who testified that in the mixture and

treatment of chemicals during the manufacture of varnish, he judged the reaction and formed all his conclusions from experience and appearances, without regard to the nature of the reaction taking place.

The plaintiff alleges infringement by the sale upon the open market of certain varnishes known as bedstead filler or gold lacquer or satin A. P. lacquer, of which admitted samples have been produced by the defendant during the course of the trial.

At the outset of the case, considerable point was made of the issue of infringement, by reason of the fact that the sample produced by the plaintiff, and obtained from a store used by the defendant as an agency in Brooklyn, was claimed by the defendant to be different in appearance from anything manufactured by him. The sample was therefore disavowed by the defendant as his product. The difference in appearance was never satisfactorily explained, but the chemical analysis of the contents and the analyses of the samples produced by the defendant were such that no issue as to the actual resemblance of the defendant's commercial product and the article described by the patents exists.

The defendant, however, contends that he does not do or use anything in the manufacture of his varnish which would be an infringement of the plaintiff's patents, and, in fact, denies the use of materials which the plaintiff, from analysis of the product, contends must be employed by him. This issue will be discussed in connection with the patents of the prior art, and we will take up at once the patents in suit and the patentee's work in connection therewith.....

Then follows a systematic review of the prior art as alleged by defendant to contain disclosures annulling the patentability of the claims of the Baekeland patents, and a comparison of these disclosures, with the claims of the Baekeland patents in suit, as well as other Baekeland patents relating thereto.

It was plainly old in the art to make pyroxylin varnishes and varnishes of phenolic condensation products. But each of these varnishes, and each condensation product, had individual characteristics, and the patents in suit involve differences in the chemical process or processes of manufacture by which the particular product, claimed in the patent as novel, is to be produced.

The defendant claims that this product, to be used in the making of varnish, was nothing more than the resin which the patentee had sought to patent for use as a varnish, and he urges, therefore, that the varnish patents themselves are invalid, citing Underwood v. Gerber, 149 U. S. 224.

He attacks further Claim 1, because the patentee is said to have acquiesced in the rejection by the Patent Office of this claim when first presented.

The application for patent 942,809, which was a renewal of application 397,560, contained the claim filed upon the 15th of October, 1907, for a varnish, and the defense claims that the rejection of the varnish claims in the condensation product patent was acquiesced in by Baekeland, and that he therefore could not divide the application and restate the claim.

Examination of the file wrapper shows that this rejection was merely because of the incompatibility, under the rules of the Patent Office, of a claim for varnish in the same patent with a claim for the condensation product with which the varnish is to be made, or a claim for the method of making that product.

Claim 2 is said to be invalid in that the specifications as originally presented, and even as finally contained in the allowed patent, do not show the rule of proportion set forth in the language "not exceeding one-fifth of the equal molecular proportion of phenol body employed." During the trial much testimony was devoted to an explanation of the meaning of "equal molecular proportion" and computation of the amount of ingredients set forth in the various patents discussed in the record.

Inasmuch as there is no dispute as to the real meaning of the phrase or as to the molecular weight of the ingredients, or as to the quantity represented by one-fifth of the phenolic body expressed in terms of molecular weight, and so long as there is no dispute as to the percentage of the whole article represented thereby, we need only look to the specifications in order to find if the language of this claim corresponds to a proposition explained in the specifications.

The patentee, when referring to the use of base, and speaking of ammonia or caustic soda as an illustration, says that so small a proportion of the base as one-half per cent of the weight of phenol, that is 1/200 by weight, and in other cases an increased amount rarely reaching 10 per cent by weight of the phenol, is sufficient. This base is, however, to be calculated from that which actually remains as such in the product or the varnish and the definite proportion contained in the claim was inserted therein after the Patent Office compelled the patentee to limit his claim of invention (but not the statement of his original experimentation or his present conclusion) to matters which the Patent Office considered new over the De Laire, Story and Luft patents.

Under these circumstances, the Court cannot see why the claims should be invalid because at the time of filing the application the patentee did not sufficiently limit the language in his claims so as to avoid interference with other patents which, however, did not disclose the precise matter ultimately proving to be that intended to be claimed as invention by the applicant, and which had been in his mind from the time of his application. Thus the small amount of base which Dr. Baekeland finds would universally produce the result desired, was not disclosed by any of the prior patents, up to the time the application by Baekeland was filed.

Subsequently a certificate of addition to the Story (French) patent was filed upon the 29th day of September, 1908, and therefrom the defendant suggests that Baekeland learned how to state the claim which he had previously been trying to formulate. But the question of patentability could not rest upon literary plagiarism even if that were shown, and the testimony in the case would indicate rather that the Story addition was an attempt to secure the French rights for the same variation from the original Story patent as were being claimed by Baekeland in the United States, even if there were reason to suppose that Baekeland had seen this addition to the Story (French) patent, which was not published until February 25, 1909.

This would not prove that Story was entitled to claim the invention over that claimed by Baekeland, and if Baekeland's invention was in fact the same as that described in the Story addition, then Baekeland would be entitled, on application to the Patent Office, to have the claim issued even in substantially the same language as that described by Story.

The defendant does not show that Story was the inventor rather than Baekeland, he merely suggests that Story's patent solicitor produced a statement of the claim in such a form that Baekeland could see at once that, stated in the same way, his invention was made valid over the prior art and would meet with the approval of the Patent Office.

But, as a matter of fact, the defense does not even make out its accusation of plagiarism, as there is nothing to show that Dr. Baekeland had the Story addition before him or called to his knowledge prior to the time when he realized the way in which to make a definite statement of what he claimed as novel in his patent over the Story or De Laire patents themselves.

The defense to the second and third patents is substantially the same as that to the first, but with the added proposition that double solvents were old in the art and that the particular double solvents claimed in the third patent were in fact but a variety of those shown in the second.

As to the last proposition which is urged (that benzol or toluol with amyl alcohol would be one of the possible components referred to in the second patent, when it suggests the use of a solvent, immiscible with water and having a boiling point higher than that of water, with one of easily volatile solvents at lower temperatures) the defendant's claim is that thereby the patentee attempts double patenting or extension of the time of protection beyond that shown by the second patent. But even though the third patent should be held to cover nothing more than one of the components disclosed by the second patent, and if the third patent should therefore be void for anything more than the period protected by the second, the defendant herein would still be an infringer of the second patent and liable.

As a matter of fact, however, the third patent is not invalid in this sense. The second patent does not teach nor show the combination of a hydrocarbon with a solvent of the aliphatic series, having the qualities of and volatilizing at the temperatures described. The testimony of the expert varnish makers in the case shows that the use of these two particular solvents would be not only an accident, but substantially improbable except as a casual experiment, and the precise nature of the product covered by the third patent is shown therein to be adapted for a particular use, and would seem to be a patentable improvement over the combination described in patent number two.

We come back, therefore, to the main defenses based upon the prior art.

The defendant attempted to show non-infringement upon his own testimony that he added no base to the commercial carbolic acid and the commercial formaldehyde solution

which he employs in making his varnish. But analysis by both the defendant's and the plaintiff's experts showed the presence of ammonia by what is called the Kjeldahl method, which shows the quantity of nitrogen and accounts for any ammonia that may have been present as a part of this nitrogenous body.

By another analysis, the plaintiff's expert, whose results compared generally closely to similar analyses by the defendant's expert, found free ammonia amounting to 13/100 per cent of the solid residue. The defendant's expert failed to take into account the combination of ammonia and formaldehyde to form hexamethylenetetramine a non-volatile base from which ammonia would not be driven off by boiling with caustic soda.

The analyses further showed that the defendant's products contained pure phenol and ammonia, and the testimony of the case shows definitely that ammonia is not found in commercial carbolic acid. But orthocresol, metacresol and paracresol, as well as pyridin are found in commercial carbolic acid. Pyridin shows by the Nessler test no trace of ammonia and yet would give by the Kjeldahl test evidence of the presence of nitrogen. Likewise by the Kjeldahl method, ammonia would be found and be calculated as nitrogen.

Commercial carbolic acid is mostly cresol, with possibly a small amount of true phenol. As true phenol or hydroxybenzol reacts more easily with formaldehyde than does paracresol or orthocresol, the fact that free phenol is found in the defendant's varnish, and that no cresols were found, would indicate that the defendant's varnish was made from phenol rather than commercial carbolic acid, and that the ammonia present must have been in some form added as a base.

While the defendant has testified to certain purchases of commercial carbolic acid, and also certain purchases of crystalline phenol, he has not testified to the use of any material which would satisfactorily account for the product shown by analysis, and it must be held that he is either making a product which infringes the plaintiff's patent, and has not disclosed the methods of so doing, or that he has added some material of which he does not know the contents himself, but which contains products that do infringe the patent.

It is no defense to a charge of infringement of a patent for a product produced by some chemical process, to assert ignorance of the reactions which take place, and thus claim the right to combine substances which on analysis are shown to cause the reactions of the process leading to the patented product, and to obtain that product itself by methods shown to be those of the patent, even though never before understood until testified to upon the trial.

If a person should attempt to excuse infringement of a patent calling for the use of iron or steel in the making of a device, by suggesting that he did not know what iron or steel was, and that he merely used a hard metallic substance which he purchased from a certain manufacturer and which did the work, it can be seen where such a doctrine would lead.

The defendant also contends that the amount of base shown by the defendant's chemist is much less than the smallest amount stated in the plaintiff's patent to be sufficient to meet the discovery therein contained. But the plaintiff's expert finds ammonia approximating 13/100 per cent of the solid residue which is within the quantity referred to in the specification.

Much of the discussion raised by the defendant with reference to the validity of the patent, both from the standpoint of the disclosures in the plaintiff's former applications and patents and also in following up the suggestions of the patents of the prior art, arise from the nature of the claims and of the invention.

It will, of course, be assumed that no chemical reaction can be patented as such. A natural product, such as ordinary salt (NaCl), could not be made the basis of a patent, nor could a discovery of the chemical reactions by which salt was formed in nature, from sodium and chlorine, be patented as a process. But if artificial salt, as a chemical substance, could be distinguished from natural salt, and if some one discovered a way to make artificial salt, he could patent the method or process, if it were novel. Provided he was the first one to produce the substance, he could patent the product as something useful in commerce or in the arts.

So it is conceivable that some gum or natural substance like shellac or amber might be found, composed of phenol, formaldehyde and a base, and transformed by heat into an insoluble and infusible substance. If such a product had been known prior to the plaintiff's patents, the plaintiff could have obtained no patent, if his product was identical and indistinguishable from the natural substance, but he would have been limited to a patent for a process.

But at a time when the only product of phenol and formaldehyde, known and described *with understanding* and *definiteness*, was a permanently fusible and permanently soluble gum, the discovery of a method of rendering this product insoluble and infusible was patentable, and provided the product could be certainly identified and distinguished from the former and known products, it could be patented as well as a combination of such substances in certain relations or proportions.

If the use of an excess of formaldehyde was overcome by the use of a large amount of base, and the base in turn removed by precipitation into an acid salt, and if the product was not identifiable or was not available for any known purpose, no patent could be issued for the process (which would be mere chemical reactions) nor for the product (see Reychler and Kleebert), and certainly the combination of that product with some other substances to form a useful article like a varnish, is inconceivable.

The patents in suit are based upon the earlier patents of Baekeland for a method of producing the phenolic gum and also his patents for the condensation product produced by the patented method. But when he attempts to make a varnish which consists of a combination based upon and making use of the patentable method of preparing the condensation product, and also upon the patentable substance itself, he has a new substance which is itself patentable. As in the case of a patentable mechanical device, this consists of more than a mere aggregation of parts.

Considering the last two patents in suit for a moment, the defendant claims that they are invalid because they show merely the use of a double solvent with a gum or product which is capable of solution for varnish purposes, which is nothing more than the ordinary defense of aggregation with respect to a combination of mechanical parts. If the use of these solvents with this particular phenolic gum presents a substance having qualities that are different from those of any other compound or substance previously used for the same purpose, it is no defense to the patent to suggest that the physical or chemical processes involved in the mixing and drying or setting of the varnish are the same as those involved in the mixing, drying or setting of a varnish which would produce different results and show different qualities.

The combination disclosed in the Baekeland patents is new for varnish purposes. It has new qualities, and meets old needs in a new way. The behavior and purposes of the double solvents, and the way in which the varnish passes through the physical and chemical changes, are, of course, not patentable, any more than the suggestion that the water present is eliminated in the form of vapor would be novel or distinguish the product from other substances. If, however, water or volatile solvents are evaporated, the patentability of the combination from which the water is produced would not be affected by the age of the world's appreciation of the principle of evaporation.

So with the first patent in suit, when we consider the various patents of the prior art by which condensation products, showing either an excess of phenol or an excess of formaldehyde, or condensation by the aid of a large amount of base, or by the acidification of the base and its removal in the form of non-soluble salts, or if we consider the possibility of obtaining a huge mass of insoluble and infusible material, of irregular shape, by a violent expulsion of steam or gas and a consequent spongy or porous form of the product, or if we consider the production of an insoluble and infusible film in small quantities upon a glass plate or in a test tube, or even if we found the product such as was shown in the Story (English) patent, where, by long application of heat a reddish or red-colored film could be produced, or if we consider a condensation product which, while capable of use as a varnish, remains permanently fusible and soluble (such as that distinguished by the novolak type) we nowhere approach to the particular condensation product and the particular combination, for use as a varnish, by which it is possible to certainly, easily and accurately begin with a condensation product that in combination with certain defined solvents will produce a varnish which with *short* subjection to moderate heat will produce a colorless, infusible, insoluble and useful lacquer film of the sort desired for use in the arts and which in certain definitely specified combinations possesses the qualities required where the surface is to be subjected to the influence of an electric current, under conditions where moisture may be absorbed or encountered.

It is unnecessary to go through the patents presented in the prior art in detail.

It is sufficient to say that in none of the earlier Baekeland patents was a varnish combination disclosed which was like that in the patents in suit, even though Baekeland in some of the earlier patents taught that his particular condensation product was available as a varnish. Nor did

any of the earlier Baekeland patents or the patents of the prior art shown in circles 2 and 3, produce the infusible and insoluble substance of the Baekeland patents shown in circles 11 and 13.

The Story (English) patent, as has been seen, presented an acid, rather than a basic condensation product, in cases where pure phenol was used; a large amount of heat or long evaporation was necessary to produce the insoluble or infusible film with the reddish tinge, while the product that Story considered available for varnish purposes was that containing the acid salts.

Such other patents as those set forth in class 15 upon the diagram, present non-phenolic or non-reactive varnishes or resins which have nothing to do with the combinations of the patents in suit, except as they may use double solvents or may set forth similar chemical reactions, or may, with the knowledge of those patents, as well as of the Baekeland patents, indicate how an exchange of substance might, by employment of the same chemical reactions as before, produce the Baekeland results. But such patents are not anticipations, nor would they be infringements of the Baekeland patents in suit, and we can therefore dismiss them, as in each case they were substantially dismissed by the defendant's expert upon the trial, by saying that no one of them showed in its entirety the precise varnish or combination of any of the three patents in suit. Even if it does not require invention to trace the resemblances between these patents and the Baekeland patents in suit, or to produce similar results by substitution of known products for those products which were different in these prior art patents, and even if we do not concede to the defendant's expert invention in tracing the points of resemblance and difference, it is evident that his recognition of these points does not raise them to the dignity of defenses, nor are they anticipations of the Baekeland patents.

The doctrine of Underwood v. Gerber (supra) is presented as authority for the claim of invalidity as to the patents in suit, because it is said that in patent 942,809, Baekeland disclosed the same form of varnish resin, and that no patentable novelty is shown in merely combining that resin with a solvent to make a varnish.

The discussion already had shows the difference between the case at bar and Underwood v. Gerber (supra), where a patented or claimed product was subsequently used as an application for the surfacing of paper. But the discussion already had shows further that patent 942,809 describes merely the process or method of producing a patentable substance, while Claim 8 describes this condensation in such general form that the description in patent 954,666, of a varnish made therewith, would still be possible as a combination, even though Dr. Baekeland might not be able to patent a second time the condensation product produced by the presence of a base condensing agent in proportions not to exceed one-fifth of the equal molecular proportion of phenolic body employed after describing that condensation product in his previous patent, 942,809, for which the application was that from which the new application was divided and re-filed.

The first patent in suit was based upon the application for 942,809, was never abandoned and was not anticipated by the subsequent separate allowances of 942,809 for one of the ingredients of the new and patentable substance which was useful commercially as a varnish.

Claim 2 of patent 954,666 is therefore valid as the definite description of the combination specifically based upon the product patented in 942,809, while Claim 1 of patent 954,666 is valid as a general description of a new form of varnish which can be produced by the methods of the specification and which is in more detail identified in Claim 2.

The patents will therefore be held valid and infringed and the plaintiff may have a decree.

The Cobalt district, Canada, has recently been visited by agents of companies operating in the Gold Coast, Africa, seeking miners for service at that place.

The manufacture of ceramic wares in the United States is a matter receiving attention at this time. According to *Technical Paper* 99 issued by the Bureau of Mines, American manufacturers have an opportunity to secure domestic trade on account of conditions created by the European war. Attention is directed, however, to the fact that the standard of American production must be maintained at the highest if permanent business is to result. The restoration of European trade in this country will require much time and money, but competition may be expected as soon as European makers can again enter the field.

Court of Appeals Decision in Nickel-Chromium Resistor Suit

In the suit of the Hoskins Manufacturing Company against the General Electric Company for infringement of the A. L. Marsh patent 811,859 (Feb. 4, 1906) the District Court of the United States for the Northern District of Illinois, Eastern Division, had sustained the patent and found it to be infringed by the General Electric Company. The latter company thereupon appealed. The United States Circuit Court of Appeals for the Seventh Circuit has now affirmed the degree of the District Court and decided that "appellant's [General Electric Company's] use of the alloy [calorite] is an infringement of the Marsh patent and should be restrained."

The case was heard before Circuit Judges Baker, Kohlsaat and Mack. The decision is written by Judge Kohlsaat.

The strongest reference brought forward against the validity of the Marsh patent was that of the English patent of Emile Placet, No. 202, Nov. 21, 1896.

"This patent was not before the Examiner, nor was it known to Marsh at the time of his invention so far as the record shows. It relates to a method of introducing pure chromium into metals and alloys in a state of fusion. Speaking of pure chromium, Placet says, 'This chromium is absolutely pure. It improves all metals and alloys with which it is mixed by imparting to them the qualities peculiar to itself. It renders them harder, more resistant to shocks, tension, and friction, and also renders them more proof against the destructive action of the air, moisture, acids, and high temperatures.' 'Chromium,' he says again, 'renders metals and alloys more resistant than heretofore to high temperatures, which renders them highly suitable for the manufacture of tuyeres, hearths, fire-arms, etc.' Again he says, 'Chromium increases the electrical resistance of manganese, ferro-manganese, ferro-nickel, and other metals employed in the manufacture of conductors of high electrical resistance.' " . . .

"Appellant [General Electric Co.] sought to purchase the patent in suit, and, failing, took appellee's [Hoskins Mfg. Co.'s] said alloy of nickel and chromium and added a small quantity of manganese and 15 per cent of iron, admittedly for the purpose of coming within the alleged disclosures of the Placet patent. These additions, appellee contends, served merely as diluents and in no appreciable degree affected the characteristics of the alloy. This element is termed calorite, and contains nickel 65 per cent, iron 15 per cent, chromium 12 per cent and manganese 8 per cent. For appellee it is insisted that, for purposes of durability as an electrical resistance element, it is practically identical with its own element.

"Appellant contends that the claims in suit are narrow and must be strictly construed, that its own resistance element does not infringe the claims as they read, that, construed in the light of the prior art and the file wrapper, the claims cannot cover appellant's element, which comes within the Placet patent and Marsh's abandoned claim four, although Placet shows no alloy, used as a high resistance element, having less than 56 per cent of iron. The patent drawing is that of a rheostat, the resistance element of which is the alloy of the patent. The patentee claims a resistance element as distinguished from a material possessed of high resistivity."

From Judge Kohlsaat's opinion we quote the following extracts:

"The invention of toasters, heaters, electrical ironers and the like had begun, and it was apparent that in these as well as in the art generally the need of conductors having great durability when subjected to heat was at hand. This involved also substances which possessed the property of ductility to a degree sufficient to permit the drawing of filaments, strands, wire, etc., for use as electrical conductors. Platinum alone was then recognized as an enduring material suitable for conductors which were required to be subjected to great heat. Its cost prohibited its commercial use. Consequently the Marsh discovery was hailed as an available substitute. It was and is a most valuable resistance material. It lasts when subjected to heat from 800 deg. to 1000 deg. C. one hundred and fifty times as long as anything in the prior art, except platinum, unless Placet may be construed to have disclosed the concept, for unless

Placet anticipates Marsh's material as an electrical resistance element it is not anticipated. It will be seen from Placet's English patent that the patentee leaves it to others to ascertain by experiment products of chromium and metals in alloy suitable for high resistance and those disclosing the element of resistance to high temperatures. Placet's discoveries were before the public about eleven years before Marsh's patent was granted, from which fact it may be at least conjectured that the valuable resistance and duration properties as resistance elements which appellant finds disclosed therein, were not ostentatiously in evidence. Now, the law is well settled that in order to anticipate a later invention, the prior description must be such as to show that the article described in the patent can be certainly arrived at by following the prior description without the assistance of local knowledge or local prior use in the locality where the description is published, and without experimentation." . . .

"Placet's statements, if taken at their face value, turn out to be untrue in many cases when subjected to experiment. It is not true that when alloyed with metal, chromium always brings to the alloy its own distinctive specific properties." Illustrations are given showing that resistivity is not increased in all cases by chromium, that the melting point is not increased in all cases by chromium and that durability is not measured by resistivity.

"There are many elements which affect the efficiency of a resistance element in an electrical circuit. The melting point, while a limit to a material's electrical resistance properties as an element, is not determinative thereof. Resistance to oxidation is an important feature. These are probably the chief factors. There must also be taken into account the temperature co-efficient, the condition of the oxide scale on the resistance material as to density, electrical conductivity, volatility, uniformity of composition of resistance material, and a number of other things. The durability of the Marsh alloy at a heat of 800 deg. to 1000 deg. C., Marsh fixes at from 200 to 2000 times that of any resistance material in the prior art. Can it be supposed that Placet, had he known of its availability as an electrical resistance element, would have overlooked it? or that all those who utilized it afterwards for the manufacture of watch springs and wheels, steel, pig-iron and precision apparatus and light filament would have passed by, as of no consequence, this great substitute for platinum, had Placet suggested its value to them, or made them understand what it was? Placet could no more claim this resistance element, as disclosed by Marsh, than could Ostermann and LaCroix with their watch spring material.

"For eleven years this device of Marsh lay hidden as a gem in its Placet matrix. There it might yet be lying had not Marsh found it and made it public. Certainly it never occurred to Placet that this chromium-nickel alloy would produce a rival to platinum as a resistance element at a cost and under conditions which made it an available article of commerce." . . .

"It is evident that Placet and the other prior-art and prior-publication references fell far short of disclosing even to those skilled in the art, the subject matter of the patent in suit.

"In his argument before the Examiner, shown in the file wrapper and contents, Marsh by his attorneys says he 'does not claim to have been the first to make the alloy itself, but to have discovered that such alloys possess certain properties adapting them for a new field of usefulness.' Again appelee says, 'Some of the most important inventions have consisted in the practical application of the discovery of a new property of matter and this invention is of that class.' And again, 'The novelty of the patent in suit consists in discovering a new use for the chromium-nickel alloy in which is produced most extraordinary and unexpected results.' And again, 'the basis of the patent is the discovery that a resistance element of the composition specified is suitable for all-round use in the various situations in which such elements are desirable.' Thus, the main feature of the patent relied upon as new is the fact that Marsh found by experiment that the alloy of the patent combined with great resistivity, marvelous durability, second only to platinum, under conditions which made its production commercially practicable. Placet merely says chromium renders certain metals more resistant to high temperature, that is, it increases the melting point in some cases—a very different thing from durability. At most, he is speaking of externally applied heat, which is no criterion for durability under internally developed heat." . . .

"If this discovery is to be judged by its contribution to the electrical art, it is entitled to be held to be measurably broad within certain lines and as such entitled to a reasonable degree of equivalents—not necessarily equivalency as found in chemical structures but, as was said in Treibacher Chemische Werkes, etc., v. Roessler & Hasslacher Chemical Co.,[1] supra, equivalency in 'functional efficiency.'

"Appellant's calorite consists in substance of appelee's alloy plus 15 per cent of iron and 8 per cent of manganese. It will be remembered that the patent specification says 'Iron, on the other hand, is readily oxidizable and will not answer my purpose when alloyed with a metal of the chromium group.' Placet speaks of the beneficial effect of an alloy consisting of chromium and ferro-nickel. Appellant claims to have brought itself within this alloy and within appellee's alleged abandoned claim 4. But Placet's alloy contained not less than 56 per cent of iron. It is evident that appellee was advised of the tendency of iron to oxidation. While possessed of high resistivity and high melting point, its duration at 1000 deg. C. is only nine minutes. Manifestly, in looking for an element possessing high specific resistance, he was awake to the necessity of such an element as had also the property of high durability. Very naturally he did not want a metal which endured at 1000 deg. C. for only nine minutes. We deem it a fair deduction from the evidence that Marsh was not thinking of a diluent of iron but of iron as a substitute for nickel, as a body for his alloy. From the record it appears that for the purpose of an all around element of great specific resistivity, including the essential companion property of endurance or resistance to the encroachment of high temperature, etc., 15 per cent of iron has no appreciable effect on a chromium and nickel alloy. Iron was supposed to increase the quality of ductility. Manganese was supposed to aid in deoxidation and refining. These elements were added to appellant's alloy, after it had analyzed two specimens of appellee's material and seem to have been added in the attempt to bring calorite within the Placet description and to avoid infringement of Marsh; but as above stated, Placet's ferro-nickel alloy contained 56 per cent iron. For all practical purposes for use in electric heating and cooking appliances and other devices employing high temperatures, the two resistance elements are equivalent. The object in increasing ductility was for the purpose of facilitating the process of drawing the alloy into strips, filaments, etc.

"As a matter of fact, appellant's resistance material is to all intents and purposes identical with that of appellee's. Its resistivity, durability, melting point, temperature coefficient, resistance to oxidation, ductility and appearance, practically coincide with that of Marsh. Appellee's element is sufficiently ductile for the uses to which it is put, as shown by the Hansen diagram above alluded to. The 15 per cent of iron is apparently lost, while the manganese makes no impression. Thus it is apparent that iron and manganese serve no purpose other than as diluents and as fictitious bases upon which to construct a claim for non-meritorious distinctions between the composition of the two alloys. Neither composition is new. When applied as electrical resistance elements, the results are identical, as is the appearance of the two. There is no other dissimilarity than the presence of small and inconsequential ingredients of iron and manganese in appellant's alloy. The new use is the same."

The Western Metallurgical Field

Colorado Manganese for the Chemical Trade

What appears to be an important supply of high-grade manganese ore in the United States, suitable more for industrial uses than for making ferromanganese, is being developed in San Miguel county, Colorado. When first discovered, the ore was submitted to certain interests in the steel trade, but was subsequently found to meet the requirements of the battery and glass trades, and is now being used for such purposes. It is claimed that large shipments can be made averaging 85 per cent MnO_2, with less than 1 per cent iron. Manganese ore of this character has been imported from Turkey; but foreign shipments have been of uncertain delivery, and an opportunity appears for the creation of a good demand for a domestic product. The Colorado Manganese Mining & Smelting Company, which owns ten claims from which ore is now being shipped, expects to produce at the rate of about 750 tons per month. The property is located in Dry Creek Basin, San Miguel county, Colorado, and the ore is hauled 40 miles to the railroad at Placerville.

[1] See pages 135 and 145 of our March issue, 1915.—Editor.

Sale of Stratton's Independence

With the sale of Stratton's Independence, Ltd., to the Portland Gold Mining Company, a most interesting chapter in Cripple Creek metallurgy is closed. Stratton's discovery and development of the Independence mine was one of the brilliant features of the early days of America's premier gold district. The subsequent sale of the property to British investors brought the property into world-wide prominence. From a metallurgical point of view, however, the chief interest centers in the successful treatment of the old mine dump, estimated to contain about 1,000,000 tons of ore worth about $3 per ton. Based on an exhaustive investigation of the tonnage, value and most economic treatment of this dump, Mr. Philip Argall represented that with a cyanide mill of 10,000 tons monthly capacity, the ore could be treated at a cost of $1.50 per ton, yielding a net profit of $1 per ton. The annual reports of the company, which have been abstracted in this journal, indicate with what precision the estimates were made and how closely they were approximated by actual results during the life of the company. The estimated profits have been slightly exceeded by the actual returns to stockholders. Mr. Argall's venture was the first in the successful cyanidation of low-grade Cripple Creek ores. In general, the methods he employed have since been adopted by other companies treating those ores locally. Special methods introduced from time to time have not proved of sufficient merit to make their use permanent. The success of the venture should encourage the company to seek other problems in which the same careful preliminary investigation can show the same probable profit.

Repairing Metallurgical Furnaces with Air Guns

Recently some interest has been aroused in the proposed use of a compressed-air gun for making repairs to metallurgical furnaces in which the linings are subject to deterioration at certain points. Inquiry among western smelter metallurgists reveals the fact that the idea is now wholly new, and has been tried experimentally. Apparently the idea occurred to a number of men about the same time, each recognizing the possibility of projecting a semi-fluid mixture of refractory material against the wall where repair was needed. An air gun for this purpose was tried at the Steptoe smelter at the time Mr. Sorensen was superintendent. At the Garfield smelter a similar device was used, made of 4-in. pipe connected with air under 100-lb. pressure and a supply of silica, with the idea of carrying the latter across the furnace. A similar scheme was contemplated by Mr. D. C. Smith, at Campo Seco; but a change in smelting practice occurring before the plan could be tried, it was rendered unnecessary. The idea appeared attractive because the repair mixture could be applied directly where needed, eliminating the waste incurred in hand work.

Since smelters have generally adopted the practice of charging reverberatory furnaces along the side walls instead of through hoppers placed centrally in the roof, the necessity for repairs to the side walls of such furnaces is no longer of great importance. The point of greatest deterioration is in the roof about 20 ft. back of the burner, and when this becomes too thin the furnace is shut down and the roof rebuilt at that point. Under present conditions of operation, therefore, the air gun would find no application for reverberatory furnaces.

In copper converters and casting furnaces, however, there might be a useful field for the device, especially of the type recently patented in which a high-temperature torch is combined with the air gun. The proposed method of operation is to comminute the refractory material of which the lining is formed, and apply it continuously in small quantities at high velocity, at the same time subjecting it to incipient fusion by means of the torch combined with the gun. The result is said to be a lining which is vitreous, homogeneous and dense throughout, fused into form at a higher temperature than that at which the furnace is normally operated. The present methods of repairing basic-lined converters consists in applying a mixture of ground magnesite and water glass with a long-handled iron spoon, or by means of a tube and plunger, the former being filled with as much of the mixture as is required and the charge pushed into place by the plunger. In casting furnaces the roof requires repairs about every six months, and while the furnace is closed for these repairs, the side linings along the slag line also are patched.

The Base-Metal Situation

The stimulating effect of the zinc market on ore production and treatment is strongly in evidence. The Joplin district especially is unusually active, record prices for "jack" being established on succeeding days. For the week ended June 12, the high price of $135 per ton for 60 per cent concentrate showed an increase of $25 per ton as compared with the previous week. Special grades brought a premium of $3 per ton. Lead ore reached the record price of $75 per ton, and calamine brought $82 per ton on a basis of 40 per cent metallic zinc.

A zinc smelter at Bruce, Kan., which has been idle for eight years, is to be put in operation. At Joplin it is reported that the Joplin Separating Company is to build a small retort plant to be operated in conjunction with the concentrator. The Delta Lead and Zinc Company, which has operated a mill at Spring City, has completed a second mill of 150-tons capacity, and several mining operators have resumed work and are shipping ore to custom mills. Romantic tales are even told of feeble old men and young children culling dumps and making startling profits. The prosperity of the district extends to miners and smeltermen, wages having been advanced materially. At the Bartlesville smelters the wages of employees have been advanced 15 per cent.

Utah lead smelters are reported operating at capacity on ores already under contract. No new contracts are being made at the present market prices for lead, and those operators who have in the past refused to sign contracts will be unable to take advantage of the rise in price.

Quicksilver is being produced by the Nevada Cinnabar Company at Ione, Nev., at the rate of about sixty flasks per week, and properties in California, Nevada and Texas that were unable to operate profitably when quicksilver was quoted at $35 to $40 per flask, are reported to be resuming operations.

Company Reports

The thirteenth annual report of the **Tonopah Mining Company of Nevada**, for the year ended February 28, 1915, shows the results of milling 143,432 dry tons of ore assaying 0.246 oz. gold and 21.22 oz. silver per ton. The costs were as follows: Mining and handling dump ore, $4.40 per ton; milling, $2.96; freight, $0.74; marketing mill products, $0.41; total, $8.51 per ton. Metal losses in milling and refining amounted to $1.23 per ton, leaving a profit of $6.51 per ton. The average gross value of ore milled was $16.25. Several radical changes were made in mill operation. It was found that the filter plant was not making a satisfactory recovery of dissolved metal, and the extraction from sand product was not as good as from slime. Filter presses were con-

sidered, but the cost for a suitable plant, including changes that would have to be made for all-slime treatment, would amount to $100,000. In addition $6000 would have to be spent for additional water supply. Finally, after considering other methods, it was decided to adopt all-sliming and decantation, which was done at a cost of $38,000. Extraction has improved, resulting in the highest recoveries in the history of the plant and the lowest total costs. The reduction in cost due to the changes, during ten months of operation, amounted to 14.4 per cent. The company owns 83 1/3 per cent of the stock of the Tonopah Placers Company, operating three dredges at Breckenridge, Col. The option on property of the Eden Mining Company, Nicaragua, was exercised in January, 1915. Sufficient ore has been developed to warrant the erection of a 100-ton unit of a mill which is expected to be in operation within a year. A two-year option has been taken on the property of the Mizpah Extension Company of Tonopah. The Tonopah Placers Company dredged 2,995,256 cu. yd. of earth, producing 22,542 oz. gold and 4781 oz. silver. The value per yard was $0.155 and the cost $0.096.

The annual report of the **Tonopah Belmont Development Company** for the year ended Feb. 28, 1915, shows marked improvement in milling operations with attendant reduction in costs. The mill treated 181,424 dry tons of ore assaying 0.2336 oz. gold and 22.3 oz. silver per ton, having an average value of $16.72 per ton. Total milling cost was $2.564 as compared with $3.049 in the preceding year. The cost per ton for labor was $0.419; supplies, $1.318; power, $0.419. In the previous year the respective costs for these items were $0.462, $1.604 and $0.494. The cost per ton for chemicals was: cyanide, $0.601; zinc, $0.0737; lime, $0.0416. The average extraction of the tonnage milled was 95.78 per cent of the gold and 91.81 per cent of the silver, or a combined extraction of 92.99 per cent. Due to the more refractory nature of the ore, resulting in a greater production of concentrates, the extraction in 1914 was 1.46 per cent lower than in 1913. The use of the Belmont type steel liner for tube-mills has shown increased efficiency, and is expected to cut lining cost from $0.032 per ton for silex to about $0.0158. At the company's Millers plant the metallurgical process was changed from filtration to continuous decantation at a cost of $24,930 for reconstruction. The mill treated 44,692 dry tons of ore at a profit of $24,344, producing 1,031,745 oz. silver and 12,469 oz. gold. Before adopting the change in treatment the extraction averaged 87.45 per cent and the total milling cost was $4.034 per ton. In January, 1915, after the change had been made, the extraction was 90.05 per cent and the cost $3.766 per ton.

The Montana-Tonopah Mines Company milled during 1914 a total of 63,754 tons of ore of average value of $8.991 per ton. The mill was closed from Nov. 15 to Dec. 31, 1914, on account of the lower grade of ore and low price for silver. The following table gives detailed milling costs:

Account	Labor Cost Per Ton	Supplies Cost Per Ton	Power Cost Per Ton	Total Cost Per Ton
Crushing and conveying	$0.079	$0.021	$0.019	$0.119
Stamping	.074	.054	.147	.275
Elevating and separating	.036	.011	.031	.078
Tube milling	.039	.103	.138	.280
Concentrating	.043	.006	.007	.056
Settling	.026	.065	...	.091
Agitating	.129	.539	.104	.772
Filtering and discharging	.087	.053	.081	.221
Precipitating	.039	.076	.029	.144
Refining	.028	.043	...	.071
Water pumping	.026	.003	.013	.042
Steam heating	.060	.183	...	.243
Mechanical department	.027	.002	...	.029
Water	...	.245	...	.245
Assaying	.016	.002	...	.018
Superintendence	.050	...	...	.050
Total	$0.759	$1.406	$0.569	$2.734

The extraction by concentration was 31.2 per cent for gold and 17.8 per cent for silver; by cyanidation, 64.5 per cent for gold and 74.4 per cent for silver; total, 95.7 per cent for gold and 92.2 per cent for silver. Cyanide consumption was 2.08 lb. per ton milled, as against 3.22 lb. per ton in the preceding year. An improvement in filtering slime was made by the adoption of the Osgood filter, designed by Mr. C. G. Osgood, mill superintendent.

The Iron and Steel Market

The situation in the iron industry as a whole is a difficult one to analyze. The steel trade proper shows continued improvement. Although production and shipments of steel products have been heavier in June than in May, the shipping orders received are stated to be in excess of shipments, and with much railroad material under contract but not yet the subject of actual specifications, steel mill operations promise to be still heavier in July, probably at the best rate since 1913. Steel prices, while not sharply advancing, are showing a stiffening tendency, and judging by conditions in their own trade steel makers feel that by August, or September at the latest, the steel mills will be operating at capacity, deliveries will be falling behind and prices will be on a firm basis at above to-day's level.

In striking contrast with this situation in the steel market proper is the fact that three important markets in the general iron situation, scrap, coke and pig iron, are dull and relatively soft. There is no distinct movement in any of them, and prices obtainable are not a particle higher than in December or January. Production and shipments of Connellsville coke are running at 330,000 tons a week, against 200,000 tons a week in December, an increase of 65 per cent, but $1.50 has lately been done for spot coke and a trifle under $1.70 for second half, prices that are if anything lower than what was obtainable in December or January. For two months scrap has been less active than in January, and prices are a shade lower. In pig iron there has been only a moderate volume of business, and indications now are that buyers are covered practically to the end of the year.

The dullness and softness in coke can be attributed to the dullness and softness in pig iron. That eliminates one unknown quantity, but still leaves two unknown quantities with only one equation from which to evaluate them. The only explanation that suggests itself is that since activity in the foundry trade, resulting in activity in pig iron, usually follows an improvement in steel by an interval of no more than a few months, and has now failed when six months or more have elapsed, and since the demand for direct export material and for material for war munitions to be made in this country involves steel rather than iron, the present condition in steel is that the activity is due chiefly to direct export and war demand, affecting steel but not pig iron. This may solve pig iron, but it does not solve scrap.

Intense activity in steel, however, is bound to affect pig iron, by creating a demand for merchant iron on the part of large steel works that are adequately fixed with blast furnace capacity for ordinary requirements, but have additional iron if their mills are to operate at an overload. The steel industry might then absorb enough extra Bessemer and basic iron to make up for the dullness in foundry grades.

Steel mill operations at the close of June are estimated at fully 80 per cent of rated capacity. The Pittsburgh district is operating at more than 80 per cent, while the Chicago, southern and eastern districts, are with a few exceptions, operating at less than 80 per cent. Here

and there mills are beginning to fall behind in deliveries, particularly in merchant bars. Predictions are made that operations will continue to increase, and if they increase much more the delay in deliveries will undoubtedly bring out a latent demand, as it always does, from jobbers and manufacturing consumers, who will see the desirability of laying in stocks to make certain of maintaining their normal operations.

At what rate the steel industry really can operate is an open question. Usually it has been able, upon occasion, to operate at an overload. At present there is some doubt whether the labor supply would admit of operating at ordinary capacity.

Pig Iron

Recent developments suggest that the pig iron market has not as strong a foundation as was assumed. The buying of the past couple months has been better than in immediately preceding months, but a survey of the whole situation indicates that the ordinary buyers, the regular consumers, are fairly well covered practically to the end of the year, while a great deal of speculative iron has been bought, and some large consuming interests are known to have large stocks. One consumer of forge and foundry grades is credited with 100,000 tons lying at its various plants. The furnaces in operation may be fairly well sold up. It may even be granted that they are fully sold up to the end of the year, still justifying the observation that the furnaces operating represent no more than about 60 per cent of the merchant capacity, and raising the question, whence is demand to arise to improve the market? We quote No. 2 foundry, delivered Philadelphia, $14.25 to $14.50; f.o.b. furnace, Buffalo, $12.50 to $13; delivered Cleveland, $13.25; f.o.b. furnace, Chicago, $13 to $13.25; f.o.b. Birmingham, prompt, $9.50; third quarter and second half, $9.75; at valley furnaces, 95c. higher delivered Pittsburgh; Bessemer, $13.75; basic, $12.65 to $12.75; No. 2 foundry, $12.75 to $13; gray forge, $12.50; malleable, $12.75.

Steel

Consumers are well covered for billets and sheet bars and the regular market is quiet, but with a very decided undertone of strength. The Carnegie Steel Company recently withdrew from the domestic market, and several recent export orders taken by the Steel Corporation have been placed at Chicago and Birmingham mills instead of the Carnegie mills at Pittsburgh. It is even reported that the Carnegie Steel Company has been a buyer of steel from other mills to apply on its contracts. We quote billets at $19.50 to $20 and sheet bars at $20 to $20.50, f.o.b. maker's mill, Youngstown, and 50c. to $1 higher delivered Pittsburgh, the lower quotations referring to prompt shipment and the higher to shipment over third quarter. Rods are $25, Pittsburgh.

Finished Steel

Prior to the middle of June the large mills were all quoting 1.20c. on bars, plates and shapes for prompt shipment and 1.25c. on contracts for third quarter, while several small plate mills were quoting 1.15c. and less on plates. On June 14 the Carnegie Steel Company withdrew its lower price entirely and since then the other large mills have been gradually working up to the higher level, while the small plate mills have firmed up to 1.15c. as minimum. Indications are that bars and shapes will be firm at 1.25c. for third quarter and 1.30c. for fourth quarter, while plates may work up to 1.20c. or possibly 1.25c., depending largely upon railroad buying of cars. June 15 steel boiler tubes were advanced one point or about $2 a ton. June 1 galvanized steel pipe was advanced five points and June 17 six points more, a point being nominally 95c. per net ton. Galvanized sheets have worked up to a minimum of 5.00c., with as high as 6.00c. sometimes quoted, while there are few sellers. The differential on galvanized wire, formerly 40c. per 100 lb., has advanced at various times this year until it is now 80c., with mills usually limiting the tonnage they will accept. These advances were occasioned by the flight of spelter, to 26c. to 27c. on June 4, and are based upon a spelter cost somewhat exceeding 20c., but after the high point was reached June 4, spelter began declining and crossed 20c. on June 17. Whether it will eventually find a level above or below 20c. no one ventures to guess.

Current quotations are as follows for ordinary deliveries, f.o.b. Pittsburgh, unless otherwise noted:

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.15c. to 1.25c.

Shapes, 1.25c.

Steel bars and bands, 1.25c., base; hoops, 1.25c. to 1.30c., base.

Iron bars, 1.20c. to 1.25c, Pittsburgh; 1.17½c. to 1.22½c., Philadelphia; 1.15c. to 1.20c. Chicago.

Sheets, blue annealed, 10-gage, 1.35c.; black, 28-gage, 1.75c.; galvanized, 28-gage, 5.00c. to 5.50c.; painted corrugated, 28-gage, 1.95c.; galvanized corrugated, 28-gage, 5.05c. to 5.55c.

Tin plate, $3.10 to $3.20 for 100-lb. coke.

Steel pipe, ¾ to 3-in., black, 79 per cent off list; galvanized, 57½ per cent off list.

Steel boiler tubes (less than carloads), 3½ to 4½ in., 73 per cent off list.

Structural rivets, 1.50c.; boiler rivets, 1.60c.

The Western Trip and the Los Angeles and San Francisco Meetings of the American Institute of Chemical Engineers

The party of the American Institute of Chemical Engineers will leave New York on Friday, Aug. 6, via Pennsylvania Railroad at 5.04 p. m.; leave Chicago on Saturday, Aug. 7, via Santa Fé, and arrive on Monday, Aug. 9, 7 a. m., at Colorado Springs, where Monday and Tuesday will be spent (trips to Cripple Creek, Pike's Peak, etc.). The party leaves Colorado Springs on Tuesday, 6.45 p. m., and arrives at the Grand Canyon on Thursday 1.50 a. m. Thursday will be spent in sightseeing in the canyon. The train leaves Grand Canyon Thursday, 8 p. m., and arrives in San Diego on Friday, Aug. 13, 6 p. m. Saturday and Sunday will be spent in San Diego in visiting the exposition. The party leaves San Diego Sunday, 11.59 p. m., and arrives at Los Angeles on Monday, Aug. 16, 3.30 a. m.

LOS ANGELES MEETING

Monday, Tuesday and Wednesday, Aug. 16, 17, 18, will be spent in Los Angeles. For Monday a trip to Redondo Beach (oil-burning power plant), San Pedro Harbor (salt plant and kelp industry), Long Beach, Huntington Beach (beet sugar factory) and Santa Ana has been arranged, for Tuesday a trip to Catalina Islands. Monday evening the mission play at Alhambra will be visited. Various optional trips have been arranged for Wednesday, while on Wednesday evening a joint meeting will be held with the Southern California section of the American Chemical Society.

On Thursday, Aug. 19, 7.25 a. m., the party will leave Los Angeles for San Francisco. Stops will be made at Santa Barbara (or Oxnard beet sugar factory) and Del Monte and the Yosemite Valley may be visited for three days.

SAN FRANCISCO MEETING

Wednesday to Saturday, Aug. 25 to 28, will be devoted to the meeting at San Francisco. On Wednesday afternoon an excursion will be made to the Protrero oil gas works, on Saturday an excursion to the Winehaven vineyard and wineries. The program of the technical sessions is as follows:

Wednesday, Aug. 25, 11 a. m., at Civic Center Auditorium, San Francisco:

A. M. McAfee—"The Improvement of High Boiling Petroleum Oils and the Manufacture of Gasoline as a Byproduct Therefrom by the Action of Aluminium Chloride."

Arthur L. Lachman—"Wine Making."

Thursday, Aug. 26, 10 a. m., at University of California, Berkeley:

Ralph A. Gould—"Costs as Applied to Professional Businesses."

Edgar Baruch—"Resources and Possibilities of the Chemical Industry in the Southwest."

Otto Best—"Manufacture of Cream of Tartar."

Friday, Aug. 27, 10.15 a. m., at Leland Stanford University, Palo Alto:

S. W. Young—"Present State of the Thiogen Industry."

Edward Bartow—"Purification of Sewage by Aeration in Presence of Activated Sludge."

Walter A. Schmidt—"Electrical Precipitation Method."

Members of the party will have the option of going from San Francisco to Seattle either by rail or partly by steamer to attend the Seattle meeting of the American Chemical Society for one day, on Thursday, September 2. On the evening of the same day the party will start on the return trip, which includes a stop at Butte and Anaconda (Saturday and Sunday, Sept. 4 and 5), and a visit to Yellowstone Park (Monday to Saturday, Sept. 6 to 11).

The party will leave Yellowstone Park at Gardiner on Saturday, Sept. 11, 7.15 p.m., and is due in New York on Sunday, Sept. 19, 7.57 a.m.

Dr. John C. Olsen, Cooper Union, New York City, is the secretary of the Institute.

The Western Trip of the American Chemical Society

As has already been announced, the autumn meeting of the American Chemical Society will be held in Seattle, Washington, from August 31 to September 2.

The following trip by special train has been arranged to take the Eastern members to Seattle:

The train leaves *Chicago* on Thursday, August 26, at 5:05 p. m., via Chicago & Northwestern Railway, arriving at St. Paul, Minn., on August 27, at 5 a. m., and leaving 30 minutes later via Great Northern Railway. It passes through the scenic lake park country of Northern Minnesota and the immense grain fields of North Dakota and Eastern Montana.

Glacier Park Station is reached on Saturday, August 28, at 2 p. m., and Saturday afternoon and Sunday are spent in the *Glacier National Park* (automobile trip on Saturday afternoon through the Two Medicine and Cut Bank Valleys to the St. Mary Camp and launch ride on the Lake St. Mary. The night is spent at the Going-to-the-Sun Camp. On Sunday return launch ride to St. Mary Camp and automobile trip through the Sherbourne Lake country to Many Glacier Camp.)

The train leaves Glacier Park Station on Sunday afternoon (August 29) and arrives in *Seattle* on Monday afternoon, 6 p. m. Tuesday, Wednesday, and Thursday (August 31 to September 2) are spent in Seattle attending the American Chemical Society meeting.

Seattle is left on the evening of Thursday, September 2, at 11:55 p. m. The train arrives on Friday, September 3, at 4:35 a. m., at Ashford, from where the trip to the *Mount Rainier Park* is made. From the National Park Inn at Mount Rainier several side trips may be made during the day.

The train leaves Ashford the same afternoon at 4:35 and arrives in *Portland* on September 4, at 6 a. m. The whole of Saturday is allowed for sightseeing in Portland. The train leaves Portland 8:15 p. m. and is due in *San Francisco* on Sunday evening, September 5.

It is of the utmost importance for the success of this trip that the Secretary of the American Chemical Society, Dr. Charles L. Parsons, Box 505, Washington, D. C., be informed as soon as possible by those members who want to join in the trip.

Special Trains of Civil, Mining, Mechanical, and Electrical Engineers to International Engineering Congress

Two special trains have been arranged jointly by the American Society of Civil Engineers, the American Institute of Mining Engineers, the American Society of Mechanical Engineers, and the American Institute of Electrical Engineers, in connection with the International Engineering Congress.

The first train will leave New York (Grand Central Terminal) on Thursday, September 9, at 7.45 p. m. and arrive at San Francisco on Wednesday, September 15, at 9 p. m. A 4-hour stop will be made at Niagara Falls (Sept. 10), a 12-hour stop at Colorado Springs (Sept. 12), and a 15-hour stop at the Grand Canyon, Arizona (Sept. 14).

The second train—or at least a number of special cars on the Sunset Limited—will leave New Orleans on Sunday, September 12, 11 a. m., and arrive at San Francisco on Wednesday, September 15, 1 p. m.

Members of the societies of Civil, Mining, Mechanical, Electrical Engineers and Naval Architects, whether members of the Congress or not, and members of the Congress, whether members of any of those five societies or not, will be welcome to join these special trains. Mr. Charles Warren Hunt, 220 West 57th Street, New York City, is the secretary of the joint committee on reception and transportation.

The Western Trip of the American Electrochemical Society

The Fall meeting of the American Electrochemical Society will be held in San Francisco on Thursday, Friday and Saturday, September 16, 17, 18, 1915; that is on the same dates as the meetings of the civil, electrical, mechanical, and mining engineers, and at the close of the week, immediately preceding the International Engineering Congress. Arrangements have already been made for joint sessions with the Electrical Engineers and the Mining Engineers.

Mr. J. M. Muir, 239 W. 39th Street, New York City, has been appointed chairman of the transportation committee. It is the intention to arrange a number of special cars for members and friends of the American Electrochemical Society, to go by as cool a route as possible directly to San Francisco, to arrive there on Wednesday, September 15. The return trip may be made as desired, and the stops for sight-seeing would be made on the return trip.

To those members of the American Electrochemical Society who want to include sight-seeing stops in the outgoing trip, two opportunities are afforded.

The American Chemical Society has extended a cordial invitation to members of the American Electro-

chemical Society to join in the special train which carries the former society to its meeting in Seattle. (See program, page 419.)

The special train of the four engineering societies for San Francisco may be used by those who are either members of the Mining or Electrical or Mechanical or Civil Engineers, or are members of the International Engineering Congress. (See itinerary, page 419.)

The Corrosion Problem Before the American Iron and Steel Institute

The meeting of the American Iron and Steel Institute, held in the Hotel Waldorf in New York on Friday, May 28, 1915, brought out quite a number of able and interesting papers, on "Blast Furnace Advancement," by Andrew E. Maccoun, on "Merchant Rolling Mills" by Jerome R. George, on "The Commercial Production of Sound and Homogeneous Steel" by Edward F. Kenney, on "Wash Boiler Heaters" by Charles J. Bacon, and on "Recent Progress in Corrosion Resistance" by Daniel M. Buck. The last paper elicited a long discussion.

Mr. **Daniel M. Buck,** who is metallurgical engineer of the American Sheet & Tin Plate Company, reported on several years' exposure tests of full-sized sheets, unprotected in any way, under service conditions.

"The influence on corrosion of carbon, manganese, phosphorus, and silicon in the amounts normally present in properly made steels and irons is practically negligible. In a steel without copper, high sulphur content stimulates corrosion. A copper content of 0.25 per cent materially increases the life of steel and iron, and the harmful effect of sulphur up to at least 0.14 per cent is neutralized by 0.25 per cent copper. More copper, up to 2 per cent, gives little, if any, additional benefit. Lesser amounts than 0.25 per cent have great influence in lowering the corrosion rate. A content of 0.15 per cent is in most cases quite as good as 0.25 per cent, and tests now under way prove that much lower amounts, down to as little as 0.04 per cent and 0.06 per cent, while not giving the best results, are superior to normal steels carrying only the usual traces of copper."

Dr. **Allerton S. Cushman,** director of the Institute of Industrial Research, Washington, D. C., opened the discussion, representing the opposite side. In his opinion "Mr. Buck's tests on which he bases his conclusions are open to criticism both in their conduct as well as in the interpretation of the results obtained."

"Mr. Buck in his paper sounds the warning that the benefits he claims accrue only if the copper is properly added to molten steel. About 0.2 per cent of benzoate of soda has been used to preserve and make salable very bad tomato catsup, but its presence cannot turn bad and dirty stuff into good and clean food. In my opinion, precisely the same thing is true of 0.2 per cent of copper in steel."

"At my original suggestion, the corrosion committee of the American Society for Testing Materials is about to undertake a series of systematic weather exposure tests on large corrugated sheets of 16 and 22-gauge iron and steel of all types now available in the open market. These sheets are not to be pickled and only a portion of the heavier gauge are to be sand-blasted. Until these authoritative and unbiased tests can be reported on, it is my belief that such sweeping claims as Mr. Buck has made in his paper are quite unjustified. My own opinion, based on what I consider the most reliable data yet available, is that in metals, as in food, purity is the safest criterion of excellence."

Mr. **James O. Handy,** director of the chemical laboratories of the Pittsburgh Testing Laboratory, sustained the exactness of Mr. Buck's tests.

"We feel certain that in some way the accelerating effect upon corrosion exercised by sulphur in steel is entirely inhibited by the addition of copper. The most probable theory is that copper unites with the sulphur and the copper sulphide dissolves in the excess copper, and the mixture dissolves in the steel itself. The sulphide of copper is not as readily oxidized as sulphide of iron or sulphide of manganese, and copper itself is extremely weather resistant. The steel, therefore, is far less readily oxidized than when the sulphides of iron or manganese are present in the steel."

"The critical percentage at which copper begins to control the corrosion of steel is between 0.03 per cent and 0.04 per cent. The difference is very striking. The corrosion rate is 100 per cent higher in the case of steels or irons containing less than 0.03 per cent copper, as compared with those containing over 0.04 per cent."

Dr. **Wm. H. Walker,** professor of chemical engineering of the Massachusetts Institute of Technology, emphasized that according to the electrolytic corrosion theory metal plus water yields metal hydroxide plus hydrogen; there are therefore four factors to be considered, and some adherents of the electrolytic theory err in considering only the effect of the metal and neglecting the effect of the other factors, the hydroxide and the hydrogen. A complete theory should pay attention to the influence which the other ingredients—not iron—may have on the solution pressure of the iron or upon the depolarization of the hydrogen or on the character of the iron hydroxide formed. His own experiments substantiate Buck's results. He has found that the film of iron hydroxide or rust which forms on a surface of copper steel is much denser and depolarizes much more slowly than does that on any other type of iron or steel.

Dr. **John S. Unger,** metallurgist of the Carnegie Steel Company, confirmed Mr. Buck's results on the beneficial effect of copper in steel. He believed that Mr. Buck's exposure tests were imitations of the conditions in actual practice, as far as this is possible.

Mr. **G. H. Charls,** vice-president of the American Rolling Mill Company of Middletown, Ohio, said it was "indeed very gratifying to observe that Mr. Buck has proved so conclusively in his table that No. 27-gauge pure iron has at least twice the life of steel. No one can justly accuse the author of this paper of being an ardent advocate of pure iron. This truth becomes more remarkable when you are informed that 27-gauge black pure iron is not even advocated by its producers because it cannot always be rolled satisfactorily. This is explained by the fact that pure iron is so soft, so ductile and welds so readily that the 27-gauge sheets stick fast together in rolling and are often damaged when torn apart.

"Due to the courtesy of Mr. Buck, a sheet taken from this lot which was to be tested came under my observation. In measuring the thickness of this sheet, it proved to be nearer 28 gauge than 27 gauge in many places, due to the difficulty of obtaining a uniform gauge in rolling such light material. It is therefore doubly gratifying to note the splendid record made by this light weight 27-gauge pure iron, pickled before it was tested to almost a tissue paper thickness, made under protest and against the advice of its producers and in every way unworthy of being considered a representative product by any fair-minded person.

"If under such adverse conditions pure iron outlasts steel two to one, it must be conceded that the claims made for this product have been thoroughly substantiated and sustained. This would be very welcome information to the thousands of purchasers of pure iron if they were not already aware of the intrinsic value of this product and its superiority to steel from the standpoint of resistance to corrosion."

Cyanidation of Low-Grade Sulphide Ores in Colorado—I

BY H. C. PARMELEE

Clear Creek and Gilpin Counties

On the eastern slope of the Rocky Mountains in Colorado, Clear Creek, Gilpin and Boulder form a trio of contiguous counties in which the earliest mining operations in the State began. Profitable mining and metallurgical treatment in this mineral empire date back to 1859. Since that time production has been continuous, with varying fortunes to individual operators, but on the whole successful and with great credit to the several districts and to the State. In general, the metallurgical treatment of the ores has followed the practice first established, amalgamation and concentration, or smelting. The milling practice has been the subject of unfavorable criticism, some of it warranted but much of it superficial and without a full knowledge of the economic conditions. Undoubtedly the metallurgical losses in concentration have been large; but the flotation process which is now being applied at some of the oldest mills should make possible an additional economic recovery of minerals hitherto lost.

Proposals to introduce modern cyanide practice in Gilpin and Clear Creek counties have been made periodically for the past five years. In 1911 Draper and Gross made exhaustive experiments on Gilpin county ores, the results of which indicated the possibility of successful cyanidation. In 1912 the Hudson mill at Idaho Springs added cyanidation to amalgamation and concentration. Little or no metallurgical difficulty was encountered, but for economic reasons cyanidation was abandoned. The practice was described in this journal at the time the mill was in operation.[1] In 1913 the Argo mill was constructed, and a treatment process adopted similar to that used at the Hudson. After a few months' operation, however, this plant also was closed, and it appeared as though it were impossible to apply the cyanide process profitably to Clear Creek and Gilpin ores. Nevertheless, the mill was started again under new and competent management and has been in continuous operation for eighteen months, demonstrating the metallurgical and economic success of cyanidation in this district.

Difficult Problems at the Argo Mill

It would be difficult to imagine more exacting and trying metallurgical conditions than those existing at the Argo mill. The mill is operated on a custom basis, sampling and buying ores as offered. There are no ore contracts, which would be of little value if they existed, for the ore supply comes mainly from leasers whose operations are irregular. Shipments are received in small lots ranging from 5 to 75 tons each, and averaging perhaps 15 or 29 tons. Frequently these lots are sampled and actually milled before assays can be made to determine their value. One lot may be of value mainly for its gold content, while the next is rich in silver. The ratios of concentration of successive lots may range from 2:1 to 25 or 30:1. Ores producing slime of fair settling rate follow those that are exceedingly difficult to settle, while the values of successive lots may range from $3 to $50 or more per ton. The sand tailings from some of the ores could be discarded without economic waste, and thus avoid the cost of regrinding; but in other instances the value of the sand necessitates regrinding in order to make an economic recovery.

Coupling these conditions with irregular and unexpected deliveries of ore, the necessity of satisfying the shipper by immediate sampling and settlement, and the impracticability of bedding ores in order to secure uniformity in mill feed, we find about as unfavorable conditions for cyanidation as could be imagined. Such conditions as these are unknown at a mill serving a single mine, where reasonable uniformity in quantity, quality and value of the ore can be expected, and where conditions of treatment can be determined and fixed by preliminary tests.

Preliminary testing at Argo has proved futile, for by the time the metallurgist may have discovered and solved a problem presented by a certain ore, production of that ore may cease. In view of these facts it is not surprising that the details of milling have undergone decided changes since operations first began, and even within the history of the present management. Hence, previously published accounts of the practice[2] do not adequately represent present operations.

Location and Construction

The Argo mill, shown in Fig. 1, is situated near the mouth of the Argo tunnel, from which the greater part of the ore supply comes. While the location is convenient with regard to delivery of ore, disadvantages have developed from the erection of the mill on a waste dump. In some parts the original excavation was not deep enough to insure solid foundations, with the result that subsequent settling dislocated part of the equipment, entailing additional expense and loss of time. Another difficulty developed due to uneven surfacing of the concrete mortar blocks, making it impossible to secure the mortars firmly on their foundations. This was overcome by loosening the bolts and calking the seams with oakum, after which the mortars could be held firmly on their foundations.

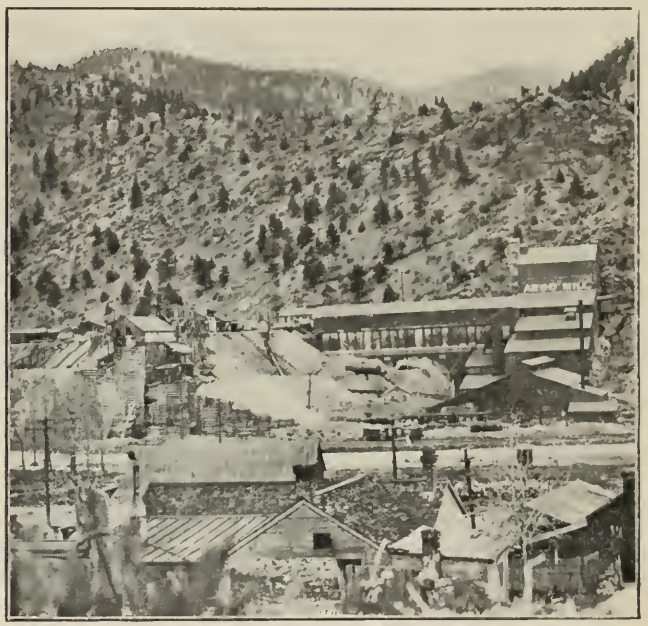

FIG. 1—THE ARGO MILL

These troubles have now been largely overcome, and in all recent work special precautions have been taken to secure solid footings. The foundation for a tube-mill recently installed is a solid concrete monolith, reinforced with steel rails with the ends bent upward into the piers which support the bearings. The mill building is of modern steel construction with concrete

foundations and floors. Argon-filled tungsten lamps are used for artificial lighting and give excellent satisfaction.

Coarse Crushing and Sampling

An accurate sampling plant is necessary in order to evaluate properly the numerous lots of ore purchased. Ore is delivered in 3-ton cars, three of which can be accommodated in a revoluble tipple that traverses tracks above a series of twenty-two individual storage bins. When a shipment is completed the ore is drawn from the bin onto a pan conveyor running the full length of the bin house, and delivered to the sampling plant. The latter is of approved modern type, in which a fraction of the lot is successively crushed and split until a suitable sample is obtained. The reject passes to an elevator and is delivered directly to the battery bins by

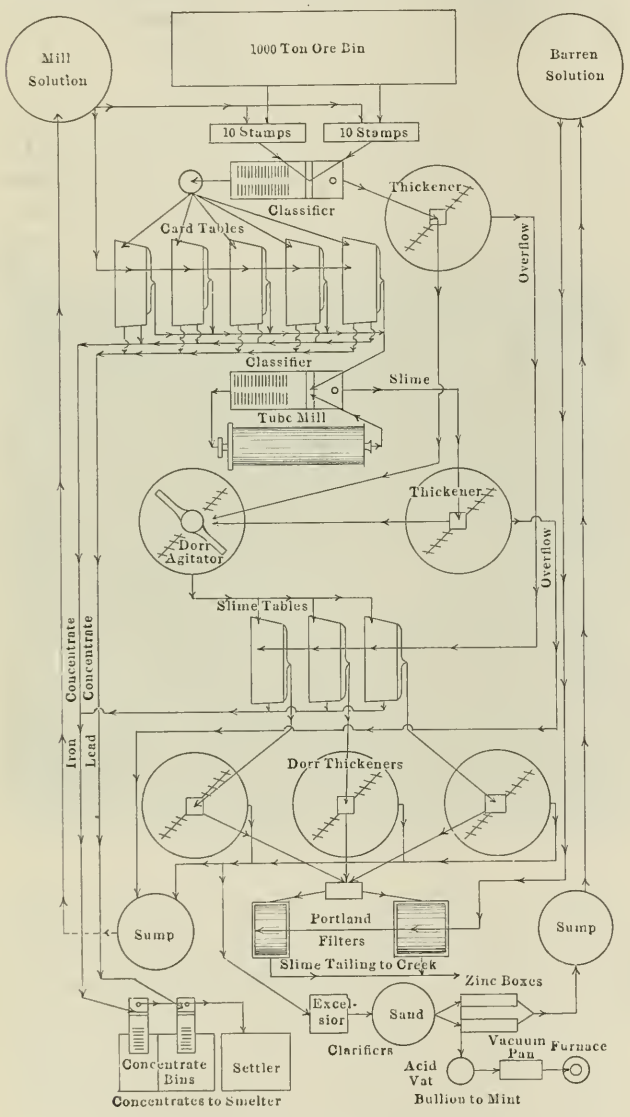

FIG. 2—FLOW-SHEET ARGO MILL

means of a conveyor and traveling tripper. This relation of the sampling plant to the mill explains why it is necessary to treat the ore as it comes, as well as the possibility of completing the treatment of a small lot before its value is known.

Flow-Sheet

The flow of the ore through the mill is outlined in Fig. 2. Briefly, the process includes stamping in cyanide solution; primary concentration to remove lead, iron and copper sulphides; regrinding the sand tailing in a tube-mill; agitation; secondary concentration to remove the sulphides unlocked in regrinding; thickening, filtration and precipitation.

The stamps are of 1050-lb. weight, dropping 108 times per minute through a height of 6 in. A heavy stamp is not required to crush those ores from which the coarse-grained sulphides are readily unlocked for concentration, while tube-milling is essential to release the minerals from the harder silicified ores. Stamp shoes and dies are of chrome steel, and the latter are sectionalized for the purpose of reducing the consumption of metal represented in discarded parts. The upper portion of the die is wedged into the lower, care being taken to get it in place evenly so that a horizontal wearing surface will be presented to the shoe. A brief experience with these sectionalized dies indicates that the upper section can be worn very thin before it is discarded. Ton-cap screens equivalent to sixteen-mesh are used on the batteries, and in crushing to this size the twenty stamps have a capacity of 120 tons per day.

The ore is crushed in cyanide solution, and the battery discharge is classified into sand and slime in a Dorr duplex classifier. The sand is treated without further classification on card tables, producing lead and iron concentrates and sand tailing. This primary concentration removes the major portion of the gold-bearing sulphides from the pulp. A secondary concentration of the slime after regrinding and agitation completes the separation of sulphides as gravity concentration can do so.

Protection of Table Decks

For the protection and preservation of the linoleum decks on the concentrating tables, a satisfactory material has been found in P & B paint diluted one-half with carbon disulphide. The paint can be used at normal consistency, but comparative tests at this mill have shown that it does not penetrate the linoleum as well as when diluted. The paint is applied hot and forms more than a mere superficial coating on the linoleum.

The lead and iron concentrates are finished products, and are dewatered, stored in bins and shipped to the smelter. The separation of the two concentrates on the tables is made with reference to their relative gold contents rather than to that of the base metals, and is governed wholly by economic considerations. The most favorable smelter rates apply to a 5-oz. gold concentrate, for which payment is made at the rate of $20 per ounce of gold. At the same time it is desirable to keep the grade of above 5 per cent lead if the most favorable treatment charge is to be obtained. Hence enough pyrite is cut into the galena to produce these conditions in the lead concentrate,and the balance is recovered as an iron concentrate carrying about 1 oz. gold per ton.

All-Sliming Following Concentration

Several methods have been in effect for the treatment following primary concentration. Originally the sand tailing was discharged as waste, being first washed with barren solution and water, and finally dewatered, in a Dorr three-deck classifier. While this practice was suitable to ores which yielded readily to concentration after coarse crushing, it was untenable with others on account of the high gold loss sustained in the finely disseminated sulphides that were not unlocked in stamping. Later a double flow-sheet was adopted, in which sand tailing from ores of the first class was washed, dewatered and discharged, while middling from the second class was reground in a tube-mill. Finally the practice was adopted of sliming all sand tailing from primary concentration, and for this purpose a new tube-mill, 5 ft. by 16 ft., was added.

The tube-mill is in closed circuit with a second Dorr duplex classifier. El Oro lining is used and the grinders

are imported Danish and French pebbles. Pebble consumption is 3.5 lb. per ton when the plant is running at full capacity, but rises with decreased tonnage.

The slime leaving this second classifier is thickened and combined with a similar product from the first classifier, and subjected to agitation. Cyanide is added at the agitator. The agitation process is continuous in a single Dorr agitator. After agitation the pulp is again concentrated, the mineral product being combined with the primary iron concentrate. The wash water used on the secondary tables is the overflow from the primary thickener, and serves to wash and dilute the pulp flowing to the final thickeners.

Diaphragm Pumps for Pulp Transfer

The transfer of slime pulp from thickeners to agitator and filters is accomplished by diaphragm pumps. The general advantages of this type of pump for maintaining uniform conditions as to quantity and density of pulp transferred have become well known. Their use in the cyanide process has led to the development of certain desirable features not usually found. An improved pump for this purpose, now in use at the Argo mill, is shown in Figs. 3 and 4, being the design of Mr. Henry Eggers of the Mine and Smelter Supply Company. It is adjustable, while running, from zero to full stroke, thus permitting an instant change in capacity without changing speed. The rocking motion usually imparted to diaphragms, and which is so destructive to long service, is eliminated by applying a vertical stroke to the diaphragm. Plunger guides and other moving parts are protected against undue wear from grit and slime. Suction may be applied from either side or from the bottom. For convenience in changing diaphragms the upper portion of the pump is hinged to the lower and can be thrown back after loosening the eye-bolts.

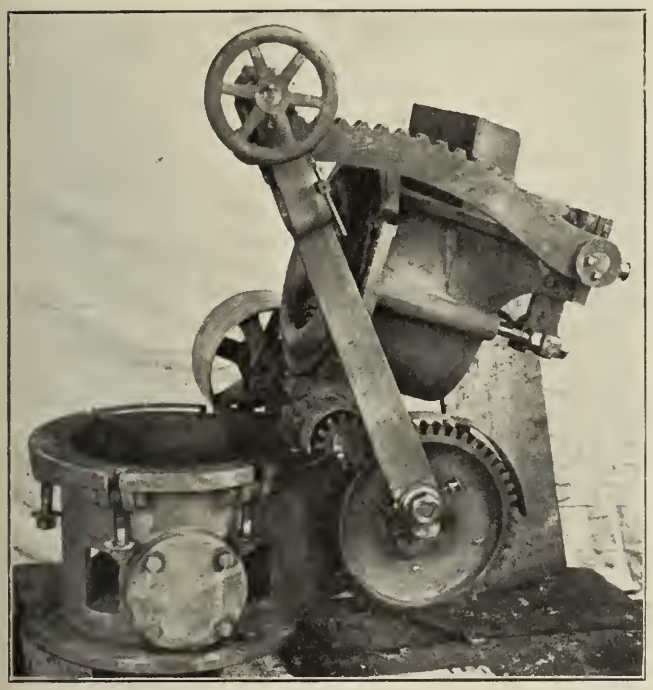

FIG. 3—DIAPHRAGM PUMP—OPEN

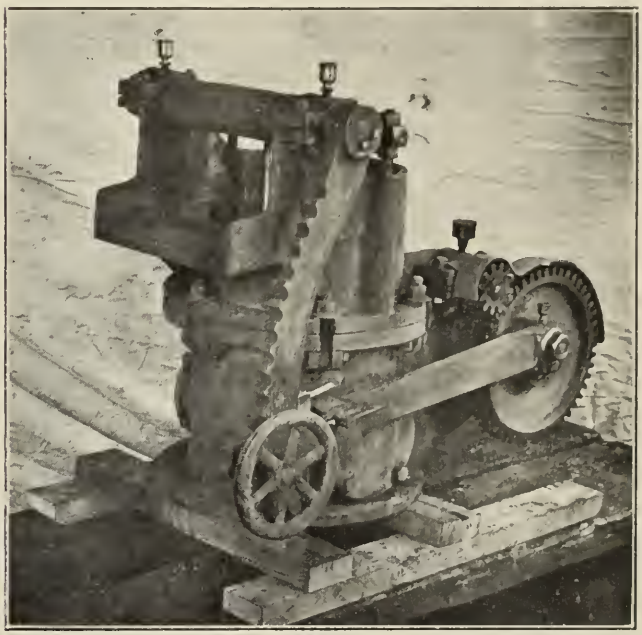

FIG. 4—DIAPHRAGM PUMP—CLOSED

Filtration of Slime

The slime tailing from secondary concentration flows to three Dorr thickeners operated in parallel. The overflowing solution is clarified and precipitated, and the thickened underflow is filtered on Portland revolving filters. Filtration was not a part of the original mill scheme, but was added by the present management after long and careful tests on the feasibility of treating these ores by continuous counter-current decantation as first attempted. As a class, the ores produce a slow-settling slime, rendering continuous decantation difficult in most cases and impossible in others, assuming a reasonable settling area per ton of material treated. This gave rise to muddy overflows and dilute underflows from the thickeners even when operated at much less than normal capacity. Considering the lack of uniformity in mill feed it is not surprising that a process which has proved so successful in many instances was not feasible here. The experience probably would have been avoided by more careful preliminary tests.

The filters give excellent satisfaction, successive washes of barren solution and water reducing the loss of dissolved gold to a negligible quantity. A vacuum of 18 or 19 in. is maintained. Little trouble is experienced in keeping the filter fabric clean and porous. Instead of giving the entire filter an acid wash at long intervals, one or two sections are treated daily with a dilute solution of hydrochloric acid, scrubbing the fabric with whiskbrooms. This method avoids the necessity of periodically removing the slime from the filter tank in order to give the entire filter an acid bath. It also eliminates acid-storage tanks and means for transferring acid solutions.

The quantity of circulating mill solution is kept constant by the addition of the requisite amount of water in the final wash on the filter.

Clarifying Solutions Before Precipitation

The marked effect of clear solutions on the efficiency of precipitation has been well exemplified at this mill. Since adopting adequate means for clarifying the pregnant solution, the earlier difficulties in precipitation have been entirely overcome. The solution flowing from the three final Dorr thickeners is passed successively through excelsior and sand clarifiers. The former consists of about 750 cu. ft. of excelsior packed in a rectangular tank having a false bottom. The solution is introduced beneath the excelsior and flows upward. The excelsior is cleaned about once in two months and re-

packed. The sand filter is about 4 ft. deep, being deeper than is usual for such purposes. Every four to six weeks a 6-in. layer of sand is removed, thoroughly washed and replaced. Previous to the adoption of these methods considerable difficulty was experienced in precipitation, chiefly in the efficiency of the operation and the grade of precipitate produced. The latter has been raised from as low as $1.50 to $40 per pound. The value of the zinc-box head solution is about $1 per ton. The tail solution has a value of about ten cents per ton.

The solution is precipitated on zinc shavings in two three-compartment boxes. No lead acetate is used, neither is any lead shaving added to the zinc. The rate of precipitation is about two tons of solution per ton of ore, when running at full mill capacity. In making the clean-up the work is done as rapidly as possible to avoid long exposure of the zinc to air. No attempt is made to effect a complete clean-up of the precious metals, as it has been found favorable to good precipitation to leave some gold on the zinc. On account of the appreciable quantities of copper in some of the ores the solution contains about 0.03 per cent copper, and this tends to lower the grade of the bullion. Until recently the bullion marketed has contained from 15 per cent to 25 per cent copper, but this has been reduced to about 1 per cent as the result of a refining process evolved by Mr. Jackson A. Pearce, metallurgist for the company. For sufficient reasons the details of the method have not yet been made public, but the benefits are very apparent.

Warm Solutions Aid Extraction

Gold and silver are the metals of principal value in the ores treated. In general, it may be said that 40 per cent of the silver in the ores is not amenable to cyanidation, but a good recovery is made by concentration. Altogether an average extraction is made of slightly over 90 per cent of the value of the gold and silver. Some lead is recovered, but there is no attempt to save zinc, nor to make an economic recovery of copper. Both of the latter metals enter into the iron concentrate.

It has been found advantageous to warm the pulp and solution to a temperature of from 60 to 65 deg. F., by means of steam coils and live steam in the thickeners. This temperature has been found to give the maximum benefit with the minimum disadvantage. It will be apparent that, with the variety of ores treated, the effect of temperature is likely to be quite as various. While extraction of silver can be increased at a higher temperature and with stronger solution, the consumption of cyanide by cupriferous ores becomes excessive. Also, the settlement of slime is variously affected by changes in temperature, being improved in the case of some ores and unfavorably affected in others.

The value of the mill feed will range from $5 to $20 per ton; and of the tailing, from $0.85 to $1. The solution in the agitator is kept at a strength of 1.7 lb. KCN per ton, with 0.8 lb. CaO.

The tonnage treated is determined by intercepting the flow of slime pulp to the filters, allowing the full stream to run into a calibrated tank for a definite time and noting the volume. Before settlement can occur, a definite volume is removed, dried and weighed, and the calculation made. This method has been found quite accurate on thick pulps, though not so well adapted to thin ones. In this case the pulp flowing to the filters contains about 1½ parts solution to 1 of solids.

Power Requirements

Electricity is the motive power used throughout the mill. A list of the motors, the machinery driven by them, and recent tests of power consumption are given below. Back-geared motors are used at the stamps.

Rated hp. of motor	Machinery driven	Horsepower consumed
25	Ten 1050-lb. stamps	22.5
50	One 5 ft. by 16 ft. tube-mill	60
5	Four diaphragm pumps, four 20 ft. by 12 ft. thickeners, one 20 ft. by 12 ft. agitator, two Portland filters, two quarter-size Dorr classifiers	2.7
5	Three Card tables, one 22 ft. by 14 ft. Dorr thickener, one duplex classifier	4.8
20	Two elevators, two conveyors and tripper	15
20	Two 12 by 10 vacuum pumps, one 5 by 8 and one 4 by 6 triplex pumps, one 1½ in. centrifugal pump	14
5	Two centrifugal pumps, three Card tables	4
25	In sampler. Pan conveyor, 4-k gyratory crusher, small jaw crusher and three sets small rolls	22

Mill Records

A system of metallurgical records devised to meet the special and varied needs at the Argo mill afford complete information regarding all operations. These are segregated under three main headings: Daily mill sheet, record of ore purchased, and record of products sold. The record sheets are 32 in. by 15 in. in size, each page serving for a month's record. The sheets are too large for reproduction in exact form, but the data can be rearranged from the following tabulations:

Tests conducted at the Argo mill indicate that the concentrates can be profitably cyanided, but at present the mill is not equipped for the work. The silver recovery probably would not exceed 60 per cent, but the gold extraction would be satisfactory. The value of the gold recovered as bullion would exceed its value in the form of concentrate, and the difference would be more than the cost of treatment. The residue from cyanide treatment would still form a low-grade shipping product, and would receive the most favorable treatment rate at the smelter. Balancing all the factors involved, the net result of cyaniding concentrates and shipping the residue to the smelter would show an increased profit as compared with the present practice of shipping direct.

The successful operation of a custom cyanide mill like the Argo depends on exhaustive preliminary tests, both chemical and physical; attention to numerous details; a careful balancing of causes and effects to secure the most economical average conditions, and last, but not least, an assured steady ore supply. The design of a new mill to meet the same conditions at Idaho Springs probably would not vary much from the present plan, which is the result of eighteen months' experience. It is likely that flotation would find a place in the flow-sheet, probably as the final step, concentrating the filter tailing. Secondary concentration after agitation could then be abandoned, and an economic advantage gained by leaving the slimed sulphides in the system to receive the maximum cyanide treatment, since gold in bullion is worth $20.67 per ounce, but only $19 per ounce in a low-grade concentrate. The cost of cyaniding would not be appreciably increased, and the flotation process would act as a final check against loss of partly extracted sulphides.

To Messrs. Richard A. Parker, consulting engineer, Ott F. Heizer, manager, and Jackson A. Pearce, superintendent, who have been responsible for the rehabilitation of the Argo mill, we are indebted for many courtesies extended in the preparation of these notes.

The Monitor Belmont Mining Co. is erecting a concentrating mill to treat silver ore valued at $10 per ton at Belmont, Nye County, Nevada. The ore will be crushed by gyratory crusher, stamps and short tube-mills, the latter being 10 ft. long by 6 ft. diameter. Coarse concentration by gravity methods will be supplemented by oil flotation.

The Testing of Materials is the title of an 89-page booklet issued by the Bureau of Standards, Washington, D. C., dealing with such subjects as metals and alloys, cements, clay products, lime, stone, paint materials, inks, paper, textiles, rubber, leather, oils, chemicals and other materials intended for technical use. The pamphlet, which contains considerable of interest, is distributed free on request.

Copper mining in Cyprus is reported to have been undertaken by an American syndicate from Arizona. Work is to be started at Skouriotissa, about 60 miles from Larnaca. Arizona mining men will compose the operating staff.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in December, 1914, was 63. The total quantity of ore milled during that period was 2,222,430 tons. There were 9807 stamps in operation, with an average duty of 9.03 tons per 24 hours. Tube mills in commission numbered 305. The yield for the month was 695,137 fine ounces gold. The total tonnage milled in 1914 was only slightly greater than in 1913. The yield for 1914 was 8,378,139 fine ounces, compared with 8,794,824 ounces in 1913.

Furnace Curves

BY R. J. WEITLANER

Every step in the direction of reducing the consumption of fuel is not only an economical saving for the individual consumer, but also for the commonwealth at large, on the principle of the conservation of our natural resources. I am referring particularly to the immense amount of fuel used in the production of iron and steel. It is to this industry that the following article is mainly devoted, although it probably has a much larger scope.

Any fuel saving must be based on an accurate account or balance sheet of the fuel consumed in a metallurgical heating or melting process. This should enable the men in charge to judge whether fuel has been saved or has been unnecessarily expended.

Having worked for quite some time on furnaces for heating and melting steel, it occurred to the writer to try to accomplish this by means of so-called "furnace curves." The results were promising, and after plotting the fuel consumption on various heating and melting furnaces, these figures could be brought into certain relations with one another.

The conclusion drawn from a great number of furnaces, covering a sufficiently long period, was that *the fuel consumption of a furnace is a function of the furnace production in a certain time-unit.*

This time-unit can be made an hour, a furnace shift, a day, a week or a month, depending more or less upon the degree of accuracy with which the amount of fuel is or can be measured during said period, and further upon the more or less great regularity with which the furnace is working in this time.

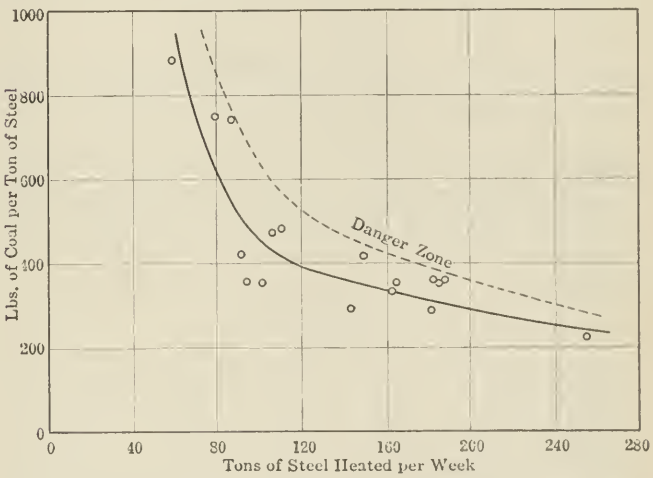

FIG. 1—FURNACE CURVE FOR COAL-FIRED HEATING FURNACE

Fig. 1 gives the furnace curve for a simple coal-fired heating furnace. The abscissas in this figure represent the tonnage produced per week, or more precisely, the tons of steel heated in this furnace during a week. The ordinates give the average fuel consumption for the same period in pounds of coal per ton (2000 lbs.) of steel heated.

Of course other units for production and fuel consumption can be chosen if more convenient as, for instance, pounds of fuel per pound of metal, etc.

The curve shown in Fig. 1 is an actual curve of a direct-fired coal furnace, and was obtained by carefully weighing the amount of coal for a number of weeks, the weekly averages being indicated by points and the curve drawn by taking the mean of all the points. Naturally all the points situated above the curve represent weeks where fuel for some reason or other was wasted:

all the points below indicate weeks where the furnace practice was better than the average.

It may, for instance, occur (see Fig. 2) that during one week we have a fuel consumption P_1 of, say, 1100 lb. per ton of steel at a weekly production of 15 tons, and during another week (P_2) the coal consumption may be 800 lb. per ton, but at a weekly tonnage of 31 tons. Yet in the first case the furnace practice was comparatively better than during the second week, as can easily be seen from the relative position of the two weekly points in reference to the average furnace curve. The saving during the first week over average practice was:

160 lb. $\times$ 15 tons = 2400 lb. of coal.

The loss during the second week amounted to:

80 lb. $\times$ 31 tons = 2480 lb. of coal.

This example should serve to illustrate the usefulness of furnace curves.

The shape of this and similar curves suggests a hyperbolic curve, and we readily see that with a smaller

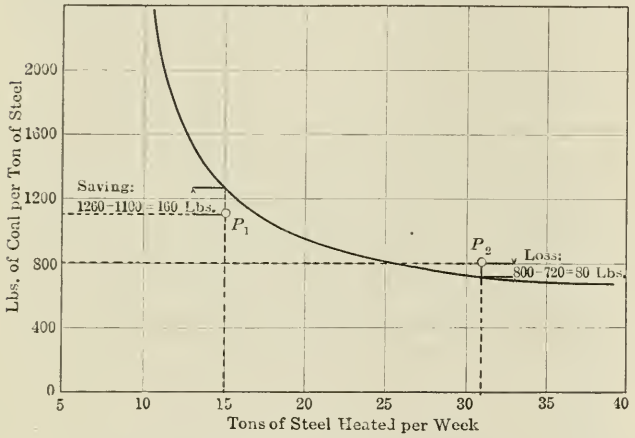

FIG. 2—FURNACE CURVE SHOWING RELATION OF FUEL CONSUMPTION TO WEEKLY OUTPUT

production the coal consumption per ton of metal increases rapidly, or, put into practical words, *we have to allow the furnace-man a higher fuel consumption for a lower production, as indicated by the shape of the curve.*

Construction and Accuracy of Curves Selection of Time Unit

Time and production units are so chosen as to give a well-shaped curve. This will especially be the case if a few points of extremely low and high production are available, that is points with simultaneous high and low fuel consumption, so that the branches of the curve are better defined. The majority of points should not be too far off from the nick or "apex" of the curve. The asymptotes are, of course, represented by the rectangular axes of the co-ordinate system (see Fig. 1).

The shape of the curve suggests at the same time at what production the furnace will work most economically; that is, we find that with decreasing production the fuel consumption increases rapidly, whereas on the other side, with a higher production, the decrease in fuel per ton becomes less and less marked.

The accuracy of the curves depends to a large degree on the accuracy with which fuel and metal is weighed or measured during a certain period. For furnaces heated by means of liquid fuel or powdered coal, where meters and automatic scales are provided, this problem becomes much easier and the resulting figures are more accurate, so that the readings should be made preferably after each twenty-four hours or better at the close of each furnace shift. By doing this we obtain a much greater number of points and the curve may be drawn with great exactness. At the same time the influence of "stray points" becomes less marked and "fake points," caused by errors in figuring, are much easier detected.

If, for instance, the fuel was stored in large piles or bins, the best we can obtain will be weekly points. At the furnace-week's end the floor or the bins will have to be cleaned up or be filled up to a certain level to obtain a fairly accurate fuel figure.

We have two ways of keeping track of the available data. Using as ordinates the fuel consumption per ton

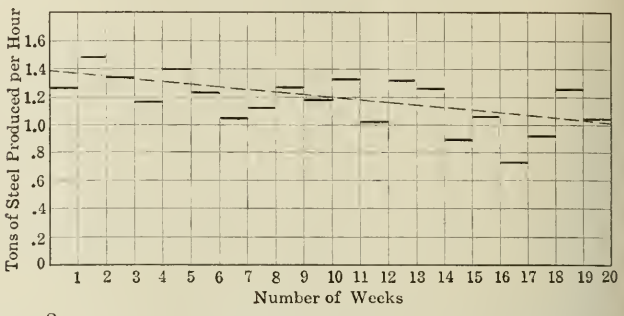

FIG. 3—INFLUENCE OF FURNACE AGE UPON PRODUCTION. ("AGE CURVE.")

of steel, we can either base it upon the entire weekly tonnage as abscissae (Figs. 1 and 2), or we divide the total tonnage by the number of hours the furnace was working and base our fuel consumption upon the tons of metal per hour (Fig. 5). In most cases this latter method will be the more accurate one, particularly if the furnace work is not continuous. With frequent intermissions of non-production or holding, it may even be necessary to deduct such fuel as was used during such intervals. In any case it will be of advantage to trace both curves, the one based upon total production, the other upon the hourly production.

Efficiency and Age Curves

If the temperature varies to which the material is heated, it will either be necessary to draw separate curves for the different temperatures or, better, to replace the fuel consumption by the term "efficiency," as outlined in the article on "comparative furnace efficiency" (see *Metallurgical and Chemical Engineering*, June, 1915, p. 357).

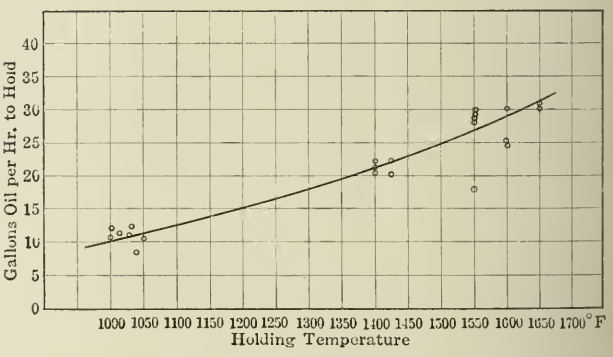

FIG. 4—INFLUENCE OF FURNACE TEMPERATURE UPON FUEL CONSUMPTION FOR OIL-FIRED HEAT-TREATMENT FURNACE

The latter method will particularly be adapted for such furnaces, where the temperature at which the metal is charged is higher than ordinary atmospheric temperature.

For melting furnaces with varying melting stock (pig iron, steel scrap, chrome scrap, etc.), either a number of "special curves" will have to be plotted, or a certain "heat content" *a* (B.t.u. per pound of metal,

see above article) will be agreed upon or determined by experiments and an efficiency curve constructed by means of it.

Such efficiency curves will also be required if, for instance, molten metal is charged into a melting furnace, although in most cases the exothermic reactions of the bath during the oxidizing period will possibly tend to cloud the fuel consumption proper.

Furnaces with a rather limited life, for example, open-hearth or crucible furnaces, will show a gradually decreasing production and increasing fuel consumption. It may sometimes be of interest to follow up this tendency by means of so-called "age curves," giving the furnace campaign week for week as abscissas and the correspondingly dropping production as ordinates (Fig. 3). It will then have to be ascertained how far the fuel consumption is influenced by the age of the furnace, besides such increases as is to be allowed on account of a lower production.

Fuel for Heating Up and Holding

Separate records should be kept of such fuel as is required to keep the furnace at a certain temperature; for instance, in heat-treatment furnaces. In this case the fuel-consumption is preferably expressed by the amount burned per hour and then made a function of the furnace temperature by means of special curves as shown in Fig. 4. Each furnace, of course, will require different amounts of fuel to be kept at a certain tem-

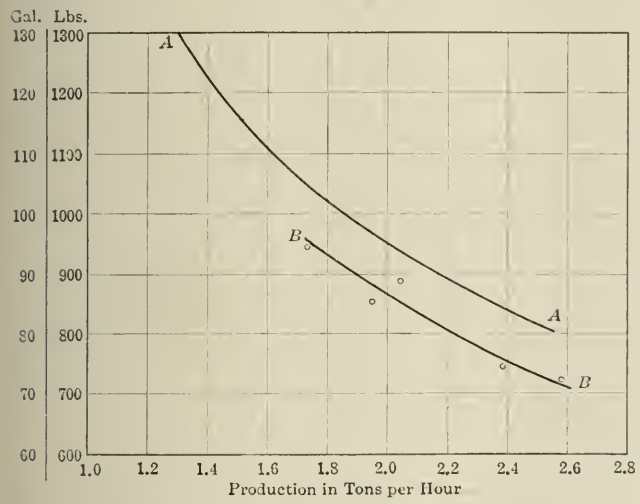

FIG. 5—COMPARATIVE COAL AND OIL CURVES FOR REGENERATIVE MELTING FURNACE OPERATED WITH PRODUCER GAS (A) OR OIL (B)

perature, depending upon the size and construction, etc., of the furnace.

If the fuel consumption per shift is kept separate and the furnace lit up every time at the beginning of the week, allowance should be made for a certain amount of fuel to be agreed on to bring the furnace up to the working temperature. A separate account should be kept of the fuel thus consumed.

Change of Fuel and Fuel Comparison

It may often occur that one and the same furnace having a well-established furnace curve is changed over to another kind of fuel. We will then find that the new fuel curve runs almost parallel to the old curve, being merely raised or lowered according to the lower or higher heating quality of the new fuel. Fig. 5 gives an idea of such curves where a furnace was changed to oil fuel after having been on producer gas for some time.

We have thus an excellent means to compare different grades of fuels as to their "thermic" value on one and the same furnace, even if the production during such periods should be at variance from points of the old fuel curve.

Fig. 6 shows a furnace curve of a coal-fired heating furnace, the average production of which with the old fuel was marked by the ordinate OP_1. The average coal consumption for this production was P_1C in pounds of

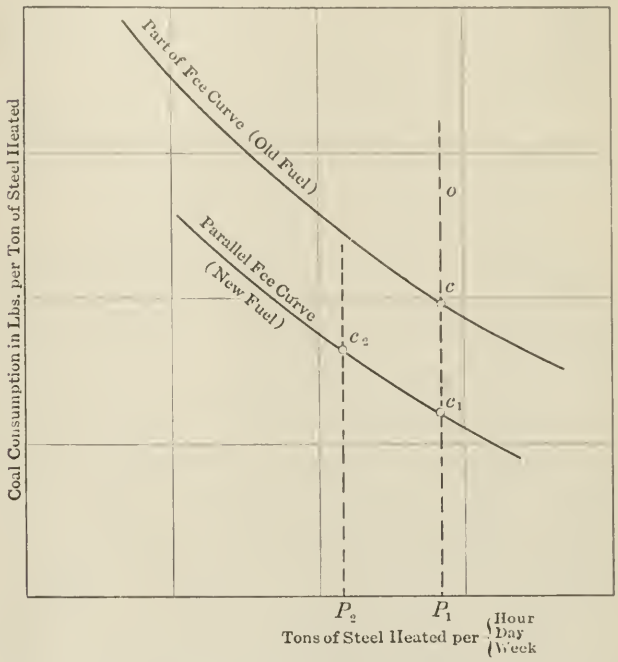

FIG. 6—FUEL COMPARISON FOR TWO DIFFERENT FUELS BY MEANS OF FURNACE CURVE

old fuel per ton of steel heated. A new fuel was introduced. The new fuel to which the furnace was changed over gave us a consumption P_2C_2 for a production OP_2 different from OP_1. Drawing through C_2 a parallel curve to the old curve we obtain C_1P_1 as the ordinate corresponding to the abscissa OP_1. The new fuel consumption, based upon the old average production (OP_1), is now represented by C_1P_1, and the distance CC_1 forms a

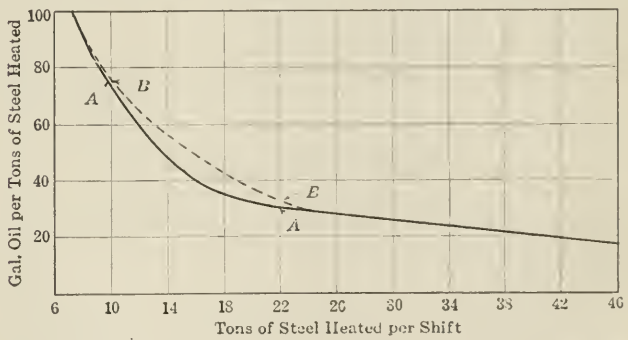

FIG. 7—COMPARATIVE FURNACE CURVES OF TWO FURNACES OF SIMILAR DESIGN—(OIL-FIRED BILLET-HEATING FURNACE)

measure of how much better the new fuel is than the original fuel. This, of course, merely indicates the heating and not the economical value of fuels, which latter shall be taken up separately.

Thus we see that with even varying production we are able to compare not only different brands of the same kind of fuel but also fuels of entire different origin.

Individual Furnace-Curves

Having constructed a certain number of furnace curves, it will soon be manifest that each furnace has

its individual curve, and that hardly two furnaces, even of apparently identical design, will have the same curve. The curves will almost always show slight variations in their fuel-consumption for varying production. This is plainly illustrated by comparing the two curves of two billet heating furnaces of similar construction, given in Fig. 7, where the fuel consumption of furnace A with a production of 10 to 20 tons per shift is decidedly lower than that of the B furnace. This may be an indication of certain slight variations in the construction of the furnaces, their stack draft, etc., which differences may have escaped notice heretofore.

In future it may be found practical to use instead of the more average fuel consumption, the characteristic furnace curves in connection with average production and fuel consumption.

Selection and Criterion of Furnaces

If a number of curves of furnaces which are not of similar construction but are used for approximately the same kind of work and production, are plotted on a sheet, using the same units for production and fuel consumption, we will notice wide discrepancies even for similar production. We therefore will try to use such furnaces which indicate the lowest consumption of fuel for certain productions if a selection of furnaces is possible.

By comparing curves of different furnaces we may even be able to draw some conclusions in regard to their construction, for instance the ratio of length to width, furnace volume, tonnage, slope, draft conditions, fire chambers, etc.

According to the curves in Fig. 7 of two similarly built billet-heating furnaces A and B, the furnace A shows a much lower fuel consumption than B at the same production. Since both furnaces were turning out same material the difference in the curves must be caused by some differences in their construction or location. In fact, certain imperfections in the location seemed to justify this conclusion.

Bonus and Cost System

After these remarks regarding the characteristics of furnace curves in general I call attention to the practical purpose for which they can be used with great advantage in my opinion.

The keeping and following-up of furnace curves seems to me the only just way upon which a bonus and penalty system should be based, if such is contemplated. We are thus able *to read off with almost theoretical exactness how much fuel was either saved or wasted* in a certain period. If expressed in dollars and cents *this system allows us to pay a certain percentage of the saving to the man responsible for the handling of the furnace or to impose penalties for any wastage of fuel.*

From the foregoing it is plain how the gains or losses expressed by the *amount* of fuel are determined. I may add that the work of keeping track of such gains or losses may be greatly facilitated if we mark on the same furnace sheets graphically the fuel costs.

If, for instance, different grades of coal and of various prices are used on a furnace, we will be able to read off the actual amounts of savings or losses in dollars and cents on the "price lines" as shown on the right side of Fig. 8. We merely draw a horizontal line through A representing 1120 lb. or ½ gr. ton of coal and measure off from A various (½) coal prices and connect with 0.0, thus obtaining price lines for any coal price. If, to give an example, one of our weekly points P should fall below the curve, we will draw two horizontal lines, through P and the ideal point P¹ of the same production (6 tons) and can now read off the actual heating or melting costs on the corresponding price lines, or as in this case on the same price line ($2.50 per gr. ton of coal) if the fuel price for P was the same as that for the curve. The difference of the two readings $0.61 — $0.50 = $0.11 tells us the cost of fuel (lost or) gained, above or below average practice.

If on a furnace, heated with oil or powdered coal, the fuel-readings can be made at the end of each furnace turn, it will be of advantage to add up all the gains and losses made by each heater, and to pay bonuses at the week's end.

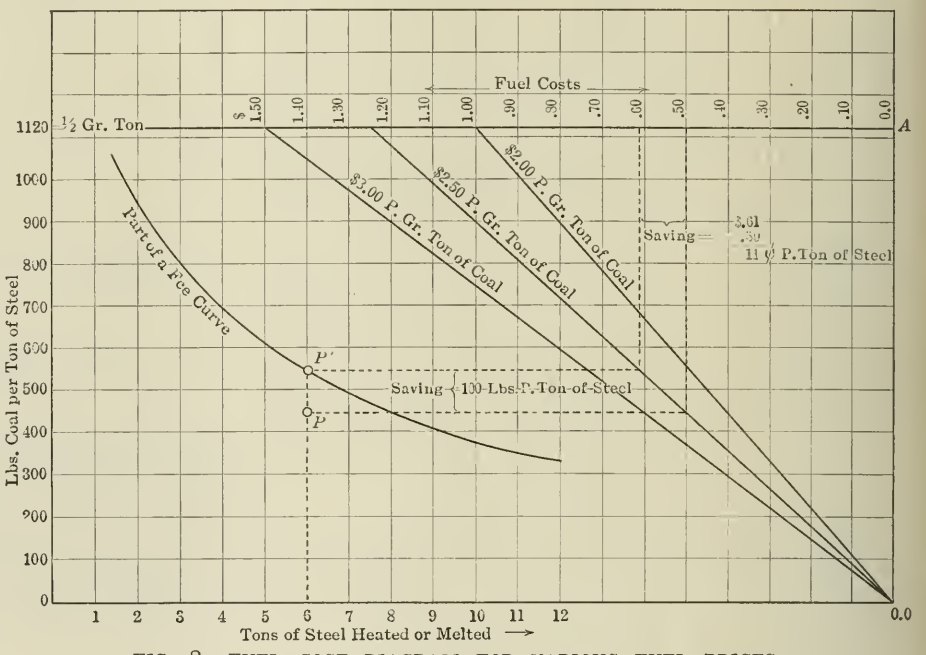

FIG. 8—FUEL COST DIAGRAM FOR VARIOUS FUEL PRICES

Should the variations from the curve be too great a so-called "danger zone" may be agreed upon, within which the points above the curve should come to fall, without imposing a penalty for such moderate losses. The dotted line in Fig. 1 suggests such a danger zone.

To sum up in the furnace curves we have a system enabling us to judge the performances of our industrial furnaces which is not only just from the manufacturer's standpoint but is also fair to the men at the furnaces.

If a furnace bonus system should be adopted and put into practice the effect will very likely be that through the endeavor of the men more and more points will come below our medium curve and thus a new improved curve will be established, which then may form the standard for future practice.

Résumé

1. Furnaces have individual curves, their fuel consumption being a function of their production in a certain time period.

2. These furnace curves should be used to determine whether fuel has been wasted or saved during a certain working period and to serve for comparing furnaces as well as fuels.

3. A bonus system can be based upon such curves.

Blast-Furnace Plant Auxiliaries and General Arrangement

BY J. E. JOHNSON, JR.

(*Continued from page* 378.)

The Dry Blast

This subject has aroused within the last ten years more comment and controversy than any other connected with the blast furnace. In dealing with the thermal principles of the furnace I shall endeavor to show that the claims for economy made on behalf of the dry blast are well founded, and in treating with the question of operation I shall endeavor to discuss the considerations other than those of fuel economy which affect the subject and must be considered before reaching a correct decision in regard to this matter. Here we have only to do with the design and construction of the plant if its installation be decided upon.

It is well known that the atmosphere contains moisture, but the laws under which the moisture exists are probably less widely understood than any others dealing with a subject which affects our daily life so much.

According to Dalton's law two or more vapors or gases can, in fact and in principle, occupy the same space at the same time, and each acts exactly as though the other were not there. That is to say, if we have two cylinders holding one cubic foot each, one of them containing nitrogen sufficient to exert a pressure of twelve and a half pounds per square inch on the inner surface of the cylinder (that is not pressure above the atmosphere but absolute pressure) and another containing oxygen sufficient to exert a pressure of two and a half pounds per square inch absolute, and pump the contents of the second cylinder into the first, each gas will continue to exert the same pressure that it did before, but in this case they will both be exerted on the walls of the same cylinder, and we shall have a nitrogen pressure of twelve and a half pounds, plus an oxygen pressure of two and a half pounds, or a total of fifteen pounds per square inch. Similarly if we have a cylinder containing a cubic foot of water vapor at an absolute pressure of half a pound per square inch, and pump that into the first cylinder we shall have a total pressure of fifteen and a half pounds per square inch, and if the cylinder were opened part of the mixture would flow out until the total pressure was down to atmospheric pressure, but the gases and the vapor would be present in the same proportions as before.

This on the assumption that the temperature is high enough to produce a vapor pressure of half a pound, and here we come into complications because the pressure of the vapor depends entirely upon the temperature, or at least is limited absolutely by it. It can never be more than the pressure corresponding to the given temperature, but it may be, and in the atmosphere generally is, less. For our present purpose it seems to me to simplify matters to consider the air not as *containing* vapor but as acting simply as a carrier for it. That is to say, if we handle ten thousand feet of air the water vapor in that air must go with it, though not in the chemical sense dissolved therein.

The determination of the quantity of moisture actually present in the atmosphere may be made in several ways. The simplest is to cool some glass or metal cup or vessel containing a thermometer by some form of artificial refrigeration very slowly, and note the temperature at which visible moisture begins to settle upon it. This is known as the dew point, and knowing this we can easily take the weight of vapor per cu. ft. directly from the vapor tables, which the United States Weather Bureau publishes in very comprehensive and satisfactory form. This, however, is not the method generally recommended for obtaining the dew point. As the result of very extensive investigations it has been stated by practically all the authorities that the wet-and-dry bulb thermometer furnishes by far the most satisfactory and reliable information. The theory of this instrument and the tables for its use have been set forth very thoroughly both in government publications and in a paper by Mr. W. H. Carrier of Buffalo before the American Society of Mechanical Engineers in Vol. 33, 1911, the latter being particularly valuable.

The quantity of moisture in air is usually given in grains per cubic foot, but this is an exceedingly unsatisfactory unit for blast furnace work because the other quantities with which we are concerned are measured in tons and pounds, but certainly never in grains, and as the effect of water vapor is purely a quantitative one it is very desirable to have it expressed in the same units as those used for other quantities involved in furnace operation. For this purpose pounds per thousand cubic feet of air are by all means the most desirable, and as there are exactly seven thousand grains in a pound avoirdupois we have only to divide the grains per cubic foot of the ordinary tables by seven to convert the results to pounds per thousand cubic feet.

Here a point of much importance arises. Air is very commonly measured at 32 deg. F., but when its temperature is raised to say 70 deg. F. its volume is increased about 8 per cent, and as the quantity of moisture increases directly as the volume, the moisture content of a cubic foot of saturated air at 70 is greater than that of the same weight of air at freezing, not only because of the increased density of the water vapor but because the carrying space in which this vapor exists is simultaneously increased.

In 1906, soon after the first announcement of the success of the dry blast, I published before the (British) Iron and Steel Institute, a paper entitled "Different Modes of Blast Refrigeration, and their Power Requirements," in which was given a chart showing the weight of water vapor per 1000 cu. ft. of air at temperatures from minus 20° to plus 80° F., but as this question of cubic feet is very troublesome, because we must always state the temperature at which the air is supposed to be measured, I converted this to 75 lb. of air which is the weight of atmospheric air at 70 deg. F. and standard barometer. This chart is shown in Fig. 2, from which it will be seen that the moisture content at saturation per 75 lb. of air rises from 0.07 lb. at zero F. to 1.14 lb. at 70 deg. F.

As normal air is about two-thirds to three-fourths saturated and as the temperature in summer may easily rise to 85 deg., it is very obvious that we have in Summer to deal with moisture sometimes reaching a pound or more per thousand cubic feet, and such is the case in many northern iron producing districts, the *average* moisture for some months being nearly a pound, while in Alabama the conditions are much worse than this, a pound and a half per thousand cubic feet being not unusual.

Accepting it as proven for the present that the action of moisture on the operation of the blast furnace is exceedingly detrimental, and realizing that the above figures indicate that we may easily be pumping 50 lb. or 60 gal. of moisture per minute into a modern furnace with the blast, the question obviously arises, how shall we eliminate it?

The metallurgical world now knows how the question was solved after many years of experiments by James Gayley at the Isabella furnaces in Pittsburg, the moisture being condensed out of the air by artificial refrigeration. Obviously, since the quantity of moisture in saturated air rises with great rapidity, with rise of temperature as shown in Fig. 1, we have only to lower

the temperature to cause the precipitation of the moisture. In practice we have to do more than this, since lowering the temperature tends to precipitate the moisture as fog, which in its form of water mechanically suspended may easily pass with the rapid current of air through the refrigerating apparatus and thus to the blowing engines and the furnace. Care must therefore be used in the design not only to condense the moisture but to precipitate it out in drops large enough to leave the air. Preferably the drops should form on the refrigerated surfaces and drip from these in such a way that the air current can not pick the drops up again.

Refrigeration requires power, and what is more serious it requires the investment of capital. Therefore it is very important to design the refrigerating plant to use the least amount of power possible since this will in general mean the smallest capital cost also, and the capital cost of this process has been its greatest disadvantage.

The original dry blast plant, that at the Isabella furnaces of the United States Steel Corporation, was of the brine circulation, single-stage type for the reason that in the vast metallurgical experiment upon which Mr. Gayley was engaged, he felt compelled to take the

FIG. 2—CHART SHOWING WEIGHT OF WATER VAPOR PER THOUSAND FEET OF AIR AT SATURATION AT DIFFERENT TEMPERATURES

simplest and easiest means to accomplish the result, irrespective of whether they were the most economical, and on account of the success of this system at the Isabella plant, and of some failures of early attempts to improve upon it, the same system was used for all the early dry-blast plants. Briefly this system is as follows:

The ammonia vapor is compressed by a steam-driven compressor and condensed in a standard ammonia condenser, from which it passes to a brine cooler where it is evaporated, absorbing the necessary heat for evaporation from the brine and thereby cooling the latter. The brine, a solution of salt or calcium chloride with a freezing point many degrees lower than that of water is then circulated through other coils in a huge chamber through which the air passes on its way to the blowing engine, the air being blown into the chamber by a large fan and removed from it by the suction of the blowing cylinders. Ice forms on the coils, which soon reduces their cooling power and obstructs the passageways for the blast. This necessitates putting out of commission each of the coil chambers in turn every few days while it is thawed off by steam, an expensive operation since not only the steam but the ice cost coal, and the operation of thawing itself takes some time and labor.

A plant of this type designed by Frank C. Roberts & Co. is shown by Fig. 3. The captions under the different views render them very easy of comprehension.

A careful study of the refrigerating process makes it obvious that this system of refrigeration is capable of great improvement, both from the point of view of first cost and that of power requirements. The general principles controlling this whole matter were pointed out at some length in my paper before mentioned, part of which is reproduced below.

It is well known that the power required for a given quantity of refrigeration per minute, Q, is theoretically proportional to $\frac{T_1 - T_2}{T_1}$ where T_1 is the absolute temperature (Fahrenheit + 460 deg.) at which the heat is absorbed by the system and T_2 that at which it is rejected, the expression being

$$\text{HP} = \frac{778}{33{,}000}\ Q\ \frac{T_1 - T_2}{T_1}$$

where Q is measured in B.t.u. per minute.

The ammonia-compression refrigerating machine having so largely supplanted all others for land service, we shall consider only that type. Upon it, fortunately, reliable investigations have been made which enable us to establish a relation between its theoretical and its actual performance, and this goes far to answering our questions.

In the original paper reference was made to the work of Professor Denton in New York and Professor Schroter in Munich on tests of the power consumption of refrigerating machines, but a much more extensive series of tests have since been conducted by the York Manufacturing Company, under the direction of Mr. Thomas Shipley, their general manager, and the results of these tests have been collected and plotted in a paper on "The Power Required for Refrigeration" (*Metallurgical and Chemical Engineering*, December, 1912) and the diagram giving these results is substituted as Fig. 4. The coefficient of $\frac{T_1 - T_2}{T_1}$ based on these results becomes 3.7 instead of 4.15 corresponding to a smaller indicated power than shown in the earlier results. The difference is not great for the conditions of blast refrigeration and makes power estimates based on the subsequent curves in this quotation somewhat high and correspondingly safe.

Tests on both wet and dry compression were given in the original paper but now the dry is so much superior that the wet compression tests have been dropped and allusions to them omitted.

For a number of tests in each of these series I have calculated the theoretical horse-power by equation (1), and compared it with the actual indicated horse-power of the steam cylinders, the ratio of the latter to the former being called R, it being, in fact, the reciprocal of the efficiency on this basis.

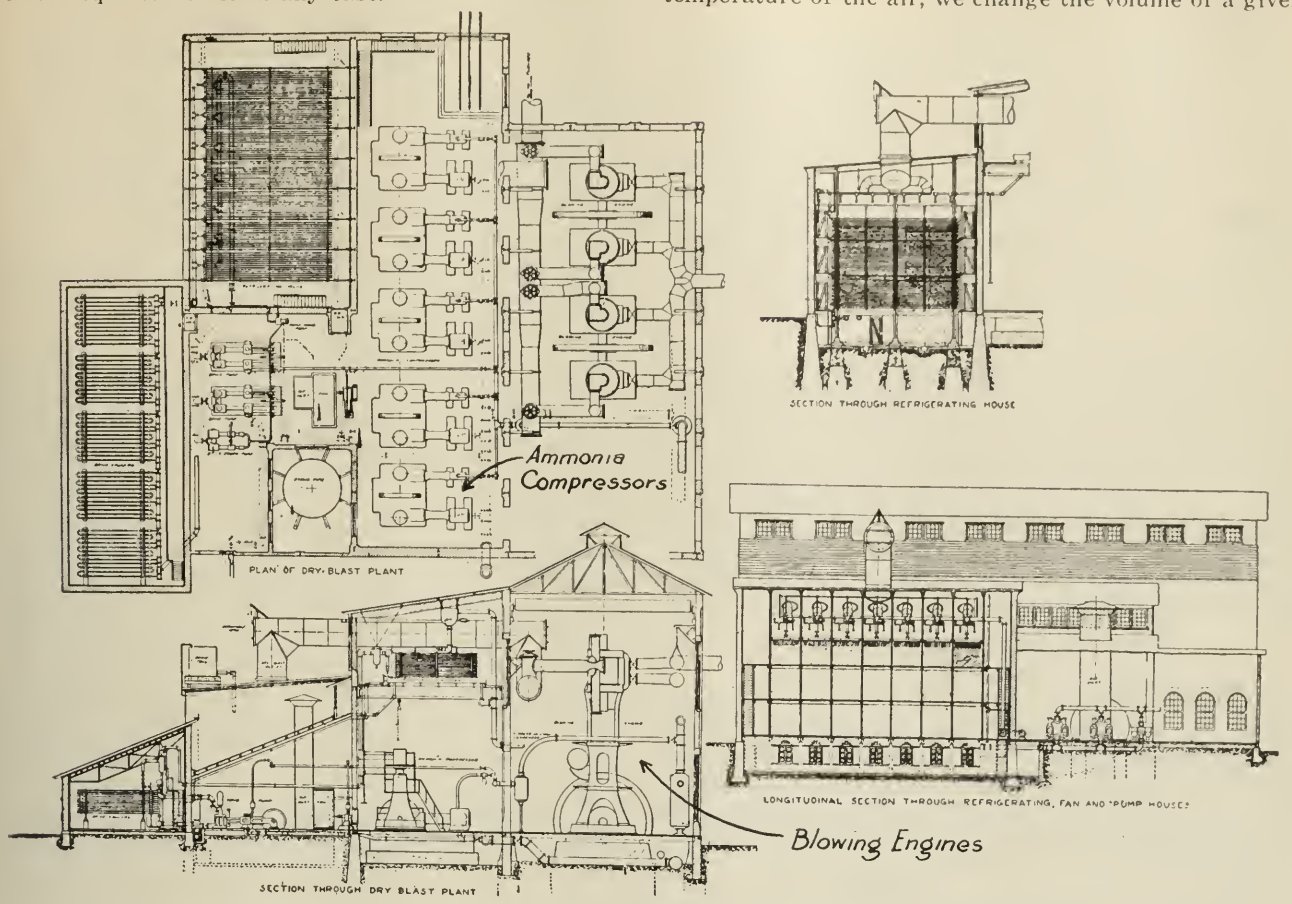
These values of R have been plotted as ordinates with the corresponding values of $\frac{T_1 - T_2}{T_1}$ as abscissas, as shown on Fig. 4.

The values of R plainly decrease with the value of $\frac{T_1 - T_2}{T_1}$, and it is clear that when the temperature range is zero, R should be 1, the efficiency being perfect. Accordingly, a straight line has been drawn passing through the point $\left(\frac{T_1 - T_2}{T_1} = 0, R = 1\right)$ and this line coincides with the points with surprising accuracy, and may be taken as expressing the law of this relation correctly.

As these tests represent widely varying conditions in

each series, it is clear that there is a trustworthy connection between the conditions of refrigeration and the power required for it in any case.*

obviously the most convenient basis, but we are at once confronted with the difficulty that, as we change the temperature of the air, we change the volume of a given



Ammonia Compressors

LONGITUDINAL SECTION THROUGH REFRIGERATING, FAN AND PUMP HOUSES
Blowing Engines
SECTION THROUGH DRY BLAST PLANT

FIG. 3—DRY-BLAST PLANT DESIGNED BY FRANK C. ROBERTS & COMPANY, SINGLE-STAGE, BRINE-CIRCULATION, NON-REGENERATIVE

The algebraic expression of these values is

$$R = 1 + 4.15 \frac{T_1 - T_2}{T_1}.$$

The relation between temperature range and power requirements for a given quantity of heat having been determined, we need only to know in addition the quantity of heat to be removed to determine the actual horsepower required.

FIG. 4—CHART SHOWING RATIO OF ACTUAL TO THEORETICAL HORSE-POWER REQUIRED FOR REFRIGERATION WITH DIFFERENT TEMPERATURE RANGES

The quantity of blast used being commonly measured in thousands of cubic feet per minute, the quantity of heat required to be removed per 1000 cu. ft. of blast is

weight as well, 1000 cu. ft. at 70 deg. F., becoming 900 cu. ft. at 21 deg. F.; so that in considering the quantity of water-vapor contained in the blast as affected by refrigeration we not only diminish it by the fact that a cubic foot of space will contain less moisture at 21 deg. F. than at 70 deg. F., for instance, but that there are only nine-tenths as many cubic feet for a given weight of blast.

To overcome this difficulty the standard temperature at which blast is measured is taken at 70 deg. F., at which 1000 cubic feet of air weigh exactly 75 lbs., and all calculations are based on 75 lbs. of air, correction being made for variation in volume.

For the convenience of those desiring to make calculations on blast drying, a diagram (Fig. 5) is given herewith, which gives various relations of this standard quantity of air, based on its temperature.

The lower half of the diagram contains three curves whose abscissæ are temperatures, and their ordinates quantities of heat above 0 deg. F.

The straight line I shows the sensible heat, above that at 0 deg. F., of 75 lbs. of air at any given temperature.

The upper curve gives the quantity of heat present above 0 deg. F. in the water-vapor which will saturate 75 lbs. of air at different temperatures.

The latter quantity is not that given in steam tables as the "total heat of steam," but represents as nearly as may be the heat which would require to be removed by refrigeration in order to reduce the vapor present in the air to the quantity sufficient for its saturation at 0 deg. F.

This is made up as follows, for temperatures up to the freezing point:

*Although this seems such an obvious means of determining the actual power requirements in any case, when the general conditions are known, it is entirely new, and has never been used by refrigerating engineers, so far as known to me.

1. The sensible heat of the ice above 0 deg. F. (the specific heat taken as 0.50).
2. The latent heat of freezing.
3. The heat of vaporization.

These are all to be taken for the given temperature and the quantity of moisture actually present in 75 lbs. of air at that temperature.

Above the freezing point the conditions are altered; for part of the water, as soon as condensed, will not wait to be cooled down to the temperature of the refrigerating coils, but will drip off them soon after its deposition. As a fair estimate, therefore, one-half of the sensible heat (above 32 deg. F.) for all the vapor in excess of that present at freezing is added to the other items.

This is shown in the diagram curve II.

The lower curve III is located by adding the ordinates of the first two and represents, therefore, all the heat requiring to be removed to reduce the air from saturation at a higher temperature to saturation at 0 deg.

The small quantities of heat $\triangle Q$, of which these larger quantities are made up, are each removed at a different temperature, and therefore correspond to a different T_1, in formula (I); hence these total quantities cannot be applied directly in that formula, but the latter must be put into the form

$$HP = R \frac{778}{33{,}000} \triangle \left(\frac{T_1 - T_2}{T_2} \right)$$

and integrated in order to give numerical results. This would be so tedious a process as to be useless if done analytically, but may be done conveniently by the application of the entropy diagram invented by Professor J. Willard Gibbs of Yale University many years since, and brought to the attention of the engineering world at large some fifteen years ago by Mr. Macfarlane Gray of England.

To many it will be a matter of indifference how the results are reached, provided only that they are reached correctly and swiftly. To these it may be said that entropy is a mathematical quantity depending upon heat and temperature such that, when any thermal operation is plotted with temperature for abscissæ and entropy for ordinates, the mechanical work involved is represented by the area included, precisely as it is with coordinates of pressure and volume in the ordinary indicator-diagram. This quantity has been determined for 75 lb. of dry air, for the vapor contained in it, and for the sum of these, exactly as for the corresponding quantities of heat, and these are plotted on the upper side of the same temperature axis as the latter. These curves are numbered respectively IV, V and VI.

The theoretical or perfect cycle of operations of the ammonia compression machine is represented on this diagram by a rectangle whose right-hand end is the ordinate at the condensing temperature of the ammonia. Its top is a horizontal line at a height determined by the total entropy of the air to be refrigerated, and its bottom one at a height determined by the entropy after refrigeration. (These will be called hereafter the lines of maximum and minimum entropy respectively.) Its left-hand end is determined by the suction or absorption temperature of the ammonia, which must be low enough to absorb heat from the air at the lowest temperature to which the latter is to be reduced. In practice the suction temperature is never less than 10 deg. F. lower than this; and similarly the compression or condenser temperature is never less than 10 deg. higher than that of the condensing water.

Under normal conditions cooling water at 70 deg. F. to 75 deg. F. will always be available for condensing purposes in hot weather, and the maximum condenser temperature used in these diagrams is accordingly 85 deg. F.; also, in all the cases taken for analysis in this article, this is the condenser temperature assumed, unless otherwise stated.

If we assume a uniform difference of temperature of 10 deg. on the two sides of the expansion coils, we might construct a curve lying uniformly 10 deg. F. to the left of the total entropy curve, that is, having a temperature 10 deg. F. lower for the same ordinate in each case, and the lower left-hand corner of every rectangle would lie on this line, thus determining the rectangle completely, as the top and bottom lines are in all cases the lines of maximum and minimum entropy, and the right-hand end is the condenser temperature as before, the left-hand end being then determined by the intersection of the line of minimum entropy with the proposed curve.

This curve, however, is not drawn on Fig. 5 for the reason that the area of the rectangle so determined would have to be multiplied by R, which would have to be determined from the absorption and condenser temperature in each case, in order to give the actual power required.

In order to avoid this necessity three auxiliary curves are plotted in dotted lines, which give the actual power requirements direct, with an assumed temperature difference in all cases of 10 deg. F. at the refrigerating coils, and with three different condenser temperatures, respectively 85 deg. F., 70 deg. F., and 55 deg. F., corresponding to the temperature of cooling water available under different conditions and at different seasons.

The simple rule for the use of these curves is: Draw the lines of maximum and minimum entropy, both extending to the proper condenser temperature on the right, and the latter extending to the left to its intersection with the corresponding dotted curve; at this point erect the vertical which completes the rectangle. The area of this rectangle in square inches gives the horse-power required per 75 lb. of air for refrigeration between the limits chosen.

At various heights on the diagram the difference in temperature between the entropy curve and the assumed condenser temperature is taken, increased by 10 deg. F., and the sum multiplied by R as determined from $\frac{T_1 - T_2}{T_1}$ for that point. This product is not in any way to be considered as a temperature, but only as a length, and is set off to the left of the condenser temperature used, with the ordinate for which the temperature difference was taken.

These points are connected by the dotted curves, and when the left end of the rectangle is drawn upward from the intersection of lines of minimum entropy with the appropriate curve, its right end and top being, as before, the condenser temperature chosen and the line of maximum entropy, it is evident that the length (and therefore the area) of the rectangle has been increased in the ratio R, thus giving actual horse-power.

In using these curves care must be taken to use the one corresponding to the condenser pressure in the given case. If this be different from any of those given, the curve corresponding can be interpolated by eye with all the accuracy necessary for most purposes.

It must also be noted that the curves are only correct for the "direct expansion" system, that is to say, where the ammonia is expanded in the coils over which the air passes.

In the brine-circulation system the ammonia is expanded in coils immersed in a tank of brine, which is afterwards circulated through coils in the refrigeration chamber.

It is obvious that this system requires twice the expense for coils or pipe surface, and also requires twice

the temperature-interval between the temperature of the expanding ammonia and that of the air, required by the direct-expansion system, since the heat requires to be transmitted through the walls of two sets of pipes instead of one.

It is for the latter reason that the curves given are not correct for the brine system. To make them correct for this case at least 20 deg. F. should be added, instead of 10 deg. F., to the difference of temperature between the points on the entropy curve and the condenser temperature. This of course would give a new value of $\frac{T_1 - T_2}{T_2}$ and a new and larger value of R to correspond, so that the length of the rectangle for this case would be very materially augmented.

This, of course, means that the power required would

be augmented in the same degree, and the cost of equipment in the same degree also, or even more, owing to the high cost of the second set of cooling coils in addition to the increased compressor capacity required.

The danger to persons in the cooling chamber, from the escape of ammonia in direct expansion, is a minimum, since no one is ever required to enter it during operation and but seldom at any time; the danger of explosive mixtures of ammonia with air does not exist, and the charge would be no more irrevocably lost in the blast in the cooling chamber than in the brine tank, in case of a bad break in the coils.

Only one possible danger exists, which is, that brass parts in the path of the blast would be rapidly destroyed if persistent leaks of ammonia occurred; but as the use of brass or bronze in such a situation is unusual and may readily be avoided altogether this is not a serious matter.

Under all circumstances there does not seem to be a sufficient reason for the use of the brine circulation now that the process of blast-drying is an established success and the need for the precautions required in an experimental plant no longer exists.

It is my conviction that, for the reason given above, the eventual progress of blast-drying will be along the lines of direct-expansion, and the curves of Fig. 5 have, therefore, been calculated on this basis. Should any one desire them for brine circulation they can readily be calculated from the entropy table given and the formula for the value of R using a temperature difference for heat-transmission of 20 deg. F. or 25 deg. F., as might be found most consonant with the results of other experience with brine-circulation systems.

It might be as well to point out that the "total entropy" curve does not give the entropy for anything but saturated air; if the air be not saturated (as it generally is not), it is necessary to know both the dew-point and the temperature in order to determine the entropy. In that case the entropy of the water-vapor alone at its dew-point must be taken from the "entropy of vapor" curve and added to the entropy of the air at its temperature, as taken from the "entropy of dry-air" curve. This is most conveniently done with dividers. The total entropy so determined will be above the total entropy curve at the dew-point temperature, and below it at the air temperature.

In regards to the temperature to which the air should be refrigerated some consideration is necessary. In Fig. 2 is given a curve showing the quantity of vapor present in 75 lb. of saturated air at various temperatures. From this it is evident that the reduction in the weight of vapor for each degree the temperature is lowered is very slow after 25 deg. F. is passed, and even at 32 deg. F. is not rapid. At the same time the horsepower curves show that the power requirements increase rapidly for very slight reductions of temperature, and it is evident that the ratio of expenditure to gain is increasing so enormously that the balance point is soon passed.

This is shown by Fig. 6, in which is plotted the ratio of water removed from 75 lb. air to the power required for its removal below 40 deg. F.

This is based on 70 deg. F. condenser-temperature and single-stage non-regenerative refrigeration.

The saving in fuel in the furnace is directly proportional to the water removed, and the cost of plant and its operation nearly proportional to the power required, so it will readily be seen from Fig. 6 that a limit must soon be reached from the commercial point of view.

In summer all the uniformity possible would be reached by refrigerating to 32 deg. F., and all trouble from ice formation would be avoided by not going below this point.

As the weather became colder and the dew-point fell so as to be sometimes below this point, the diminished refrigeration required, and the lower temperature of cooling water available, would enable the same plant to maintain a lower temperature and still retain the uniformity desired by reducing the temperature of the air below the lowest natural dew-point probable.

This change being entirely under control of the manager would lead to no sudden changes, and would give a coke consumption in summer so nearly the same as that in winter that the difference would probably be inappreciable.

As between a refrigeration temperature of 32 deg. F. and one of 22 deg. F., with a blast temperature of 1000 deg. F. and normal coke practice, the saving for the latter would be about 2 per cent.

Using this chart as an implement of investigation we may now proceed to examine various methods of refrigeration.

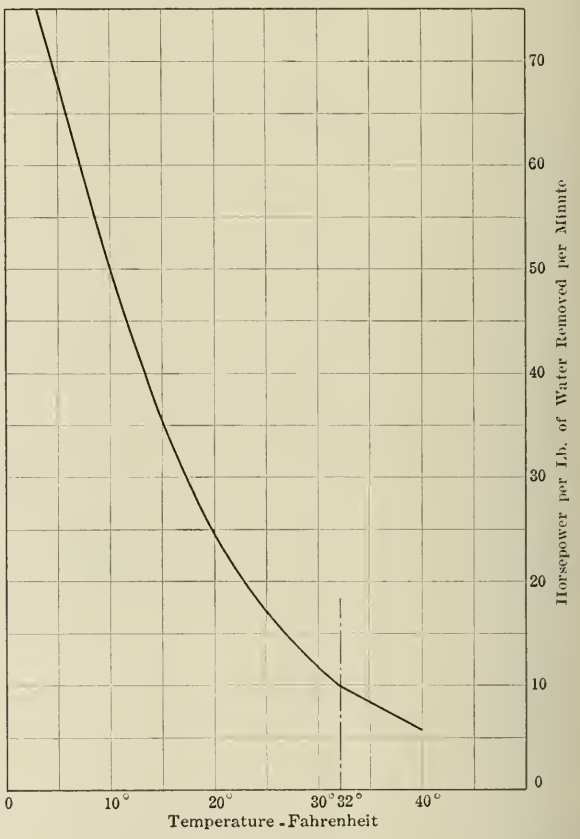

FIG. 6—HORSE-POWER REQUIRED PER POUND OF WATER REMOVED PER MINUTE IN REFRIGERATING BLAST TO TEMPERATURE BELOW 40 DEG. FAHR.—(DIRECT EXPANSION, SINGLE-STAGE, NON-REGENERATIVE REFRIGERATOR, CONDENSER TEMPERATURE 70 DEG. FAHR.)

In order to represent these methods graphically, and at the same time avoid marring the diagram, Fig. 5, for independent use, it is reproduced in Fig. 7 with the rectangles representing the cases to be discussed drawn upon it.

In order to facilitate comparison and reference certain data corresponding to frequent summer conditions, namely, a temperature of 85 deg. F., and a dew-point of 70 deg. F., a condenser-temperature of 85 deg. F., and that the air is to be refrigerated down to 25 deg. F., may be assumed.

Let us also draw for convenience on Fig. 5 the line of 10 deg. F. temperature-difference parallel to the curve of total entropy (VII).

The conditions assumed are then represented on the diagram by the figure *JadH*.

The rectangle drawn for these conditions is *ZJHG*, and its area is $5.60 \times 1.89 = 11.56$ sq. in., corresponding to 11.56 hp for drying 75 lb. of air between the limits and under the conditions assumed.

It is evident that the area below the curve of total entropy and the line of maximum entropy, above the line of minimum entropy, and to the left of the line of condenser-temperature, represents the theoretical minimum work for the performance of that amount of refrigeration. This must be increased in practice by moving the curve of total entropy 10 deg. F. to the left to give the necessary temperature-head. This is the curve of 10 deg. F. temperature-difference on Fig. 7, and is approximately a diagonal line across the diagram, making the area roughly triangular. On the other hand, the energy-diagram of the ammonia refrigerating cycle

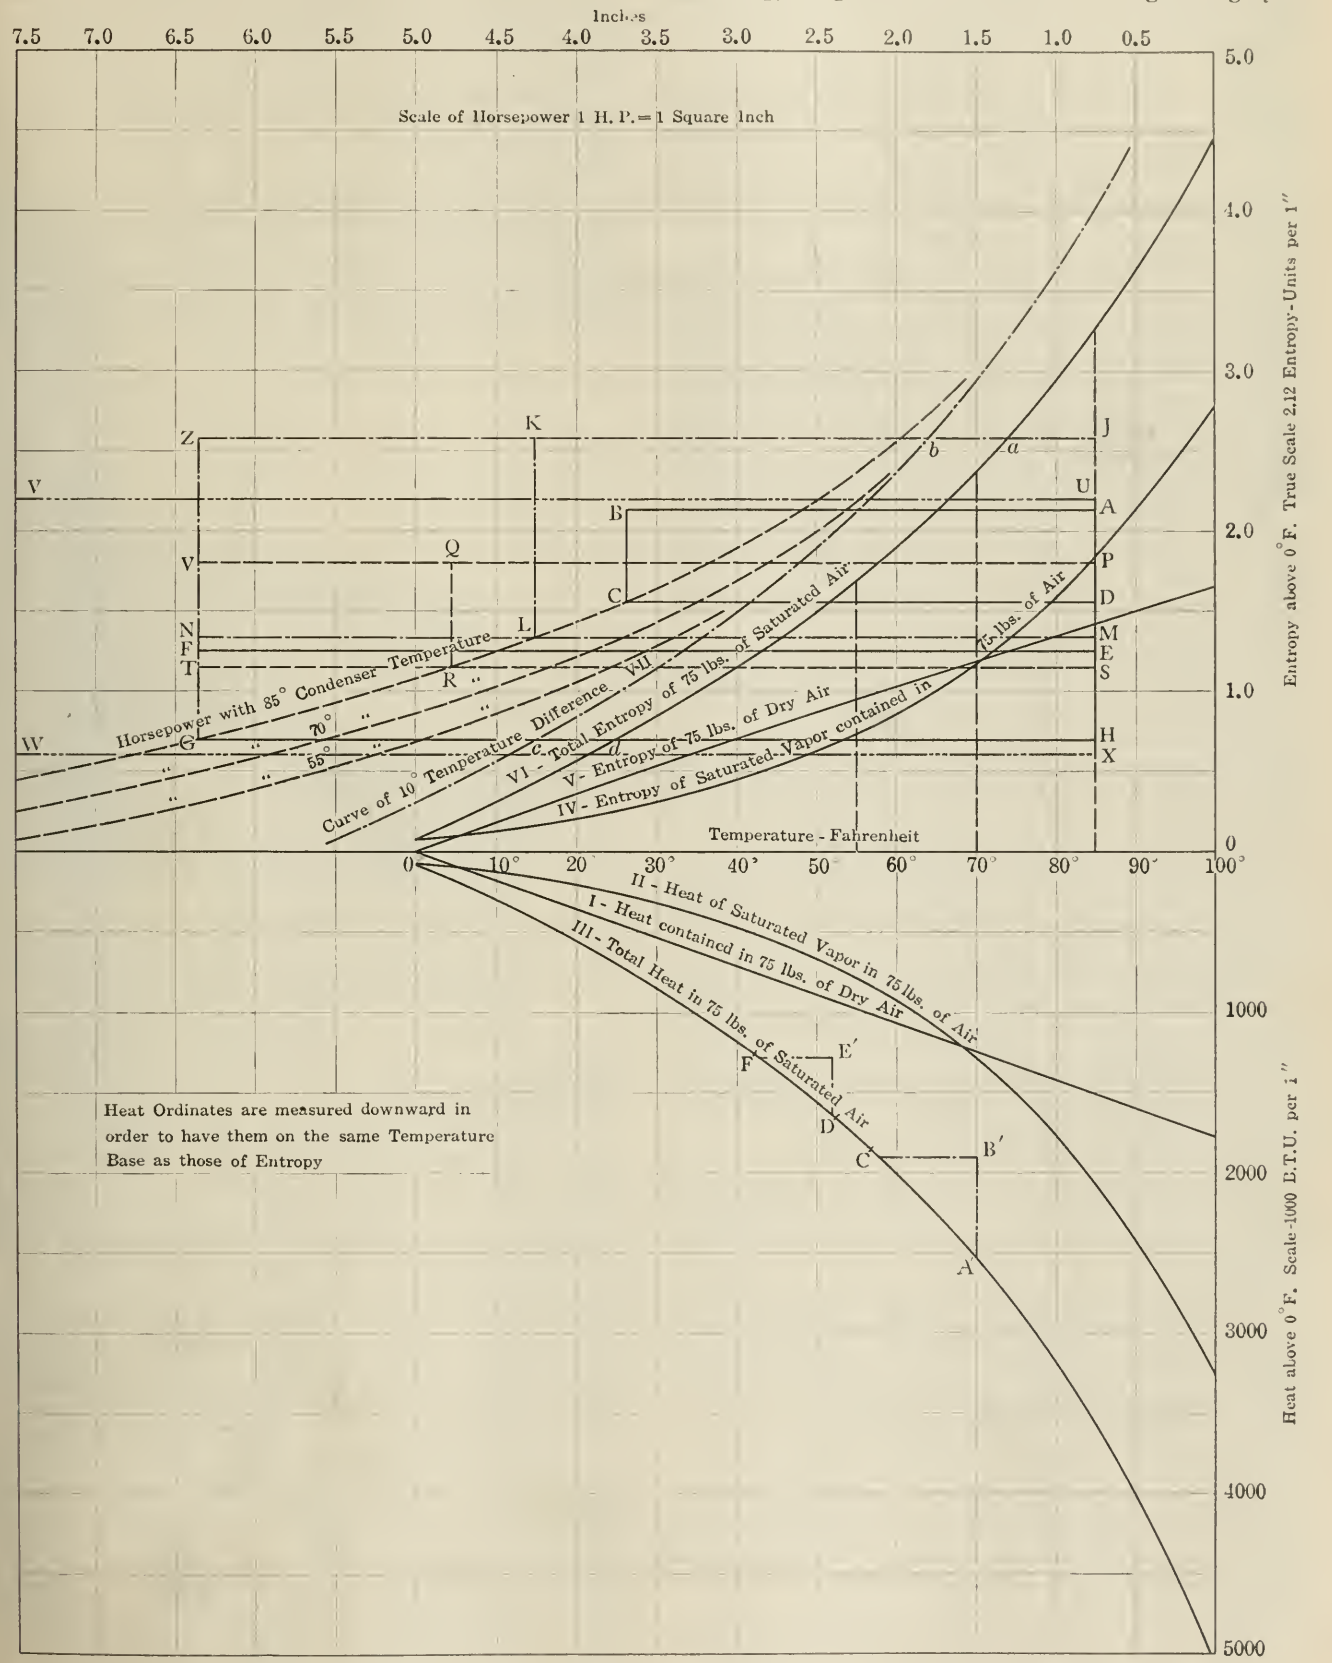

FIG. 7—TOTAL HEAT TEMPERATURE ENTROPY DIAGRAM APPLIED TO DETERMINING POWER FOR DIFFERENT METHODS OF BLAST REFRIGERATION

is, as already stated, a rectangle, and as it must be as large in every direction as the diagram of energy required, it is obvious that there must be a large quantity of waste room in the former diagram and that, accordingly, energy is being wasted.

This is also evident from an inspection of Fig. 2 since this shows that of all the moisture contained in the air at 70 deg. F. half is precipitated when the temperature is lowered to 50 deg. F., and of that removable down to 25 deg. F. almost two-thirds, yet the heat of all this is removed at the temperature of 25 deg. F.

This is precisely as if, in pumping from a shaft 45 feet deep, in which three-fifths of the water entered in the upper 20 feet, we put one pump at the bottom and let all the water run down to that level before pumping it out. It is really much worse than this, because in pumping heat the power required increases much faster than the head, while with water this is not so.

The remedy is as obvious in refrigeration as it is in pumping, to have two pumps, catch the greater part of the heat near the top of its scale and pump it out from there, pumping from the lower level only the heat which comes in at or near that level, a much smaller quantity.

This means the use of two ammonia compressor-cylinders, one working from the 15 deg. F. suction-temperature as before, the other working from a much higher suction-temperature, say 36 deg. F., both, of course, working to the same condenser-temperature.

The rectangle for the latter of these extends from the line of maximum entropy for the case assumed, *JK* in Fig. 7, down to the line *IM* through 46 deg. F., on the "total entropy curve," the end lines being drawn as before, the whole rectangle being *JKLM*.

The rectangle for the first-mentioned cylinder extends from the line *NLM* down to that of minimum entropy *GH*, the completed rectangle being *MNGH*.

The area of the first of these is $3.50 \times 1.25 = 4.375$ square inches; of the latter $5.60 \times 0.64 = 3.575$ square inches; total 7.95 square inches, corresponding to 7.95 horse-power per 75 lb. of air, as compared with 11.56 horse-power for doing the same work in one stage.

This involves also the great advantage that most of the water is removed at a temperature above freezing, so that the quantity of ice which can form is greatly reduced, even in the coils of the second stage.

Three stages could similarly be used, but with a much smaller saving, as an inspection of the area outside the "85 deg. horse-power curve" will show, so that the added complication of another stage would probably be a poor investment, especially as other considerations, to be mentioned presently, contribute to reduce the relative economy and desirability of this step.

The air leaving the refrigerator chamber is at the temperature of 25 deg. F., and it is plain on the briefest consideration that this may be used for cooling the incoming air, with a saving of power to the refrigerating machine.

What the amount of this cooling will be is, of course, not a question of entropy, but simply one of heat. It is not, however, one of easy algebraic solution, since the total heat of the vapor is a very complicated function of the temperature, that of the air being, of course, a perfectly simple one of direct proportion.

It is for this purpose that the curves of heat are added below those of entropy on the diagram.

The problem is: Given 75 lb. of dry* air at 25 deg. F., allowing a temperature-difference of 10 deg. F., and using the counter-current system of cooling, to what temperature will 75 lb. of air at 85 deg., saturated with vapor at 70 deg. F., be cooled?

Neglecting the insignificant superheat of the vapor, the air must be cooled from 85 deg. F. to 70 deg. F. before the moisture will be a factor, and the specific heat of air being constant this will obviously warm the dry air up from 25 deg. F. to 40 deg. F.

As 10 deg. F. difference of temperature to give the necessary thermal head is assumed, the dry air will be discharged at 75 deg. F., and the heat absorbed by it, from 40 deg. F. to 75 deg. F., is obviously that available for cooling the saturated air below 70 deg. F.

Taking from the curve "heat of dry air" that due to 35 deg. F. difference of temperature, we measure it off (towards the axis) from the 70 deg. F. point on the curve of total heat; it comes to 1992 British thermal units, the line through which intersects the total heat curve at 58 deg. F.

This transaction is shown by the lines $A^1B^1C^1$ in Fig. 7. From this it is obvious that the line of maximum entropy for this case is that through the temperature 58 deg. F., which is simply transferred vertically over to the total entropy curve. This line is shown at *VP* in Fig. 7, the whole rectangle being *VPHG*, whose area

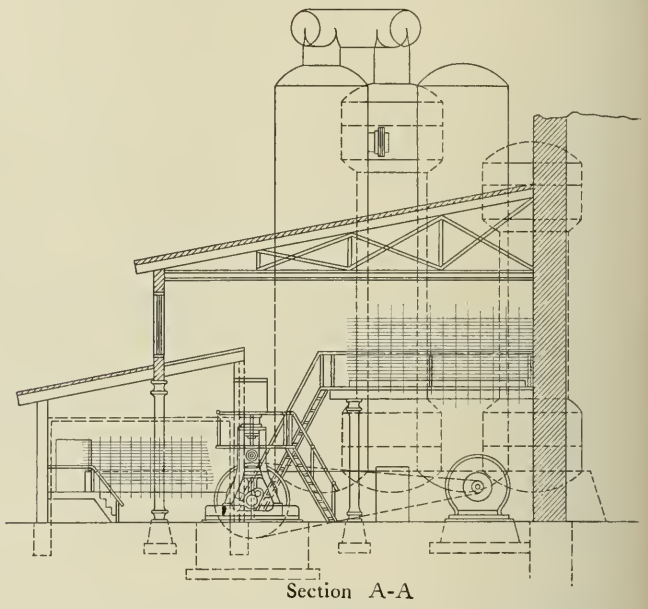

FIG. 8—ELEVATION OF CARRIER DRY-BLAST PLANT—(AMMONIA COMPRESSORS, MOTOR DRIVEN)

is 1.11 x 5.6 = 6.22 square inches = 6.22 horse-power, as compared with 11.56 horse-power for the same work without regeneration.

With this improvement can now be combined that of stage refrigeration, by which is obtained the two rectangles *PQRS* and *TSHG*, whose areas are 3.72 x 0.66 = 2.45 square inches, and 5.6 x 0.45 = 2.52 square inches, corresponding to a total of 4.97 horse-power per 75 lb. air when refrigerated in stages and with the aid of regeneration.

From this it will be seen that great economies are effected by the use of the direct expansion system, by refrigerating in two stages and by regenerating the "cold" in the air which has passed through the system, for the purpose of cooling down the incoming air.

There is also another possibility in the direction of economy which received consideration in the original development of this process by Mr. Gayley and was brought out in the discussion of my paper, that is, the utilization of the reduction of the volume of the air due to its being compressed for delivery to the furnace. If the blast pressure is fifteen pounds obviously the volume of the blast at atmospheric temperature is reduced to fifty per cent of its original amount, and obviously also since the quantity of vapor present per cu.

*The trivial amount of water vapor still present is neglected, being only 0.4 per cent. of the total weight.

ft. is a function of temperature only, this means that if the air were saturated before compression half the moisture would be squeezed out of it by compression, if its temperature were reduced to that of the atmosphere after leaving the blowing engine. This means plainly two things. First, less moisture to be condensed; second, the moisture present will be condensed to any desired limit with a higher dew point. This also means a saving in power.

In the early plants where the air was cooled by the introduction of vast masses of pipe coils into its path it was virtually impossible to have chambers which would withstand the blast pressure necessary, and of a size to contain this mass of coils without prohibitive expense and perhaps danger, therefore in these the refrigeration is always done before the air enters the blowing engine, but in later years the system of cooling the air by direct contact with a "rain" cooled by the refrigerating coils has been introduced and this eliminates the necessity for pipe coils in the refrigerating chambers, thus reducing the latter to relatively small dimensions, and this makes possible the use of the "post-compression" system of refrigeration.

This system has been worked out and applied by the

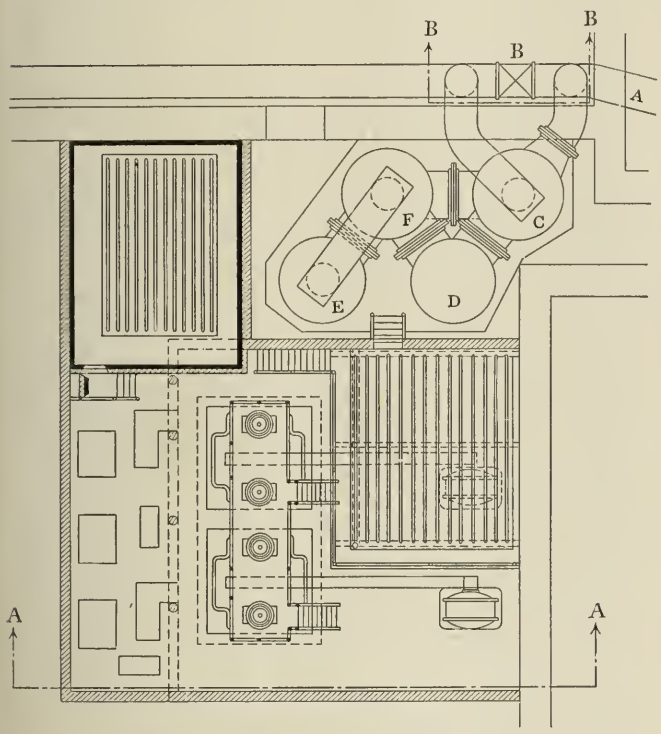

FIG. 9—PLAN OF CARRIER DRY BLAST

Carrier Air Conditioning Company of America, who also use regeneration and refrigeration in stages. A plant designed by them is shown by Figs. 8, 9 and 10. Fig. 8 shows a side elevation of the ammonia compressor (motor driven), and the ammonia condenser, also of the brine coolers, while behind, rising above the shed roof of the compressor house, are shown the outlines of the cooling chambers. Fig. 9 shows a plan of the same equipment. *C*, *D*, *E* and *F* are the various cooling chambers which can best be described by reference to Fig. 10, but before passing to this it is well to note that the cooling chambers are so arranged in reference to the blast main *A* that the blast can be thrown through them by closing the intermediate valve, or by closing the cut-off valves in the connecting necks and opening the intermediate valves, the cooling chambers can be cut off and the blast can go to the stoves direct, thus giving an opportunity to throw the refrigerating plant out of service without shutting down the furnace.

Fig. 10 shows the coolers *C*, *D*, *E*, *F* as if they were arranged in a straight line so as to show the currents through them. *C* is a heat exchanger in which the cold outgoing air is warmed up almost to inlet temperature by the warm incoming air from the blowing engine. This accomplishes two good results. It sends the air warm to the stoves, and, much more important, it does a part of the cooling which would have otherwise to be done by more expensive means, i.e., direct refrigeration.

From *C* the blast passes into *D*, which is simply a spray tower supplied with natural cold water. This continues the refrigeration begun in *C*, and remembering that cooling water is generally available at or below the dew point of the air, and that the density of the air is approximately doubled by compression before entering this system, it is obvious that the temperature produced by such natural cooling water will precipitate much of the moisture. From D the air passes into the base of *E*, which like *C* is a heat exchanger. The cold air coming from the second spray tower presently to be described, and at the lowest temperature reached in the system, enters at the top of *E* as shown, while the incoming air to be refrigerated enters at the bottom, and passing in counter-current through the tubes of the exchanger is cooled to an important extent, while the outgoing blast is, so to speak, prewarmed for its entrance into *C*, because of course it is by-

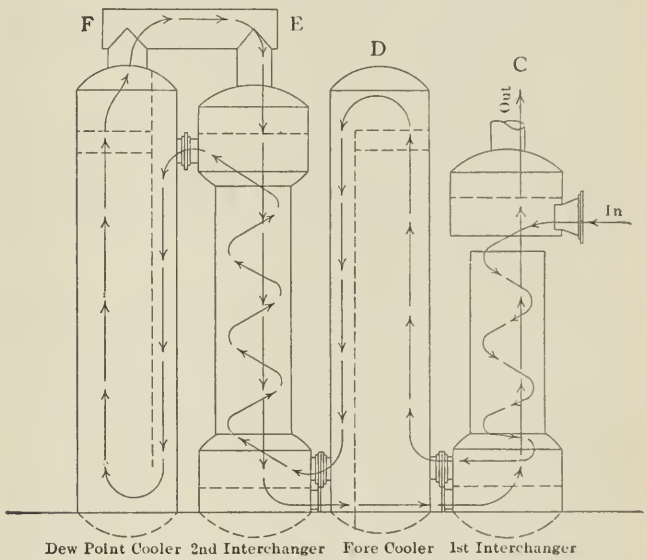

FIG. 10—DIAGRAM SHOWING ARRANGEMENT OF COOLING TOWERS AND REGENERATORS IN PROPER RELATION

passed around *D* and passes directly from *E* to *C*. From *E* the ingoing air enters the second spray tower *F* cooled with water refrigerated to a temperature between 32 and 40 deg. F. These spray towers have two great advantages. First, they avoid the use of expensive tubes for heat transmission. Second, they obtain immediate and practically unlimited contact with the air to be cooled so that the drop in temperature between the two is practically negligible. The incoming air therefore is reduced virtually to the temperature of the cold rain, or somewhere about 38 deg. F. From Fig. 5 it will be seen that at this temperature the moisture is .38 lb. per cubic foot; from this, remembering the compression of the air under which these conditions prevail, we find .19 lb. per cubic foot as the equivalent moisture in uncompressed air. This corresponds to a dew point of 22 deg., and is as low as it is economical to go in blast refrigeration.

One point of much importance is to be noted here. The temperature of the cold rain is well above the freezing point, while to secure a corresponding degree of refrigeration on the precompression system it is necessary to refrigerate well below the dew point, and this introduces all the complications caused by ice.

Both the pre-compression and post-compression systems have their advantages and their disadvantages. One of the principal merits claimed for the dry blast in its early days was that it produced a uniformity in conditions, in the quantity of air and the oxygen contained therein, delivered to the furnace per minute, and a considerable number of metallurgists attributed entirely to this fact the improvement in the operation of the furnace which it brought about. To the latter view I have never been able to subscribe. I shall later show what seemed to me conclusive reasons for believing that the great advantage of the dry blast lies in its dryness. At the same time the advantages of uniformity are not for a moment to be ignored. Now it is obvious that if the blast be reduced to a constant temperature, say to 25 deg. F., which was the practice at one time, nearly all the moisture as shown by Fig. 5 is removed from it, and the quantity remaining is made perfectly uniform while the temperature and therefore the density of the air are likewise rendered uniform. It then becomes necessary only to run the blowing engine at a constant speed to secure all the advantages of a constant weight of air per minute to the furnace. If a constant quantity of air be blown it is obvious that its volume after compression must vary from hour to hour and day to day on account of the varying pressure required by the blast furnace which produces a corresponding variation in the density of the air. Therefore if the quantity of moisture per cubic foot be kept the same by having an absolutely uniform temperature after refrigeration, the variation in the number of cubic feet due to the cause just explained still causes some variation in the actual quantity of moisture delivered to the furnace.

In recent years it has become the practice to change the speed of the blowing engine according to changes in the temperature of the inlet air to compensate for the corresponding variations in its absolute volume. So far no one has as yet introduced a compensation for variations in barometric pressure, though doubtless that refinement will come at some plants in time.

No difficulty is found in keeping constant the weight of air delivered to the furnace by this simple means. The Carrier Air Conditioning Company have applied the same idea to securing a constant quantity of moisture in the blast irrespective of the blast pressure, regulating the dew point by means of changes in the temperatures of the refrigerating apparatus; they have also developed a mechanism whereby this change is automatically made, thus securing a constant weight of moisture with varying blast pressure.

Another respect in which the pre-compression and the post-compression system differ is that with the former all the air is delivered to the blowing engine cold, and the reduction in volume resulting from this causes proportional reduction of the power required by the main blowing engine. On the other hand the refrigeration expended upon the air at a considerable expense, is lost except for this saving. Now it can easily be proven by thermo-dynamics that if both the refrigerating machine and the blowing engine were perfect the total power required to refrigerate the air down to any desired temperature, and then compress it from that low temperature, would be exactly the same as the power required to compress it directly from atmospheric temperature. It becomes therefore a question as to which machine is the most efficient, a question easy to decide, for we know that good blowing engines are from 85 to 90 per cent efficient, while even good refrigerating plants are only around 55 per cent. It is obvious, therefore, that it pays to save power in the refrigerating machine even at the expense of the blowing engine. But another point is to be considered here. When the pre-compression system is used the blast containing much of the heat of compression passes at once to the stoves and of course reduces the amount of heat to be imparted by the stoves proportionately, whereas the post-compression system if applied the same as the original pre-compression systems would deliver strongly refrigerated air to the stoves with corresponding increase in the heat required of them.

It is partly to overcome this disadvantage that the Carrier Company uses the first exchanger shown in their system since by the aid of this they can warm up the outgoing air within a few degrees of the temperature of the incoming air. This puts matters on practically an even basis as regards the heat to be supplied by the stoves.

Using the post-compression system permits giving paramount consideration to the power requirements, and these, as has been pointed out, are greatly reduced by the use of exchangers and the two-stage system. They are also further reduced by the fact that the temperature to which the air must be refrigerated is not nearly so low as under the pre-compression system to reduce the moisture to the same number of pounds per minute. This has a very decided bearing on the power requirements, since it has been shown (see article in *Metallurgical and Chemical Engineering*, December, 1912, above mentioned) that the power required for any given quantity of refrigeration (Q) is

$$HP = 0.0235Q(Z + 3.7Z^2)$$

in which Z is equal to $\frac{T_1 - T_2}{T_1}$ and this is obviously less as the temperature to which we refrigerate is raised. Moreover, while the quantity of refrigeration for the condensation of the moisture is the same, that for the cooling of the air is less, because the temperature to which the given weight of air is cooled is not so low in the post-compression system as in the other, it is therefore obvious that the power required must be very materially less with this system than with pre-compression.

A considerable advantage in the use of exchangers inheres in the post-compression system for the reason that the greater density of the air greatly increases the ease with which heat may be imparted to or abstracted from it, and the exchangers can therefore be smaller on this system than they could for an equal degree of efficiency if used on the pre-compression system.

The slightly lowered temperature at which the air is delivered to the stoves constitutes the principal objection to this system when the blast furnace pressure is twelve pounds or more, but when the pressure is less than this the reduction in volume of the air is very much smaller, and the advantage of the system falls off proportionately, so that there may be cases in which it is desirable to use the pre-compression system, but in such cases there is no excuse for not using two-stage cooling and regeneration.

It may be thought that the cost of the regenerator is just that much addition to the total cost, but this is by no means the case. The regenerator does, without consuming any energy, a part of the refrigeration which would otherwise have to be done by the refrigerating machine, and therefore makes a proportionate reduction in the size of refrigerating equipment required, whose cost per unit of work done is of course very much greater than the cost of the regenerator.

By the use of the rain system two great advantages are obtained. First: The avoidance of the heavy cost for brine circulating coils and the chambers in which to enclose them. Second: The avoidance of the additional drop of temperature required to force the heat from the air into the brine through pipe walls which involves a lower temperature of refrigeration for a given degree of moisture removal. The whole plant is made smaller and more compact and in every way cheaper and better by this system.

If rain be used for carrying the heat from the refrigerating coils to the air, as is most desirable, it becomes necessary to use a non-freezing solution for this purpose if the second stage of the refrigeration takes the temperature below the freezing point as a pre-compression system should probably do. For this purpose brine, preferably made with calcium chloride, should be used, and as this obviously takes up most, if not all of the moisture from the air which it cools, an evaporator must be arranged at some point in the circuit to remove the accumulated water from the system and maintain the strength of the brine. In such a case a heat exchanger should be installed between the refrigerating system and the evaporator so that the "cold" in the incoming and the heat in the outgoing brine may both be conserved.

(*To be concluded in August issue*)

The Relative Migration Velocities of the Ions in Complex Electrolytes

BY A. MUTSCHELLER

In a former paper on "The Action of Certain Colloids on Ions During Electrolysis,"[1] the author has given experimental data which are in support of a theory explaining the function of certain colloids when added to a heavy-metal electrolyte for the purpose of obtaining a smooth and consistent metal deposit on the cathode. The discussion relates to the change of velocity of the ions which take part in the electrolysis, which change is brought about by the addition of a certain quantity of certain colloids to the electrolytic bath.

It is shown in that paper that certain reversible colloids, as for example, gelatine, gum arabic, soluble starch, etc., exert a neutralizing action on one of the ions, thereby rendering it unsusceptible to the force of the electric field across the bath so that the other ion is left alone active in the electrolyte. This formation of an electrically neutral complex is due to the so-called protective action of the colloid added and consists in the formation of absorption compounds, the colloid which carried an electric charge having combined with the ions of opposite charge, which are in this case the anions.

The removal of one ion by the oppositely charged colloid causes the ionization of the unionized part of the salt in solution to continue until the ionization constant is again satisfied. Under these conditions, therefore, the free ions, i.e., those left in the solution, are the sole ionic constituent of the electrolyte, hence the flow of electric current through the bath is effected through the transport of electricity from the anode to the cathode by the remaining cations in case the colloid was positively charged and was, by virtue of this charge, absorbed by the anions. This, then, it was found, is the condition of successful deposition of metals, for, as long as the concentration of the cations is being maintained constant around the cathode, no formation of trees or loose and brittle deposit is taking place.

Since it is well known that the charge carried by a particle of a colloid is not that of one electron but ordinarily an indeterminate multiple thereof, it is necessary to find by experiment the right amount of colloid, or rather the right amount of electric charge on the colloid, that must be added to the electrolyte in order to just balance the electric charge of the anions. It has been shown in the above mentioned paper that, if there is an excess of positively charged colloid, the absorption complex is positive and will migrate to the cathode and deposit there, i.e., the anions are actually carried to the cathode. If, however, on the contrary, there is a deficiency of positively charged colloid, the negative character of the charge of the anions will prevail and the complex of colloid and anions will migrate to the anode.

While the above-named paper was in preparation, the experimental part of the present communication was in progress. Moreover, the conclusions of the first paper could not be accepted as general principles if they did not apply to the case of the complex electrolytes which are used in practical work for the reason that they also give smooth and compact deposits.

Collections of the formulæ[2] of various solutions that have been proposed for the electrodeposition of the more common metals consist characteristically of complex solutions of cyanide or ammonia salts of the metal to be deposited or potassium cyanide or some ammonium salt is mixed with the electrolyte. A few "plating solutions" have been selected as typically representative of these classes, and in the following is given a discussion, together with the results of an experimental investigation, on the relative velocities of migration of the ions involved in the process.

The Silver-Cyanide Plating Solution

According to Bodländer[3] silver forms a series of complex ions with potassium cyanide, the composition of which depends on the relative quantity of cyanide present in the solution. The formation of the first salt takes place according to the following equation:

$AgNO_3 + 2KCN = KAg(CN)_2 + KNO_3$. The next salt which forms with a greater excess of cyanide is

$AgNO_3 + 3KCN = K_2Ag(CN)_3 + \ldots$ and so on for the higher salts. If these salts are submitted to electrolysis, using inert electrodes, it is found that the silver does not migrate to the cathode but instead goes to the anode, whence silver must be a component of the anion. This complex anion has been formed then by the combination of a positive silver cation with two negative cyanide anions which produce the monovalent negative argento-cyanide[4] ion $Ag(CN)^-_2$, or the divalent ion $Ag(CN)^=_3$, etc. These ions themselves, however, are not completely stable; they in turn dissociate, satisfying a certain equilibrium constant. Hence, for the dissociation or splitting up of these complex ions we have the relation

$$KAg(CN) \rightleftarrows K^+ + Ag(CN)^-_2.$$
$$KAg(CN) \rightleftarrows 2K^+ + Ag(CN)^=_3, \text{ etc.}$$

Moreover, as these complex ions are not absolutely stable, a further ionization takes place according to the following scheme

$$Ag(CN)^-_2 \rightleftarrows Ag^+ + 2CN^-.$$
$$Ag(CN)^=_3 \rightleftarrows Ag^+ + 3CN^-; \text{ and so on.}$$

Or $[Ag^+] \times [CN^-]^2 = [Ag(CN)^-_2] \times k_1$

$[Ag^+] \times [CN^-]^3 = [Ag(CN)^=_3] \times k_2$, etc.

Bodländer determined these constants and found k_1 equal to $8.8 \cdot 10^{-22}$ and k_2 to $1.13 \cdot 10^{-22}$.

The instability of these ions is probably considerably

[3] *Zeit. f. anorg. Chem.*, 39, 196 (1904).

[4] The acid $HAg(CN)_2$ is crystallizable and is found to be a strong acid. Its potassium salt $KAg(CN)_2$ is, therefore, also highly ionized. (Stiglitz, Qual. Anal.).

increased while the complex ion migrates to the anode. The residual positive charge of the silver ions bound in the complex ions enters more and more into the region of the repelling positive force of the anode while the attractive force on the negative cyanide ions due to the same electric force increases at the same rate. The cyanide anions, therefore, are attracted toward the anode whereas the silver cations are repelled toward the cathode. With the products of this ionization thus rapidly removed, even the very small degree of dissociation is sufficient to furnish a sufficiently abundant number of silver ions which are to be deposited. The cyanide anions, in case that a silver anode was used, forms the argento-cyanide[5] salt of silver ($Ag\,Ag(CN)_2$). This salt then immediately breaks up again as above outlined and the silver ions migrate to the cathode in order to be deposited there.

Again, there being potassium ions present from the first ionization, we must naturally expect them to appear at the cathode where the potassium formed acts on the water and forms the hydroxide and hydrogen gas. These products act on the complex cyanide salt present and thereby set silver ions free; thus

$$2K^+ + 2H_2O = 2KOH + 2H^+.$$

$$2KOH + 2H^+ + 2KAg(CN)_2 = 4KCN + 2H_2O + 2Ag^+.$$

$$2K^+ + 2KAg(CN)_2 = 4KCN + 2Ag^+.$$

It is to be observed at this point that potassium does not deposit, but only frees the silver ions, and those require for their own deposition new electrical energy, hence the equivalent of silver ions that originate at the anode are not deposited at the cathode and so we should expect an increase of silver at the cathode side of the bath. If, again, this increase actually occurs, this would be an equally sure indication that the dissociation of the complex salt does not take place throughout the bath but at the anode only and thus it would become evident that the cyanide ions do not at all take part in the migration or transport of electricity across the bath.

In order to fully investigate this question, the following series of experiments have been performed.

EXPERIMENTAL PART.

The formulæ generally recommended for the silver plating solution differ considerably in the quantity of free potassium cyanide that should be present in the solution. The solution used for the present purpose was prepared by precipitating silver nitrate with potassium cyanide and washing this precipitate by decantation. It was then redissolved by further addition of potassium cyanide solution employing care to make the excess very small. The excess was tested by adding $\frac{N}{10}$ silver nitrate solution to 10 cc. of the prepared solution. About 0,7 cc. were required to cause a permanent precipitate. The chemicals used were of c.p. quality.

This solution was introduced into the H-shaped migration tube described in the former paper and platinum was used as cathode but pure silver wire as anode. The silver in the original solution and the silver in the solution of the cathode compartment after various times of run was determined by electrolysis with a platinum dish as cathode and a heavy platinum foil as anode. The deposited silver was pure white after washing, drying and slight heating.

In table I the increase of silver in the cathode compartment is given for various amounts of silver deposited on the cathode in runs from ½ to 3 hours. The concentration of the electrolyte was 5 $KAg(CN)_2$ to 100 water, with a slight excess of KCN.

[5]Bodländer shows that silver forms ions of this type more readily and completely than $(AgCN)_2$. *Zeit. f. anorg. Ch.*, *39*, 196 (1904).

Table I

Experiment No.	Amount of Silver Deposited on Cathode	Silver Migrated Toward Cathode	Increase of Silver in Cathode Compartment
1	0.0147 gr.	0.0228 gr.	0.0082 gr.
2	0.0234 "	0.0363 "	0.0129 "
3	0.0652 "	0.0984 "	0.0332 "
4	0.0761 "	0.1152 "	0.0391 "

It follows, therefore, from the experimental determinations that there is actually an increase of silver found on the cathode side of the plating bath. The silver ions are the only carriers of electricity across the solution and the single anions (the CN^- ions) do not participate in the transportation of electricity such as they do in non-complex-ion electrolytes and in the absence of certain colloids such as described in the first publication.

The Nickel- and Zinc-Ammonia-Sulphate Plating Solution

The electrolytic baths generally recommended for the deposition of the metals nickel and zinc consist almost exclusively of an aqueous solution of a salt of the metal and an ammonium salt or the metal-ammonium double salt. In some cases other additions are made: for example, more ionized salts are added to decrease the resistance of the bath (such as $ZnCl_2$ to the zinc plating solution). Other additions such as sulphides, thiosulphates, hyposulphites, etc., are made for the purpose of influencing and changing the color of the deposit. Their functions are secondary and their presence has no bearing on the general form and quality of the deposit.

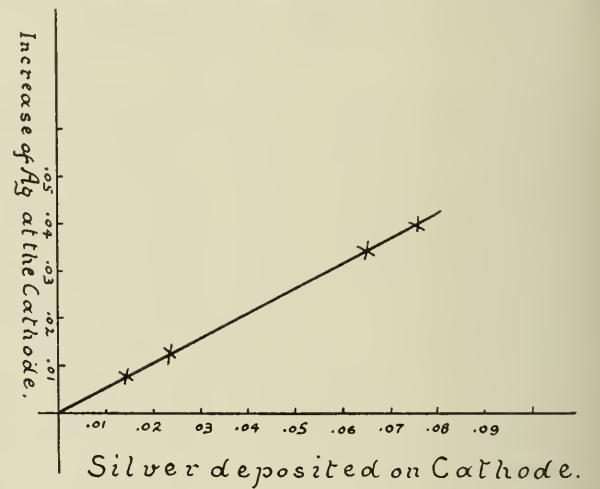

FIG. 1—SHOWING THE GRADUALLY INCREASING SILVER CONCENTRATION IN THE CATHODE COMPARTMENT

In view of the fact that all these metal ions enter into the formation of complex ions, it would appear that, if the relation of their ionic migration velocity should turn out to be approximately the same as that in the silver-cyanide salt, the same working principle would apply for the complex metal-ammonia ions. Assuming for an instant that all these conditions do hold, it must be remembered that cyanogen with silver forms a complex anion, whereas ammonia with metals forms complex cations. The mechanism of the working of these ions must, therefore, be different from that of the silver-cyanide ions.

When ammonia is gradually added to a solution of a zinc salt the following changes probably occur: In the first stage zinc hydroxide is precipitated

$$ZnSO_4 + 2NH_3 + 2H_2O = (NH_4)_2SO_4 + Zn(OH)_2 \quad (1)$$

The zinc hydroxide then dissolves in an excess of ammonia with the formation of a soluble base

[6]Abstr. *Chem. Zentralblatt*, *11*, 265 (1900).

$$Zn(OH)_2 + 2NH_3 = Zn(NH_3)_2(OH)_2 \quad (2)$$

the complex zinc-ammonia base probably reacts further with the ammonium sulphate

$$Zn(NH_3)_2(OH)_2 + (NH_3)_2SO_4 = Zn(NH_3)_4SO_4 + H_2O \quad (3)$$

The complex zinc-ammonia salt is probably electrolytically dissociated according to

$$Zn(NH_3)_4SO_4 \rightleftarrows Zn(NH_3)_4^{++} + SO_4^{=} \quad (4)$$

Konowaloff[6] determined the partial pressure of ammonia in ammoniacal salt solutions by drawing a current of air through the solutions contained in a thermostat at 60° C. into a standard acid solution. He finds that the partial pressure of the ammonia of the salt solutions is expressed by the formula

$P = P_1(n - km)$, . . where P_1 is the partial pressure of ammonia from pure aqueous ammonia solutions, n is the number of grammoles of ammonia and m the number of grammoles of salt per liter; k is a constant. For silver nitrate he finds $k = 2$; for zinc nitrate, nickel chloride, copper and cadmium nitrate, etc., k is approximately 4 (3.4 to 4.04). In the case of some other solutions which are not precipitated by ammonia and afterwards redissolved he found the partial pressure of ammonia in such ammoniacal solutions to be greater than in pure aqueous ammonia solutions (except in the case of calcium and strontium chloride). Hence, the compounds existing between the salt and ammonia are of the type $M(NH_3)_nX_2$, or for nickel and zinc $Ni(NH_3)_4SO_4$ and $Zn(NH_3)_4SO_4$.

Dawson and McCrae[7] applied the law of distribution (Nernst), according to which the condition of equilibrium at a given temperature is determined by a constant ratio of the concentrations in the two immiscible solvents, if the molecular weight of the distributed substance is the same in the two media. In other words, this constant or coëfficient of partition of a substance between two solution media indicates any change which took place in the molecular configuration when the substance entered the other medium. (Hantsch and Sebaldt.[8]) The deviation of the distribution coëfficient for the salt solution from the value found for pure water and a non-miscible medium will measure the complexity of the compound. As such molecular changes probably occur in some ammoniacal salt solutions, the investigation of the distribution coëfficient of ammonia between such salt solutions and a medium non-miscible with water will indicate the formation of any complex compounds produced by the combination of the salt and ammonia.

The results of these investigations indicate that in a certain number of solutions investigated in presence of a considerable excess of ammonia one molecule of the salt takes up four molecules of ammonia, and that this ammonia can no longer act as free ammonia and enter into the establishment of the equilibrium between the aqueous medium and chloroform. The ratio obtained suggests the existence of compounds of the formulæ

$Cu(NH_3)_4SO_4$, $Ni(NH_3)_4SO_4$, $Zn(NH_3)_4SO_4$, etc.

If we now assume that these salts ionize according to the scheme

$$Cu(NH_3)_4SO_4 \rightleftarrows Cu(NH_3)_4^{++} + SO_4^{=}$$
$$Ni(NH_3)_4SO_4 \rightleftarrows Ni(NH_3)_4^{++} + SO_4^{=}$$
$$Zn(NH_3)_4SO_4 \rightleftarrows Zn(NH_3)_4^{++} + SO_4^{=}$$

we should expect that the addition of sodium sulphate would have an influence on the equilibrium between the copper salt and ammonia. This, however, is not the case, for experiment shows that the addition of sodium sulphate has no influence on the equilibrium, the proportion of combined ammonia remaining the same.

[7] *J. Chem. Soc.* 77, 1239, (1900).
[8] *Zeit. phys. Chem.* 30, 258, (1899).
[9] *Ber. d. chem. Ges.*, 36, 3403, (1903).

The further dissociation of the resulting complex ions has also been investigated and it was found that they also ionize according to the scheme

$$Ni(NH_3)_4^{++} \rightleftarrows Ni^{++} + 4NH_3^{\circ},$$
$$Zn(NH_3)_4^{++} \rightleftarrows Zn^{++} + 4NH_3^{\circ}, \text{ etc.}$$

Euler[9] determined the constant of dissociation for the zinc-ammonia ion

$$[Zn^{++}]\,[NH_3^{\circ}]^4 = [Zn(NH_3)_4^{++}] \times 2{,}6 \cdot 10^{-10}.$$

Ammonia originating from this dissociation is not an ion, but ammonia in the elementary state. As such it diffuses rapidly into the solution and as the investigations of Konowaloff and Dawson and McCrae show, it forms the complex ammonia-metal ions with the zinc or nickel salt in the solution.

Leaving for the present the question undecided, whether the Cu^{++}, Zn^{++}, or Ni^{++} exist as single or complex ammonia ions in the solutions which are recommended as electrolytes, there can be no doubt that the metal ions and the ammonium ion together migrate to the cathode. That ammonium, after being liberated, forms ammonia, and as such interreacts with the metal ions present to form the complex ions follows from the above mentioned investigations. Hence, this case is of the same mechanism as the silver-cyanide equilibrium. That is, the complex ammonia ion forms an intermediate product which dissociates in turn, forming with the anions a salt by means of which the anions are withdrawn from the function of transporting electricity from one electrode to the other.

From this hypothesis it must again be concluded that the cations alone transport electricity, so that the full equivalent of metal that is deposited must migrate toward the cathode. If, then, the ratio between the metal and the ammonium salt are properly balanced, there should be no decrease of concentration of the metal ions in the fluid of the cathode compartment during the run.

This investigation was carried out and the results together with a description of the methods of procedure are given in the following:

EXPERIMENTAL PART.

The determination of the relative migration velocities of the ions of the zinc and nickel plating solutions was carried out in the manner already described. The anodes were sheets of zinc and nickel respectively, and the quantitative determinations of the metals in the solutions were made by electrolytic analysis, using platinum as anode and a platinum dish as cathode. The solutions used were of the following composition:

The nickel plating solution contained $Ni(NH_3)_2(SO_4)_2$, 46 grams per liter of solution, and 5 drops H_2SO_4.

The zinc plating solution had the following composition: $ZnSO_4$ — 50 gr, $(NH_4)_2SO_4$ — 10 gr, $ZnCl_2$ — 2.5 gr, water — — 250 cc. The migration ratios were found such as given in the following tables:

TABLE II

Experiment No.	Amount of Nickel Deposited on Cathode	Nickel Migrated Toward Cathode	Decrease of Nickel in Cathode Compartment
5	0.0966 gr.	0.0870 gr.	0.0096 gr.

TABLE III

Experiment No.	Amount of Zinc Deposited on Cathode	Zinc Migrated Toward Cathode	Decrease of Zinc in Cathode Compartment
6	0.1507 gr.	0.1496 gr.	0.0011 gr.

As will be seen from these tables, there is a slight decrease of the concentration of the metal ions in the

cathode compartment. It is to be recalled, however, that the electrolysis starts with a liberation of ammonium at the cathode. At the anode we must naturally have the corresponding equivalent of sulphate ions appear. Probably the liberation of ammonium and subsequent formation of ammonia causes the formation of the complex ammonia-metal ion, hence, while the first complex ions are being formed at the cathode, there are some anions migrating and this then reduces the migration velocity of the cations to a value slightly less than one. Moreover, in the case of the argento-cyanide electrolyte the case is just reversed, for there the complex ions are already formed, but as the potassium salt which later changes into the silver salt. In case of a complex anion, there is a slight increase of metal in the cathode compartment, but in case of complex cations there is a slight loss and this fact is brought out by the results given in the tables.

Conclusion

Although Faraday's law is sometimes stated in the form that if a certain quantity of electricity passes across the solution of an electrolyte, there will be deposited the corresponding electrochemical equivalent of metal on the cathode, this statement of it is inadequate and does not include that the principle can be employed technically with success without further provisions as a process for the deposition of metal upon objects by simply making them the cathode in the electrolytic bath. The technical man says that in most cases the deposit does "not stick"; in other words, the metal deposit lacks certain qualities such as smoothness, purity, and consistency, which are indispensable for the successful technical utilization of the electrodeposition of metals.

In a former paper[10] the writer of this article has reported experiments which show that the addition of certain colloids, at the same rate as it improves the qualities of the deposit, influences the ionic migration velocities of the ions. The relative velocity of the cations is increased nearly to unity and that of the anions is decreased nearly to zero, while the quality of the deposit improves.

In the present paper an attempt is made to demonstrate that the same principle applies to the formulæ which are used as electrolytes for the deposition of the more common metals. There is agreement of the results, since all the solutions investigated, which give more or less smooth deposits on the cathode, have the relative velocity of migration of the ions altered in the way that the velocity of migration of the cations comes nearly to unity and the anions cease to take part in the migration so that their velocity is lowered to near zero velocity.

It appears, therefore, justifiable to state that the condition under which good deposits of metals are obtained is that the concentration of the metal ions at the cathode must remain constant during the deposition. This condition can only be obtained by excluding all ions ordinarily migrating toward the anode from the function of transporting electricity, so that the cations must migrate toward the cathode as fast as they deposit there. We have observed that if this condition is fulfilled there will be obtained the optimum of quality of the deposit.

Finally, it has been shown that this effect on the migration velocity of the ions can be exerted (1) by making the proper addition of positively charged colloid to the electrolyte, whereby the anions are absorbed and electrically neutralized, hence cease to migrate, or (2) either by composing the electrolyte of such complex ions whose products of dissociation re-engage the anions into a non-ionized or little ionized salt, leaving only the cations intact; or by using additions of such salts, which, as the electrolysis proceeds, form complex ions, the products of dissociation of which combine into non-ionized or little ionized salts with the anions, thus leaving the cations free and intact.

Good Advice to Consulting Metallurgists and Others

In a paper published by Mr. W. B. Blythe in the *Proceedings* of the Australasian Institute of Mining Engineers, the author closes with some counsel to consulting metallurgists which is particularly appropriate for young engineers, and perhaps some older ones. We quote the following:

When everyting is running well and smoothly, and good profits are being made, there is no cause for worry; but with the turn of the tide of prosperity a reverse current generates doubt and uneasiness, and, among other things, a metallurgical examination is demanded. There is no finer test for genuine metallurgical ability and common-sense than these plant investigations. The operation calls for the exercise of skill, tact, diplomacy, patience, and analytical reasoning of the highest order over an extended period.

There is a tremendous inducement to rush in "where angels fear to tread" and condemn everything offhand as being antiquated, and insist on modernizing the whole scheme of operations. This inclination must be held firmly in check. Always remember that the man you superseded had brains, and that his length of service on the mine (if no other reason) renders his advice and recommendations of value. You will probably see anomalies staring you in the face at every corner. After you have been on the mine for some weeks you will find that most of them are not anomalies, but are real necessities under the existing circumstances. Never run down that predecessor of yours; the inclination to do so is strong at the beginning, but your respect for him increases later on.

When you make changes in the circuit of an old plant of an experimental nature, always, wherever possible, leave a loop-hole to get back to the old circuit. A sudden change usually upsets the equilibrium at some unforseen point, and unless precautions are taken a heavy loss will occur before these subordinate factors are straightened out. Start your investigations at the residue end of the plant—this is the most important, as an indicator of efficiency or otherwise; work back gradually to the mill; and do not hurry. Start by checking the results being obtained at the time of your arrival, and accept these as the basis of your recommendations. Do not accept for granted any previous figures as to extraction or tonnage.

Get your assays prepared by your assistant, and assayed by an independent operator. If they do not agree with the mine results, look for the reason. You will probably find that the error has crept in during the preparation of the samples for assay. Anyone can obtain a reliable result from a powdered sample, but it requires careful and conscientious labor to ensure that that ground sample is strictly representative of the original large bulk sample. The assayer is usually a conscientious, trained worker, who, under the stress of heavy routine duties, has not the time to superintend thoroughly the preparation of his samples—often this work is outside his province.

Keep all your assay results, and ideas generally, to yourself for the first week or two, and encourage the foreman to talk and advise you what to do. They probably all know more than you do at this stage, and they think more of you if you listen to them than if you adopt a bombastic attitude and start to lay down the law. Gradually introduce a few small improvements—if possible, some that the plant men have suggested first. They will work with you heart and soul to make these a success, and the personal element is an important factor in metallurgical operations. Clean the plant up, and the men will take a pride in keeping it clean, and in their work generally.

An eminent mining engineer once went to West Africa to report on some properties, and instead of starting in his report to discuss rises and winzes and the usual profit-making consideration, he launched off on to a technical dissertation on the mosquito. Well, the mosquito is a big factor in West African finance; so also are filthy conditions and general untidiness in the ordinary plant work. Dirty plants and low residues do not co-exist, but, unfortunately, the reverse does not always apply.

Improving plant conditions is a slow and tedious operation, but it must not be rushed. The investigator usually meets with silent and carefully veiled antagonism, and this must be overcome. The easiest way to overcome it is to improve the workmen's conditions, and these begin to improve from the commencement of the general plant clean-up.

The penny-wise-pound-foolish type of manager cuts down the number of hands until no cleaning or repair work is done at all. Temporarily reduced labor costs follow, but not for long; the increased losses and breakages resulting from this policy soon overshadow the saving in this direction.

Give the leading plant men, to a certain extent, your confidence, and show them the results of their work. There is no gain in the profound secrecy policy of some managements. It reminds one rather of the dark chamber of the alchemist and its veiled mysteries. Thrust on the leading men's shoulders a little responsibility; it pleases them and relieves your own, and they take an increased interest in their work.

Do not do any manual labor yourself, and remember that each man around the works can do his own particular duties a little better than you can, although at times you do not think so. When they seem slow, remember that they are not paid so much as you are. You are paid for your brains, and if you want to use them to the greatest advantage for your company you must not get physically tired. Always make out that things are quite as bad as they really are, and if you can improve them you will get due kudos. But if you are enable to realize your original reported anticipation you will meet with scant consideration. Never boast of your knowledge or achievements, as, excepting perhaps golf, the writer knows of no scientific pursuit where the boaster is so liable to be "hoisted with his own petard" as the searcher after the truth in the fields of metallurgy.

Lead Poisoning in Manufacture of Storage Batteries is the subject of Bulletin 16S of the Bureau of Labor Statistics of the Department of Labor. The author is Dr. Alice Hamilton. It is thought that the dangers of the industry can be reduced to a minimum by installing hoods and exhausts to carry off fumes and dusts by substituting machine for hood work, by providing ample washing facilities for the workmen and insisting on strict cleanliness everywhere and by providing a separate lunch room as the only place where food may be kept and eaten.

Metallurgical and Chemical Engineering in Great Britain

(From our London correspondent.)

Recent Progress in Pyrometry

Mr. C. R. Darling's paper with this title, read before the Royal Society of Arts on May 12—Sir Robert Hadfield presiding—almost synchronized with the Iron and Steel Institute meetings. It was both useful and interesting—particularly so with reference to the "ageing" of the thermo-couples of thermo-electric pyrometers, and to the protecting sheaths necessary to shield junctions from the corrosive action of furnace gases. Alundum, silfrax and silit were dismissed as not wholly suitable, the two first named owing to their being permeable to gases at high temperatures, and all three because of brittleness. A new type of sheath for use with molten brass or bronze, possessing a tip of molybdenum connected to a nickel tube covered with a protecting material was mentioned as being said to be satisfactory.

The use of resistance pyrometers at high temperatures was remarked as depending upon a protecting sheath capable of withstanding temperatures of 1400 deg. C. and over. Given the requisite material the author indicated that alundum would form a suitable resistance material.

Radial and optical pyrometers were explained and an excellent exhibition of typical pyrometers attracted attention at the end of the meeting. Before this, however, the discussion on the paper, opened by the chairman, was concerned with the importance of accurate measurements of temperature, and the citation of instances of the great changes in physical properties occasioned by small temperature differences. Sir Robert expressed his own preference for platinum and platinum-rhodium couples.

Dr. Harker of the National Physical Laboratory and Mr. H. C. Jenkins also spoke.

The Scottish Kelp Industry

A leaflet issued by the Board of Agriculture for Scotland says the kelp industry has improved in the last five years, and it would pay crofters and others in districts where the right kind of seaweed is found on the shore. Up to about seventy years ago kelp was made for the soda which was obtained from it. Other and cheaper ways of getting soda were found out, and the price of kelp became lower and lower, so that in many districts the people gave up the making of it. Soon afterward iodine and potassium began to be extracted from kelp and the price rose slightly. There were ups and downs but on the whole the value increased. From 1907 to the early part of 1914 this rise in value became marked.

Potash has been obtained almost entirely from Germany where there are mines of it. Consequently, as long as the war lasts, the only important available source of potash will be kelp and hence the price of kelp has increased since the war. The consumption of potash is very great. It is the main constituent of several important artificial manures, besides being largely used in manufactures. Also, since iodine is in growing demand in military surgery, its value, too, is likely to become higher; though even during the war the increase is not likely to be so great as in the case of potash because iodine is obtained from the nitrate fields in Chile as well as from kelp.

Just before the war it may be estimated that the price which the workers might except to receive for 1 ton of kelp was £5 to £5 10s. It is probable that this season at least £1 more per ton may be obtained. To secure this sum the worker will have to gather the proper weed, to dry it and then burn it. It requires about 5 tons of dry weed to make 1 ton of kelp.

International Commerce

There will be some startling national trade balance sheets when once the war ends. One does not only refer to casualty lists, national indebtedness or property destroyed. There is, too, the cost of the industrial dislocation inseparable from the diversion of labor from the loom to the trench and the exchange of the plough for the machine gun. Some indication of this is given in some recently published statistics of the external trade of France. In these imports and exports for the first five months of the war are compared with the imports and exports for the similar months in the preceding year. The net result is that imports fell to 59.5 per cent and exports to 66.5 per cent of their previous value.

Research Work by the Institution of Mechanical Engineers

According to the annual report of the Council of the Institution of Mechanical Engineers, the Alloys Research Committee has continued its work and the eleventh report will be ready this year. The results of research at Sheffield on chemical and mechanical relations of iron, tungsten and carbon, and iron, nickel and carbon were presented in the form of a paper during the year. This work is being continued in connection with the carbides of cobalt and molybdenum. A paper on the former will shortly be presented. The Refrigeration Research Committee has presented its first report and is now conducting experimental work. The Wire Ropes Research Committee has collected a large amount of data and hopes soon to carry out tests. A committee is investigating the action of steam passing through nozzles and steam turbines, and the Brush Electrical Engineering Company has lent a three-flow condenser for the purpose. A research committee is investigating the question of a hardness test for hardened journals and pins. An advisory committee has been appointed to prepare a scheme for the co-ordination of research.

The Estimation of High Temperatures by the Method of Color Identity

Messrs. Paterson and Dudding's paper published in the April issue of the Proceedings of the Physical Society of London is modestly described by the authors as a preliminary note. Yet it is no idle praise to state that the paper represents original work of a very high order. Covering as it does some thirty printed pages abstraction is not easy. The general contents are best indicated by the following extracts of the authors' synopsis:

1. Preliminary experiments are described on the method of "color identity" adapted to the estimation of the temperature of incandescent substances such as metal or carbon radiating in the open: by this method the "true" temperature of certain bodies as distinct from their "black-body" temperature can be arrived at with a very fair degree of accuracy.

2. By the color identity method the total luminous radiation (white light) from a black body is made identical in color with that from the incandescent metal under examination by adjusting the temperature of the black body until there is color identity in the field of a Lummer-Brodhun photometer.

3. Comparisons are made of the results so obtained with those obtained by other methods and the color identity method is shown to give the correct result for melting platinum.

4. An explanation is given of the principal factors and limitations of the color identity method in which it is shown that accurate results should be obtained so long as the bodies under consideration act as "grey" bodies throughout the visible spectrum and that there will be a tendency to error to the extent that they depart from the grey body condition in the visible spectrum.

Laboratory Glassware

A most invaluable piece of investigatory work of great and immediate industrial value forms the subject of a short report just issued by the Council of the Institute of Chemistry. This summarizes the work of the Glass Research Committee appointed last October to conduct investigations with a view to arriving at suitable formulæ for the use of manufacturers willing to assist in maintaining the continued supply of laboratory glassware.

The chief aims of the research have been: (1) To produce working formulas for all glasses used in laboratory work, and (2) to ascertain the influence of various ingredients on the physical and chemical properties of glasses. The work was extended to include glasses for miners' lamps following the suggestion of the Home Office; and also glass for ampoules, to meet the needs of wholesale pharmaceutical chemists engaged in the production of army medical products. The committee have also examined and reported on samples of British and French laboratory glassware, produced since the beginning of the war, a number of the specimens being made from formulas similar to, and in some cases almost identical with, those recommended by the committee.

The committee have had before them many specimens of glasses used for various purposes of which analyses have been made by Mr. Blount, Mr. Hancock, and Mr. Heyner. It has been found, however, that mixtures prepared in accordance with the analytical results were not always satisfactory, but the analysis was helpful in suggesting synthetic experiments, and during recent investigations some intricate analyses made by Mr. Gilbert J. Alderton, under the supervision of Mr. Blount, have proved especially valuable. Apart from the analyses, the work has been almost entirely carried on at King's College by Professor Jackson and Mr. Merton, and by the former at his own house. The work has evolved a careful study of the chemistry of silicates, aluminates, borates, etc., in their relation to the manufacture of glasses. A detailed report of these experiments will be published in due course.

Up to the present time the research committee have reported eleven formulas for glasses for various purposes, based on the results of about 400 experimental melts on a scale large enough for drawing rods and blowing small vessels. In addition, a very great number of experiments have been made in order to study the influence of the various constituents employed. No formula has been issued without submitting the specimens made to rigorous tests to prove their suitability for the purpose for which they are intended. Moreover, by varying the experimental working conditions, it can be said with reasonable confidence that the mixtures will prove equally satisfactory under the actual working conditions of a glass furnace. The question of workable temperatures has been carefully considered, and so far as it is possible to judge, the melts on a small scale indicate that even better results will be obtained on the industrial scale. This view has been justified by the samples already received from manufacturers who have tried some of the formulas.

In deciding the formulas it has been found necessary to pay special attention to the proportion of basic and acidic substances in respect of the action of glass mixtures on clay crucibles during fusion, and it has been shown by careful investigation that the formulas pro-

posed give melts in which the influence of the ingredients of the crucibles is very slight, and in some cases practically inappreciable.

The Iron and Steel Institute Meeting

THE FIRST DAY'S MEETING

It is not unknown in the chronicles of scientific institutions that a president should be unable to read his presidential address. But the *force majeure* has generally been a matter of the ruling of medical advisers rather than that of one's King's enemies. The stress of war kept Monsieur Adolphe Greiner from presiding at the May meeting of the Iron and Steel Institute this year. Indeed there was no presidential address, but after the formal business of the meeting first place was given to a paper by M. Greiner. Formal business under the chairmanship of Dr. Arthur Cooper included the annual report of the council indicating a satisfactory financial year, the announcement of the postponement *sine die* of the International Congress of Mining and Metallurgy, the presentation of the Bessemer Medal to M. de Fleurer, attaché to the French embassy, on behalf of M. Pierre Martin.

Mr. ADOLPHE GREINER'S paper was then read—it was a brief but interesting note on **"The Heating of an Open-Hearth Furnace by Means of Tar"**—interesting not only technically but because of the circumstances leading to the solution of a fresh problem. In the author's words: "After the total stoppage of the works entailed by the foreign occupation, and once the preliminary period of disorganization had passed it appeared to us that we had a pressing duty before us—that of helping the working class population around us to the utmost extent of our power to earn its livelihood. For this reason I decided to undertake at once the manufacture of a portion of the orders we carried on our books so far as circumstances would allow.

The steel works were thus compelled to contemplate the necessity of relighting an open-hearth furnace. Our reserves of gas coal had been speedily exhausted; the only battery of coke ovens which was working was unable to furnish us with gas, of which it was itself in pressing need; the importation of British coal was impossible, and, as a matter of fact, we felt the need of freeing ourselves from the long established dependence of the works upon foreign countries as regards the supply of gas-coal. There remained as our sole resource the tar from the coke ovens.

In the present arrangement the tar is delivered to the sprayers (one only in each burner) with a regular feed and under a uniform pressure of half an atmosphere. It is sprayed by means of air compressed at about three atmospheres. The hot air of combustion is admitted above the injector through the existing port inclined at an angle of 45 deg. The average consumption of tar throughout the whole campaign has been 133 kg. (293 lb.) per ton of steel, including in this figure the amounts required for lighting up and for heating during stoppages. On the other hand, with an uninterrupted run this average falls to 115 kg. (253 lb.) per ton of steel. The average weight of the charges had to be diminished in order to avoid any deflection of the jet of flame issuing from the pulverizer toward the crown of the furnace. Nevertheless, several charges of 15 tons have been worked successfully without any other inconvenience than a proportionately longer working time. The proportion of pig-iron found necessary in the charge rose to 28 per cent.

I may add, after these 215 charges, the furnace is still in an excellent working condition. The roof appears even less damaged than after a similar campaign with coke-oven gas; only the chambers became encrusted. The bricks of the checker work became covered with a carbonaceous substance, and it will be necessary to devise some means of remedying this inconvenience.

This paper was not discussed, Dr. Cooper remarking that it was really an addendum to Mr. Greiner's paper of last year. A hearty vote of thanks was accorded together with an acknowledgment of the value of his service and hopes for his continued activity.

The second paper, by Sir ROBERT HADFIELD and Dr. GEORGE K. BURGESS of the Bureau of Standards, Washington, on **"Sound Steel Ingots and Rails"** evoked a lengthy and spirited discussion. This was opened by Mr. B. Talbot, who criticised the authors for having based their standards on a comparison of special acid open-hearth ingots with ordinary acid Bessemer ingots instead of with basic open-hearth ingots. Mr. Talbot also asked for an explanation of the statement that casting big end up was superior to casting with the small end up, which was the invariable custom in rail and many other steel works. While Sir Robert's conclusion might be correct for small ingots, it was doubtful if it was safe to dogmatize for all sizes of ingots. He had had some photographs prepared of ingots of a weight in common use in rail works—namely, some 3½-ton ingots—in order to see what the results really were. As Sir Robert used a refractory top on his mould, he had done the same, so as to make a fair comparison. Personally, he was a believer in the brick-lined top when it was desired to reduce the piping in the ingot, or, at any rate, to bring the pipe nearer to the top, and it was to the use of that well-known device that he attributed Sir Robert's better results, rather than to his special blow-pipe arrangement, which he used in addition.

Mr. C. E. Stromeyer expressed the opinion, in regard to failures in steel plates, that these failures were largely due to the use of Bessemer steel scrap in the open-hearth furnaces, and that was one reason for which he welcomed the paper. In a general way, the question of piping and that of quality should, he thought, have been kept separate; the method might not improve the quality, although it might reduce the piping. Fractures in rails were not due to piping, but to defective material. Bad qualities of steel were very much worse at cold than at ordinary temperatures. He did not think the method would improve the quality, although it would reduce the piping.

Mr. W. H. Hewlett said that segregation was a very detrimental occurrence, and as Sir Robert Hadfield by his method reduced segregation he was rendering a very great service.

Mr. F. W. Harbord expressed the same opinion, adding that they welcomed any process which gave sounder ingots, and the reduction of blow holes was what all steel manufacturers had been aiming at. The proportion of seconds seemed to him very high, and he would have liked the figures to have been given for the American ingot also.

Mr. T. Twynam asked whether Sir Robert Hadfield had found an increase in the carbon content of the metal just below the cavity; in other words, did there occur carbon impregnation? He (the speaker) said he had found impregnation to occur, and he wanted to know whether the author had had the same experience. A segregation of carbon at that part was dangerous.

Sir Robert Hadfield, in replying to the discussion, said that he would be very pleased to reply fully to all remarks by correspondence. If Mr. Talbot made an ingot exactly on the lines indicated in the paper, he would obtain about 90 per cent of good work. The specimens of sound ingots he had exhibited in the rooms were all of converter steel. The War Office and Navy specifications were most difficult specifications to meet;

in order to show the success of his method of manufacture, he added that ingots manufactured by his firm to the number of 120 had been cut through, and not one had been found defective. The ingots in question were representative of makes which extended over a period of from seven to eight months. If Mr. Talbot obtained similarly good results, he (Sir Robert) would be the first to congratulate him. When casting the larger end upwards, he (the author) added that there was a large ferro-static pressure, and a better result was obtained. In regard to Mr. Stromeyer's remarks, Sir Robert stated that his method of manufacturing the ingots did certainly lead to the manufacture of better rails, as was evidenced by the etchings. In the matter of carbon impregnation, when 9 to 10 per cent discard was cut off, all trace of carbon impregnation was removed with the discard; if it were not so, the British Government would have rejected material for that reason, and so far there had been no rejection in a total quantity of about 70,000 tons of ingots made in the manner described.

Comments on the second day's proceedings are held over to my next issue.

Market Prices

MAY, 1915

Tin showed a downward movement at the beginning of the month, but stronger in the last fortnight. It opened £159.10, rose sharply to £162.10 (3rd), dropped to £160.10 (4th), then rose to £165.10 (10th), fell slowly to £162.10 (14th), and after a slight rise declined to £160.10 (19th). It then improved to £164 (25th), but fell away again after to £162 (26th) and closes £163.5.

Copper opened £76 and rose smartly to £79.10 (7th). It then dropped to £77.12.6 (11th), but recovered to £79.15 on the 12th. Declining slowly it touched £75.5 on the 19th, but recovered to £76.17.6 on the 20th. On the 21st it was again £75.7.6. It then rose decidedly, being £78.15 by the 28th, and closes £79.2.6.

Haematite has been 95/- throughout the month.

Scotch Pig opened 70/- and after rising to 70/10½ on the 6th was inclined to weaken, being down to 69/3 on the 10th. It then appreciated to 71/4½ on the 12th, but went lower to 69/10½ on the 14th, recovering to 71/- on the 17th. It kept at 71/1½ after the Whitsun holidays till 25th, rising to 71/9 on the 26th.

Cleveland opened 64 - and rose to 66/10½ on the 6th, then dropping to 64/7½ on the 11th and 55/4½ on the 12th. On the 14th it was 63/10½; it then recovered to 65/7½ (25th), but subsequently went lower, closing 65/7.

English Lead opened £21, then dropped to £20 (5th), sharply recovering to £21.5 (7th), and keeping between £20.15 and £21, and closes £21.10.0.

	£	s.	d.
Aluminium, ingots, ton lots	90	0	0
Antimony, Blk. sulphide powder, ton	70	0	0

An antimony refinery is reported under construction at Harbor Industrial City, Cal. The capacity is said to be 1500 tons per month, and the operating company is reported to be producing ore from desert claims in southern California.

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Concentration of Gold in Bottoms in the Copper Converter.—A method of recovering the gold in converter copper not rich enough to warrant electrolytic refining, is described by Mr. H. F. Collins in *Bulletin* No. 128, Inst. Min. & Met. The process has been standard practice at Cueva de la Mora since November, 1914. The operation depends on the incomplete oxidation of white metal to "pimple" metal and "bottoms," and separation of the latter before completing the oxidation. The author has adapted it to 3-ton acid-lined converters by providing a cast-iron tapping block opposite the tuyeres, having a tap-hole 1½ in. in diameter.

"When the lining is being rammed this hole has an ordinary ⅞-in. steel bar pushed through up to within an inch of the mould, so that the lining may be rammed round it as tightly as possible, and when the moulds are removed the bar is at the same time withdrawn in order to facilitate 'drying out.'

"When the converter is placed upon the stand for use the tap-hole is closed by a plug of clay, and a short ⅞-in. bar is then driven in so as just to protrude on the inside of the lining while the head stands out some 16 to 20 in. from the front of the converter shell. After blowing to precipitate as metal the required quantity of copper, the converter is turned down till the bar stands at about 75 deg. from the horizontal.

"After knocking it in an inch or so in order to penetrate any skin of copper that may have formed on the inside, the usual ring and wedge are affixed, and the bar is driven out as quickly as possible by rapid blows; as its point leaves the converter shell the mould car held in readiness at the back is rapidly pushed forward, while the converter is at the same time turned until the tap-hole is vertical.

"After one, two or three moulds have been filled, according to the size of the charge, and the issuing stream is evidently white metal and not copper, the converter is turned up as rapidly as possible, the tap-hole being plugged with clay while in motion until the next operation, and blowing is restarted to finish the charge as usual."

The success of the operation depends on not losing too much time in skimming and not adding too much scrap after skimming, so that the reduced copper is at a temperature above the melting point of the pimple metal.

"As regards the concentration of gold in the bottoms, in practice it is easy to recover 70 per cent of the gold originally existing in the charge in the form of bottoms, amounting to 9 per cent of the total weight of converter copper produced, and 25 times as rich. The richness of the bottoms in gold depends upon the relative proportions of bottoms and residue bars from each charge."

The workmen apparently have no difficulty in becoming expert in operating the converter in the proper manner, and in securing bottoms of uniform weight and value.

"In order to obtain good results, it is necessary to hit the point of 'white metal' with considerable nicety before the final skimming prior to commencing the blowing for bottoms, since if the white metal is low and contains more than 4 per cent iron, as occasionally happens when the skimmer is either careless or timid, the time required for oxidation of the excess iron will vitiate the calculation of that required for blowing to 'bottoms'; and insufficient copper will be reduced. Pro-

vided, however, the point at which the white metal is skimmed be kept fairly uniform, it is only necessary to proportion the time for 'bottoms blowing' roughly to the size of the charge."

Assay of Gold-Bearing Cyanide Solution.—A method for this purpose that has been in long use at the St. John del Rey property, Morro Velho, Brazil, is published in *Bulletin* No. 128, Inst. Min. & Met., by Messrs. DONALD M. LEVY and HAROLD JONES. The method is based on the precipitation of the gold by means of zinc shavings, or a zinc-load couple, from the boiling solution, in the presence of suitable quantities of silver and lead salts. Sufficient silver is introduced to form a parting alloy in the button. The following stock solutions are used:

Silver Solution.—1 grain silver per 10 cc. Dissolve 36 grains silver nitrate in water, add sodium cyanide in small quantities till the precipitate first formed is just dissolved. Dilute the solution to 2½ liters.

Sodium Cyanide Solution.—10 per cent. Dissolve 250 to 260 grams sodium cyanide in 2½ liters of water.

Sodium Plumbite Solution.—Dissolve 65 grams lead acetate in water, add sodium hydroxide solution till the precipitate first formed just redissolves, then dilute to 2½ liters.

The quantity of solution taken for each test is one two-thousandth part of the I. M. M. ton (7000 grains, or 453.6 cc.), so that using the ordinary bullion assay weights for weighing the final gold the result is read off directly as grains fine gold per ton. "This volume of solution is poured into a flask of 1¼ liters capacity and the silver solution is added; for the rich solutions (before passing zinc-boxes), 15 cc. of the silver solution are used, for the poor solutions (after passing zinc-boxes) and for wash-waters only 5 cc.

"Next 10 cc. of the sodium cyanide solution are added, then 5 cc. of the plumbite solution, and the mixture shaken.

"Twenty grams of zinc-shavings are now placed into the solution and the contents of the flask gently boiled for half an hour and then filtered at once, through a 9-in. filter-paper, the clear filtrate being rejected. To the flask containing the residual zinc-shavings a little water is added (say about 20 cc., only just so much being required as will prevent the cracking of the flask by the drying and heat produced on the subsequent addition of acid), then 70 cc. of commercial hydrochloric acid. After the complete solution of the zinc the contents of the flask are poured onto the filter, flask and filter being subsequently well washed with water.

"The wet filter is now transferred to an assay crucible placed in the furnace, dried slowly and then simply carbonized at a moderate heat, and the pot withdrawn from the fire. The following fluxing charge is now added:

Red lead	12.5 grm.
Borax	22.5 grm.
Sodium carbonate	12.5 grm.
Sodium chloride	2.0 grm.
Flour	2.0 grm.
Powdered glass	2.0 grm.
Potassium nitrate	2.0 grm.

"The crucible is returned to the furnace and the charge run down in the usual manner, from twenty to thirty minutes being required to complete the fusion, after which the contents of the crucible are poured, the metallic button detached and cupelled in a small magnesite cupel, the resulting beads being rolled out and parted directly in the usual manner."

Zinc and Lead

Flotation at the Timber Butte Mill, Montana.—In a paper to be presented at the San Francisco meeting of the American Institute of Mining Engineers next September, Mr. THEODORE SIMONS gives many details of the design, construction and operation of the Timber Butte concentrator now treating Elm Orlu zinc ore. Since flotation plays an important part in the scheme of treatment at this mill, the information given on that point is timely. The ore contains zinc, lead, copper, gold and silver. The gangue minerals are quartz, barite, fluorite, rhodonite and rhodocrosite. The ultimate aim of the treatment process is to produce three classes of concentrates suitable for copper, lead and zinc smelters. Table I gives the metallic contents of crude ore and mill products.

TABLE I.—AVERAGE ANALYSIS OF CRUDE ORE, CONCENTRATES AND TAILINGS

Name of Product	Cu Per Cent	Ag oz. per Ton	Au oz. per Ton	Fe Per Cent	Zn Per Cent	Pb Per Cent	Insol. Per Cent
Original ore	0.73	6.23	0.013	3.29	18.52	0.75	62.23
Copper-iron conc.	2.25	21.01	0.04	19.78	22.78	13.01	2.30
Lead-iron conc.	1.13	18.91	0.04	9.99	9.15	50.60	5.05
Coarse-zinc conc.	1.96	14.74	0.035	9.15	47.77	1.88	3.47
Fine-zinc conc.	2.22	16.84	0.036	4.45	52.44	1.72	5.05
Tailings	0.07	0.60	0.0017	0.44	1.20	0.05	95.42

The design and flow-sheet (Fig. 1) of the mill are the result of extensive tests. There are but two essential operations in the process: table concentration and flotation. Wilfley and James roughing tables make a lead-iron product rich enough for retreatment, and a finished zinc concentrate, the latter representing 25 per cent to 30 per cent of the total original zinc in the ore.

The mill proper consists of three separate buildings, connected by runways for conveyors and concentrate launders. The lower building, 155 by 70 ft. in size, contains the concentrate plant and bins, the coarse-ore bins and coarse breakers, the boiler plant and coal bins. The next higher building, 260 by 80 ft., contains the roll-crushing, table-concentration, and flotation plants. The highest building, 20 by 30 ft., contains the supply bin and feeders.

Rough concentration begins on No. 8 Wilfley tables, the feed ranging in size from 2.5 mm. to the finest product of crushing. Each table handles 100 tons of ore per day. In addition to the finished coarse zinc concentrate of about 50 per cent grade, several intermediate products are cut out for regrinding and further treatment by classification, jigging and concentration on Wilfley and James tables. The tailings from the James sand tables are reground for final separation of sulphides by flotation.

To unlock the finest included grains of mineral from Elm Orlu ore it is necessary to grind to about 60 mesh, and this is the maximum size of the flotation feed. The pulp is kept at a uniform density of three parts of water to one of ore, and is heated to a temperature of 130° F. by the introduction of live steam. Temperatures below 125° F. reduce the efficiency of the operation. Sulphuric acid also has been found essential, and is added at the rate of 7 to 8 lb. per ton of original ore. Oil is added at the rate of 0.5 lb. per ton. An outline of a cell of the Minerals Separation machine is shown in Fig. 2. Oil is introduced in the mixing compartment (*A*) of the first cell where the pulp is violently churned by the action of the agitator (*B*), which at this plant makes 265 rev. per minute and causes the propellers (*C*) to run at a peripheral speed of about 1500 ft. per minute. The aerated mixture passes through the opening (*D*) into the flotation compartment (*E*), where the froth containing the sulphides of lead, copper, zinc and iron, as well as some of the richer middlings, immediately rises to the surface, while the clean gangue and the leaner middlings drop to the bottom.

The flotation compartment has the shape of a spitz-

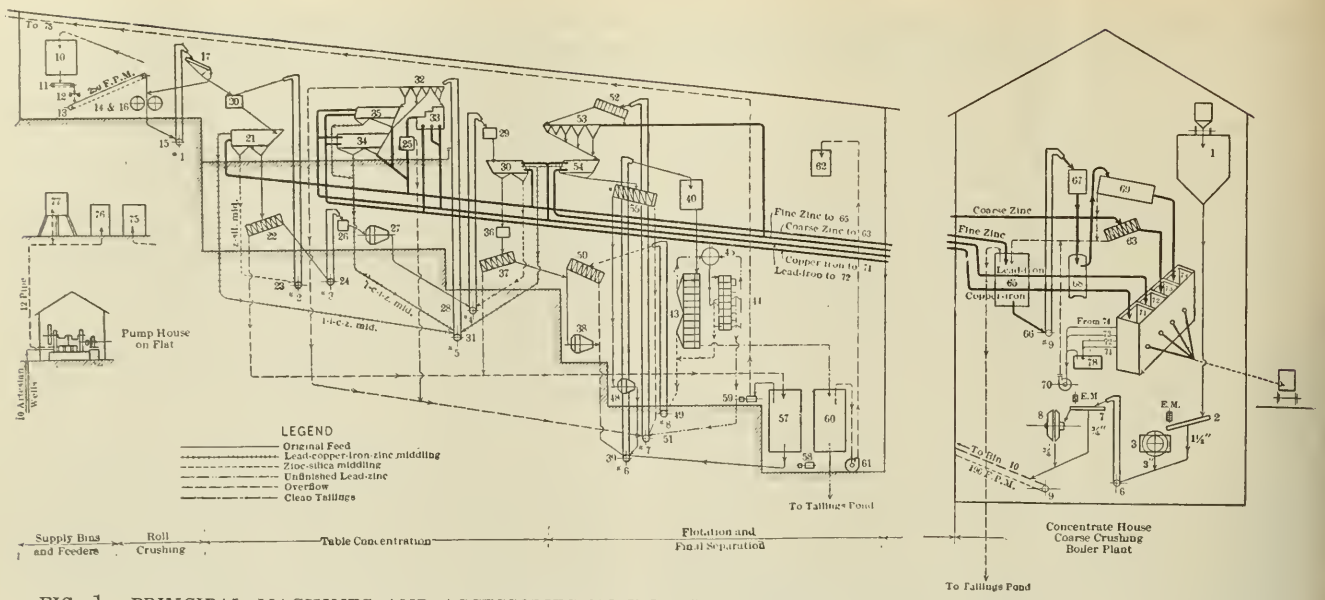

FIG. 1—PRINCIPAL MACHINES AND ACCESSORIES IN THE CONCENTRATOR OF THE TIMBER BUTTE MILLING CO., SHOWN ON FLOW SHEET

Flow Sheet Number	Number of Pieces	Description of Machine
1	2	Crude-ore bins, 750 tons combined capacity.
2	1	Shaking-screen feeder, 1½-in. square openings.

kasten, the apex of which is provided with a valve (*F*), adjustable by a hand wheel (*G*). Through this valve the material that has settled to the bottom of the first cell is drawn into the adjoining cell by the pumping action of its propeller. The process is here repeated and sulphides which did not float in the first cell are given a chance to do so in the second one, and so on.

The agitating compartments of the flotation cells are lined with cast iron, and the propellers are made of brass. All agitators of a standard machine are driven from one main shaft by gears which are protected from dust by steel housings. Gears are placed so that propellers in adjoining cells revolve in opposite directions, thus equalizing the strains on the machine and the power transmission.

The following statement gives in detail the flow of ore through the flotation section:

"From the sludge tank (40), which acts as an equalizer between the gravity-concentration and flotation section, the pulp flows to a standard 600-ton Minerals Separation unit (43) known as the 'rougher machine.' It consists of eleven cells, each divided into a mixing or agitating and a flotation compartment. The intensely agitated pulp discharges from the mixing into the flotation compartment, where the pulp is comparatively still and where a portion of the sulphide minerals rises to the surface to be skimmed off by revolving paddles and discharged into a launder in front of the cells. The remainder of the sulphides and the gangue that has settled to the bottom of each flotation

compartment are drawn into the adjoining cell by the pumping action of its agitator. Here the process is repeated and sulphides not floated in the first cell are given a chance in the second cell, and so on.

"The overflow from the last five cells of the 'rougher machine' (43) is a middling that goes via No. 8 elevator (49) to Akins classifiers (50). The classifier overflow returns to the 'rougher machine' of the flotation section. Sands are reground in two 8-ft. by 30-in. Hardinge mills (38) to an approximate 60-mesh maximum size and return via No. 6 elevator (39) to flotation section.

"Finished tailings from the eleventh cell of the 'rougher machine' (43) flow to a 36-ft. Dorr thickener (60) to be partly dewatered and thence to the tailings pond. The overflow from this tank is hot water, free from solids. It is pumped by a two-stage centrifugal

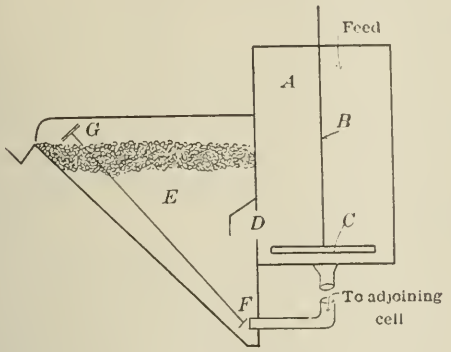

FIG. 2—OUTLINE OF M. S. FLOTATION CELL

pump (61) to a 10 by 10 ft. tank (62), which supplies the flotation machines with hot water.

"The mixed sulphide concentrate which overflows from the first six cells of the 'rougher machine' (43) goes via air lift (45) to a 200-ton Minerals Separation unit (44), consisting of eight cells, known as the 'finisher.'" Here the 'rougher' concentrates are refloated for the purpose of removing more of the gangue minerals. Cells Nos. 1—2—3—5—6—7 of this machine (44) make a float sulphide which goes via No. 7 elevator (51) to classifiers and James tables for final separation of lead and iron from the zinc.

"Overflow from cells 4 and 8 of 'finisher' (44) returns via air left (45) to the same unit. The bottom discharge from cells 4 and 8 is a middling which joins the middlings from the 'rougher machine' (43) to be reground in Hardinge mills (38) and returned to the flotation section.

"The float concentrates from unit (44) are lifted by No. 7 elevator (51) to an Esperanza classifier (52), the overflow from which is a finished fine zinc concentrate that goes to two 28-ft. Dorr thickeners (65) in the concentrate building. Sands go to a five-spigot Richards hindered-settling classifier (53), whose overflow is a finished fine zinc concentrate, which joins the overflow of the Esperanza classifier.

"The discharge from the five spigots of the Richards classifier is distributed on seven No. 3 James sand tables (54), where the lead and zinc are separated and the insolubles in the zinc concentrate reduced to about 3.5 per cent. Each table makes the following products:

"1. A finished lead concentrate, which goes to bin (72).

"2. A lead-copper-iron-zinc middling, which is returned via No. 5 elevator (31) to the primary jig and table retreatment circuit.

"3. A fine zinc concentrate, which goes to Dorr thickeners (65) in the concentrate building to be partly dewatered.

"4. A tailing, which is reground in a 4½-ft. Hardinge mill (48) after passing through a 30-in. Akins classifier (55) whose overflow returns via No. 7 elevator (51) to the final table-separation circuit.

"The product of the Hardinge mill (48), which is of about 60-mesh maximum size, goes to flotation section via No. 6 elevator (39).

"The Dorr thickener (57) receives practically all the fines and slimes coming from the mine and those made in the crushing operations. The overflow is dirty water, which is pumped by a double Cameron steam pump (59) to the 'dirty-water tank' (75) at the top of the mill, whence it returns for circulation throughout the mill. A duplicate auxiliary Cameron pump (58) is put into service whenever pump (59) is stopped for repairs. From the bottom of tank (57) the thickened pulp is lifted by hydrostatic pressure to the boot of No. 6 elevator (39) to go to flotation section."

Taking the mill as a whole, the ratio of concentration for zinc is 2.89, and for lead and iron 125, approximately 20 per cent of which is lead concentrate. Treatment costs have averaged between $2 and $2.25 per ton of crude ore, including labor, power, water, supplies, repairs and general expenses, but not interest on investment or depreciation. Extraction is about 96 per cent for zinc and 92.6 per cent for silver.

Recent Chemical and Metallurgical Patents

Copper and Zinc

Leaching Copper with Ammoniacal Solutions.—The proposed method of leaching metallic copper from the tailings at the Calumet & Hecla, in Michigan, is disclosed in a patent granted to Mr. C. H. BENEDICT, metallurgist for the company. A brief statement of the

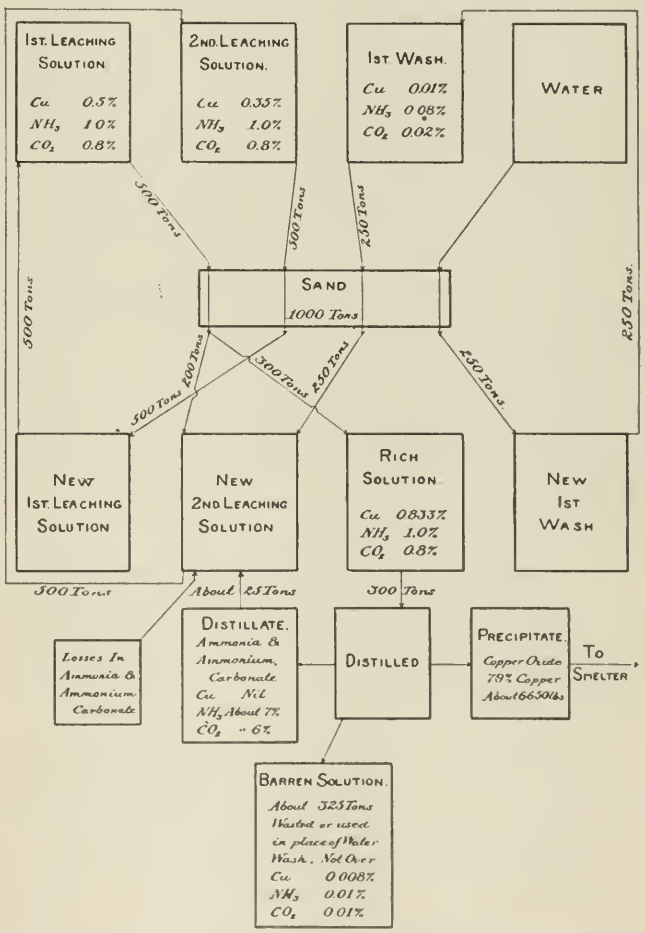

FIG. 1—AMMONIA LEACHING PROCESS FOR METALLIC COPPER ORES

process appeared in Metallurgical and Chemical Engineering for April, 1915, page 233. The flow-sheet of the process is represented in the accompanying Fig. 3. In view of the interest in the process, we give an extended abstract of the patent specifications, which are unusually instructive and complete.

"It has long been recognized that—(1) copper oxide will dissolve in ammoniacal solutions, yielding copper-ammonium compounds; (2) solutions of cupric-ammonium salts are capable of dissolving native or metallic copper, yielding cuprous-ammonium salts; (3) these cuprous-ammonium salts may be oxidized, by air or other suitable oxidizing agents, to cupric-ammonium salts; and (4) copper-ammonium solutions subjected to distillation are decomposed with separation of copper oxide, ammonia being volatilized." The difficulties encountered in applying these ammoniacal solutions to copper extraction in a commercial way have been the heavy loss in ammonia and the high cost of apparatus adequate to prevent such losses. According to Mr. Benedict's investigations, he is of the opinion that the loss of ammonia is not due exclusively to volatilization, but to adsorption of ammonia by the fine sands and especially by slimes. He has discovered also that this adsorption is generally proportionate to the concentration of ammoniacal solution, being less in dilute than in strong solutions. Thus, in solutions containing 2 per cent or less NH_3 in the free state, adsorption is so small as to be negligible from the aspect of commercial success.

"It is a primary object of the present invention so to operate a cyclical leaching-process as to render it practicable to use these highly dilute ammoniacal solutions of copper for solvent purposes, securing thereby the advantage of small or negligible losses of ammonia and of copper, without unduly increasing the cost and size of the installation. To this end, the cycle of operations is so arranged that an amount of copper equal to that extracted from a given batch of ore will be found concentrated in a relatively small proportion of the total volume of solution brought into contact with this ore. A suitable volume of this stronger solution is subjected to distillation to precipitate its copper-content in the form of oxid, and to recover the free ammonia and any volatile ammonium salts, which are restored to the cycle at the appropriate point, the volume so distilled preferably containing an amount of copper practically equal to the total quantity of copper extracted from the ore in the same cycle."

"The four typical solutions, as applied to a sand assaying approximately 0.5 per cent of copper, in the order of their application to the sand, are designated and characterized as follows, percentages being by weight:

(1) "First leaching solution": 0.5 per cent Cu: 1.0 per cent NH_3: 0.8 per cent CO_2.

(2) "Second leaching solution": 0.35 per cent Cu: 1.0 per cent NH_3: 0.8 per cent CO_2.

(3) First wash": 0.01 per cent Cu: 0.08 per cent NH_3: 0.02 per cent CO_2.

(4) "Second wash": Water, or a distillation reject containing only traces of copper and ammoniacal compounds."

"Sand finer than forty mesh, previously freed from slime by means of a Dorr classifier or otherwise, is run into a tank which for illustrative purposes may be 54 ft. in diameter by 12 ft. high. This tank should be covered, fitted with valve-controlled vents, provided with a false bottom of filter-cloth supported on a wooden frame and fitted with an overflow and with appropriate means for receiving and delivering the sand and the various solutions. The sand is run in with water in such manner as to be uniformly distributed. After one thousand tons of sand have been delivered to the tank, filling it with sand to a height of about 10 ft., the water meanwhile overflowing, the excess water is removed by decantation and the sand drained to the surface. The first bleaching solution is then led into the tank from above, the bottom valve opened, and the water displaced at as rapid a rate as filtration will permit. As soon as ammonia begins to appear at the outflow, indicating substantial displacement of the water, the lower valve is partially closed and the percolation rate adjusted as may be found necessary to secure a satisfactory solution of the copper-content of the ore. The first portions of the solution are found to be poor in copper and low in ammonia-content, owing to diffusion and imperfect displacement, and are run into the sump for the second leaching solution. Soon the first leaching solution, properly enriched in copper and now termed 'rich' solution, appears and is permitted to flow to the 'rich' solution tanks for subsequent distillation. This 'rich' solution is the richest portion of the effluent coming from the sand, and is ready for distillation. The volume of rich solution distilled for any one batch of sand is dependent upon the copper-content of the sand, and in practice will be, on the average, such volume that the copper-content of the rich solution distilled is practically equal to the copper extracted from the sand. The rich solution on distillation breaks up into copper oxid for the smelter, ammonia and ammonium carbonate for the second leaching solution, and a reject containing traces only of copper, ammonia and ammonium carbonate; this reject may be used instead of water for the second wash if desired."

"As soon as the first leaching solution, amounting in all to some five hundred tons, has been run upon the sand and has reached the sand line, the second leaching solution is run in, in approximately equal volume; and when this in turn has all reached the sand line, the first wash is added, followed in the same manner by the second wash, the effort in all cases being to avoid mixing solutions, and to displace each by that next succeeding it in the cycle. The several effluent solutions are so manipulated as practically to maintain the proper composition balance, as between the chemical contents of the various solutions, a typical method by which this may be done being illustrated graphically in the diagram before referred to. There is thus established an equilibrium in the process, there being also a regular progression of solutions in the following general manner: The second wash of charge N takes up a little copper and becomes the first wash of charge $N + 1$; this in turn takes up a little more copper and receives the distillate and some dissolved copper from previous cycles and becomes the second leaching solution of charge $N + 2$; the free ammonia of this second leaching solution is partially used in dissolving copper, when it becomes the first leaching solution of charge $N + 3$, its copper content having been fully oxidized to the cupric condition; this first leaching solution having become saturated with copper by its passage through the sands, and having thereby lost its solvent power, is in part distilled, as before described, depositing its copper values as a 79 per cent oxid, yielding its ammonia and ammonium carbonate as a pure product to join cycle $N + 4$ as a second leaching solution, and furnishing from its almost barren reject a second wash for a following cycle. In a plant containing more than one leaching tank, these several operations are of course all going on at the same time, the total volume of solution in circulation being practically a constant: thus "rich" solution is continuously withdrawn from the leaching circuit, and is replaced by an equal volume of

oxidation through the surface contact of the dilute solutions with the atmosphere, particularly after the process has reached the desired equilibrium, so that relatively large amounts of copper are being carried in solution.

"It is accordingly quite unnecessary, as a rule, in the regular operation of the process, to use any system of mechanical aeration of the several solutions. These are stored in covered tanks, with controlled vents, whereby air may be admitted as required. Means for injecting air under pressure may also be fitted both to the storage and leaching tanks. It has further been shown, in practice, that whereas there is some appreciable adsorption of ammonia by the sands, even from solutions so dilute as those contemplated under the present invention, the adsorption of copper is practically nil; and the losses of copper are materially reduced by the employment, as described, of at least two leaching solutions, applied successively, the second leaching solution being poorer in copper than the first, and both solutions being highly dilute.

"Obviously, the loss due to ammonia adsorption may be somewhat lessened by repeated washings, and it is possible and may be advisable to have a 'third wash' following the 'second wash,' the expediency of this being a commercial circuit of pipes, pumps, storage room, and the like. So, too, the balance between the amount of 'rich' solution distilled and 'second wash' used is in part a commercial one, depending upon the cost of steam and the distillation loss, as against the recovery of additional copper and ammonia by more complete washing."—(1,131,986, Mar. 16, 1915.)

Copper Hydrometallurgy.—Improvements in the treatment of such copper ores as chalcopyrite and chalcocite, by roasting, leaching and electrolysis are contained in a process patented by Mr. E. A. CAPPELEN SMITH of New York City. In the roasting process the ore is treated in a furnace of the Wedge or Herreshoff seven-hearth type, at a temperature of between 600 deg. C. and 750 deg. C. in the first five hearths and between 450 deg. C. and 500 deg. C. in the last two hearths. In

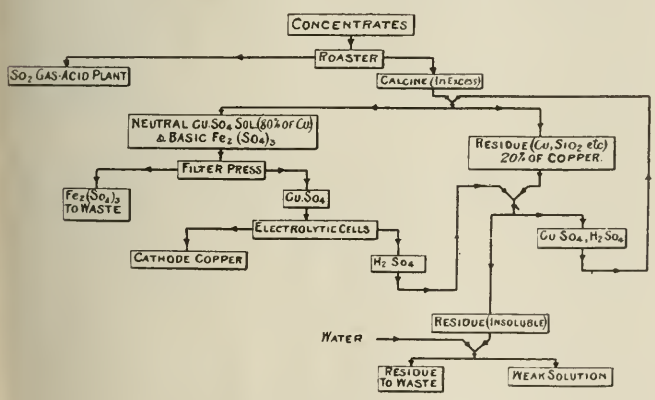

FIG. 1—COPPER LEACHING PROCESS

the hotter hearths sulphur is eliminated and FeO formed; in the last two cooler hearths the FeO is converted into Fe_2O_3. The copper compounds are completely oxidized, and the iron content is in a form practically insoluble in sulphuric acid.

The roaster gases are converted into sulphuric acid for leaching.

A diagrammatic flow sheet of the process is shown in Fig. 1. The process is cyclic, and is thus described:

"Assuming that the cycle of operations is fully under way, a quantity of partially leached ore from which about 85 per cent of the copper has been removed, in the step hereinafter referred to as the neutralizing leaching, is treated by agitation with the electrolyzed solution returned from the electrolytic vats. The solution thus employed will contain usually about 10 to 12 per cent of free sulphuric acid, and say from 1.5 per cent to 2.5 per cent of copper, according to the extent to which the electrolysis has been carried. Practically all the copper still remaining in the partially leached ore is taken into solution by this leach liquor, and also a very small amount of iron in the ferric state; the resulting solution is then drained into another agitating tank, where, in order to remove the ferric iron, a fresh batch of ore from the roasting furnace is added in sufficient quantity to neutralize practically all of the acid remaining in the solution. By this operation, the ferric iron taken up from the partially leached ore by the acid electrolyzed solution, is precipitated as a basic sulphate of iron, while about 85 per cent of the copper contained in the fresh batch of ore used in the neutralizing leaching is dissolved. The solution and the ore are then withdrawn to a settling tank, where the partially leached ore quickly separates out from the solution, which latter retains suspended therein, practically all of the basic iron salts. The solution is then immediately tapped off or siphoned off from the top of the ore before it has time to deposit any material part of its salts in the ore. It is then filter pressed, which removes the suspended iron salts and gives a clear electrolyte, almost devoid of iron salts, which electrolyte then passes to the electrolytic tanks.

In the electrolytic tanks, the copper is electrolyzed out of the solution between a practically insoluble or non-corrodible anode and a copper cathode. For the insoluble or non-corrodible anode, the usual lead anode, preferably having a small proportion of antimony may be employed. It has not always been possible to conduct the roasting operation in such manner that all of the iron present in the ore is converted into ferric iron; a small amount, say, less than 1 per cent, will usually remain as ferrous iron, and, in the leaching which follows, this ferrous iron being much more readily soluble in sulphuric acid than the ferric iron will enter the solution. After the ferrous iron is in the solution it will run through the operation up to the point of electrolysis. At a certain stage of the electrolysis, however, practically all of the iron present in the electrolyte is converted into ferric iron. If now it should be found desirable to remove the iron from the solution, the electrolysis can be stopped at this point and the solution can be used over again in leaching, whereupon, in the neutralizing leaching, all of the iron in solution which is now in the ferric state will be precipitated, even including the iron which originated from the ferrous iron present in the roasted ore. If the electrolysis is continued until the solution is very low in copper, the small amount of iron remaining dissolved in the solution will be reconverted into ferrous sulphate, which is not removable, as a basic sulphate in the neutralizing leaching." (1,134,767, April 6, 1915.)

A briquet for use in zinc furnaces is patented by Mr. GEORGE S. BROOKS of Depue, Ill., and assigned to the New Jersey Zinc Company. It is composed of four parts by weight of zinc ore crushed to the usual degree of fineness; one part of more finely powdered ore, or in lieu thereof, one part of commercial zinc oxide; one and one-half parts of powdered coal; and a sufficient quantity of common salt dissolved in water, to form a thick plastic mixture of the several ingredients. The amount of salt usually used is about 1½ per cent in weight of the ore in the mixture. The mixture is pugged and formed into briquets about 7½ in. in diameter and 7 in. long.

The briquets, in whatever way formed, are then subjected to about 90-lb. pressure per square inch. The briquets are kiln-dried for twenty-four hours at a tem-

perature of about 200 deg. F. During the drying the salt forms a crust or shell on the surface of the briquet, which protects it in handling and forms a filter about the ore through which the distilled zinc must pass. This results in a high production of spelter and a reduction in production of blue powder. The briquets are charged into the retorts by means of a semi-cylindrical chute long enough to contain enough briquets to fill the retort. With 50-in. retorts, six 7-in. briquets form a charge. The practice increases the capacity of retorts about 15 per cent to 20 per cent, and when the reduced quantity of blue powder requiring further smelting is taken into consideration, the capacity of a furnace treating briquets is increased 33 1/3 per cent. (1,137,835, May 4, 1915.)

Iron and Steel

Sintering Ores.—In a patent granted to Mr. Albert F. Plock of Pittsburgh, Pa., and assigned by him to the Pittsburgh Metallurgical Company, disclosure is made of apparatus for sintering ores. Fig. 2 shows the arrangement of apparatus. Cars 10 provided with grate bottoms are delivered from transfer trucks 6 to elevated tracks 2. The cars 10 successively pass under the ore

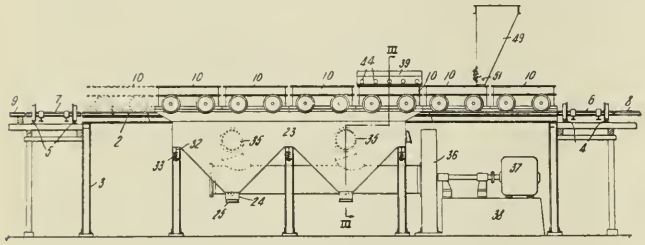

FIG. 2—SINTERING APPARATUS

hopper 49, receiving a charge of material to be sintered, thence into the furnace 39 where the top of the charge is ignited by means of gas or oil burners. On entering the furnace the cars register also with the suction box 23 placed below the tracks and connected with a fan 36 operated by a motor 37. While passing over the suction box the ignited charge is subjected to a downward draft, whereby the mass is sintered. When this operation is complete the car is delivered onto transfer truck 7 and removed to a point of discharge. No means is disclosed for mechanically moving the charge cars over the elevated track, nor for regulating the rate of travel. (1,140,710, May 25, 1915.)

Gold and Silver

Automatic Regulation of Pulp Thickening Apparatus.—In the operation of such apparatus as the Dorr continuous thickener, in which overflow and under-

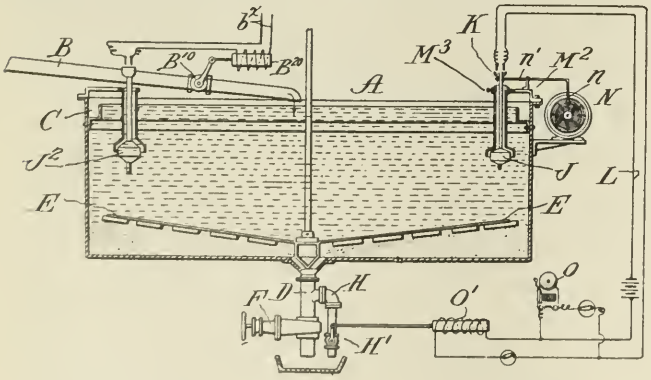

FIG. 3—REGULATION OF PULP THICKENING

flow products of certain character are sought, it is desirable that the apparatus should be operated in a uniform manner. With this object in view, Mr. J. V. N. Dorr of Denver, Col., has patented means for automatically giving warning when a change of density occurs in a selected zone of either product, and to regulate the discharge of the products for the purpose of maintaining constant conditions. Use is made of a hydrometer which rises and falls as the density of the liquid in a predetermined zone varies, and which may be made to operate mechanism to sound an alarm or regulate the apparatus, or both. The idea is illustrated in Fig. 2, applied to a Dorr thickener. A hydrometer J is adapted to close an electric circuit when the density of the liquid in a certain zone varies, and this circuit includes a bell or other alarm and a solenoid operating a discharge cock for the settled material. Recording apparatus N can be used by attaching a pen n by lever n' to the hydrometer. A similar hydrometer J^2 can be made to operate a cock on the feed line B by means of

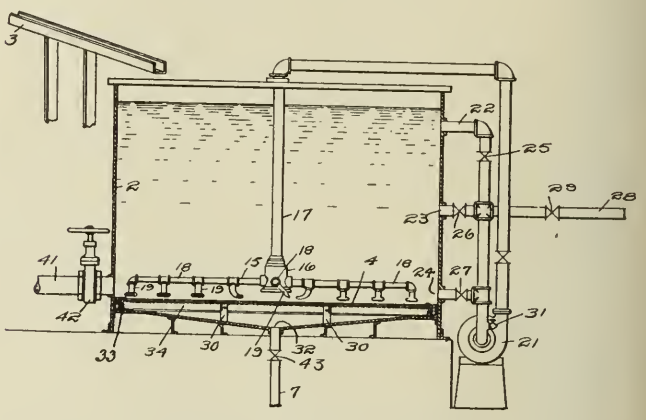

FIG. 4—FILTRATION OF SLIME

the solenoid as shown in the diagram. (1,140,131, May 18, 1915.)

Apparatus for Cyaniding Slime.—A method of treating slime pulps and separating the metal-bearing solution from the valueless gangue by filtration without forming a filter cake, is patented by Mr. Albert E. Vandercook of Alameda, Cal. Interest attaches to the process inasmuch as it is reported that it is to be adopted at two properties in California and Nevada. One of the mechanical features is illustrated in Fig. 4, being a vat in which the treatment and the filtration take place.

The vat has a filter bottom and is connected with a source of vacuum not shown. Within the vat is a distributing pipe and nozzles through which the slime pulp is forced by the centrifugal pump 21. The pump has three connections with the vat at 22, 23, 24, either one of which can be used while the others are closed. In operation the vat is filled with pulp which is circulated by the pump through the pipes and nozzles. The streams of pulp issuing from the nozzles sweep the filter surface and keep it free from accumulations. Filtration proceeds without the formation of a cake, and when the filterable liquid is practically removed and a thick pulp remains, wash solution or water is added through pipe 28.

The pulp is again thoroughly mixed and filtered as before. The operation may be repeated and the final thick pulp is sluiced out through pipe 41. (1,139,825, May 18, 1915.)

Smelting Process

Recovery of Elemental Sulphur.—A process for so operating smelting furnaces as to prevent the escape of noxious fumes, principally SO_2, and the production of elemental sulphur, is patented by Messrs. William F. Lamoreaux and Charles W. Renwick of Isabella, Tenn. The process is based on the reduction of SO_2 to sulphur

by means of carbon, and consists in passing the smelter fumes through an incandescent mass of coke. The electric current is used to heat the coke to the proper temperature and maintain uniform conditions. The temperature produced by the combustion of the coke alone in an atmosphere of sulphur compounds will not suffice to produce the reactions, as the product of combustion will mix with the smelter gases and vitiate the results. Hence the coke is heated electrically. The conversion from SO_2 to S depends on the temperature and length of time of contact with the coke. A temperature of 1300 deg. C. and a period of contact of five seconds accomplishes practically 98 per cent reduction. (1,140,310, May 18, 1915.)

Another process for accomplishing a similar purpose is patented by Mr. WILLIAM A. HALL of New York City. The reduction of SO_2 to S is accomplished in the smelting furnace by maintaining the top in as cold condition as practicable, by introducing continuously fresh ore to be smelted and by spraying the top of the ore with water. A portion of the water descends to a point where it is converted into steam, which reacts with the sulphide ore to form H_2S. This combines with the SO_2 present in the gases to form water and elemental sulphur, the latter being carried out in the gases and recovered in washers. (1,133,637, March 30, 1915.)

Metallurgical Furnaces

An improvement in hearths in roasting furnaces of the McDougal type is claimed in a patent to Messrs. JOHN H. KLEPINGER of Great Falls, Mont., and FRANK R. CORWIN of Douglas, Ariz. Instead of forming the hearths of numerous molded forms of refractory material, a monolithic structure of reinforced concrete is formed for each hearth. The construction is practically free from joints and uneven surfaces which, in the usual furnace, tend to weaken the hearth and increase the growth of accretions of fused particles. (1,140,042, May 18, 1915.)

The effective heating of the hearth of a roasting furnace by means of an electric current is the basis of a patent granted to Mr. UTLEY WEDGE of Ardmore, Pa. In a nine-hearth furnace, in which hearths 1, 3, 5, 7 and 9 are fixed, and 2, 4, 6 and 8 rotatable, electrical heating devices are applied to hearths 3, 5 and 7. Each of these hearths has sector-shaped recesses or chambers for the reception of electrical resistance blocks. Each recess is closed at its top to provide a continuous upper surface for the hearth, but is open below for the radiation of heat from the resistance block directly upon the material carried by the hearth beneath. (1,137,559, April 27, 1915.)

Sulphur Burner.—The Valley Iron Works Company, Appleton, Wisconsin, is now prepared to furnish the Vesuvius sulphur burner for producing pure sulphur dioxide gas in nine sizes from laboratory size to 9-ton capacity.

The **Clarage Fan Company,** Kalamazoo, Michigan, have opened a Cleveland sales office in the Rockefeller Building, Cleveland, Ohio. This office is in charge of Mr. R. G. Ferguson.

The **U. S. Blow Pipe & Dust Collecting Company** is the new name of the former U. S. Steel Tank & Pipe Co., exhaust-system contractors of 2090 Canalport avenue, Chicago, and 3000 N. Ninth street, St. Louis, Mo. The new name is more representative of their ever-growing business in shaving and fine dust collecting for woodworking, grain elevators, mills and all industries where dust and refuse are created.

Ore from the Boss mine, near Goodsprings, Nevada, containing the platinum group of metals, has been shipped to the American Smelting & Refining Co., according to a bulletin from the Mackay School of Mines. The shipment weighed 56,267 pounds and assayed as follows: Platinum, 1.1 oz. per ton; palladium, 5.47 oz.; gold, 8.75 oz.; silver, 9.0 oz.; copper, 0.97 per cent; insoluble, 80.7 per cent; sulphur, 0.5 per cent; iron, 6.7 per cent.

Welding Up Scrap Nickel Anodes

Some interesting experiments in the welding of nickel anodes by the oxy-acetylene process have just been concluded in the large plating department of The Prest-O-Lite Company, Inc., at its Indianapolis plant. As a result of these experiments and tests, worn nickel anodes which have previously been scrapped and sold at less than half price are now being reclaimed at a saving of more than 100 per cent.

The anodes used by The Prest-O-Lite Company, Inc., are castings of 90 per cent nickel, 8 per cent carbon and 2 per cent iron. They are elliptical bars approximately 1½ in. x 3½ in. cross section and 30 in. long and weigh about 30 lb. Their market value varies between 46 and 50 cents per pound. On the basis of the latter price, each 30-lb. anode has a value of $15.

By welding up old anodes which have been in the solution, and which have a junk value of between 22 and 25 cents per pound, The Prest-O-Lite Company, Inc., is now converting its entire pile of scrap nickel into what are practically *new anodes* at a total cost for gas

FIG. 1—SCRAP NICKEL ANODES WELDED TOGETHER

and labor of less than 6 cents per pound. This estimate is based on a recent test at Indianapolis in which 421 lb. of scrap anodes were welded up at the following costs:

463 cu. ft. oxygen, at 2 cents	$9.26
480 cu. ft. acetylene, at 2 cents	9.60
24 hours labor, at 25 cents	6.00
Total	$24.86

In view of the fact that this test was made before any experience in the operation had been gained, it is

apparent that better results and greater savings are sure to be the result of practice.

The method of handling this operation is as follows: As the anodes are eaten away by the solution they are turned over to an oxy-acetylene welder who "tacks" on scraps of old anodes by welding to increase the surface. One, two, three and sometimes four pieces of scrap are welded on, depending on the size and weight desired.

The welding flame is also employed to remove the brass hooks which are used to support the anodes while in solution. Under the intense heat of the oxy-acetylene flame (approximately 6,300 deg. F.) the solder melts away rapidly, leaving a pure nickel bar which is later welded up.

Thus, by the addition of from, say, 5 to 15 lb. or more of scrap nickel a brand new anode is manufactured at trifling cost and every bit of scrap is utilized without the loss of a single pound of metal. No flux is employed as this has been found to be unnecessary. The pieces of scrap are simply melted on or "fused" together, using another piece of nickel as a filling rod.

The welding process is a great benefit in obtaining perfect fusion, which is essential, as all joints must have electrical conductivity equal to that of new anodes.

Another great advantage is the fact that no skill or experience in the art of oxy-acetylene welding is required to weld up scrap nickel anodes—in fact, any workman with average intelligence can do the work without any previous knowledge of the process. The apparatus required to do the work is inexpensive.

Many previous attempts have been made to utilize scrap nickel anodes, the most common practice being to drill holes through several pieces and bind them together by means of lead rivets. This method depends upon the contact of the wire or rivet and the piece of scrap to conduct the current, and is therefore of uncertain value and in many cases a flat failure. If, for any reason, the contact is bad and offers too much resistance to the current of electricity, the metal might or might not dissolve. Therefore, by using the welded anodes as much scrap may be used in a tub as is desired without any danger of depleting the solution of metal.

The welding process solves an important problem in the nickel plating industry as hundreds of tons of scrap nickel anodes can now be utilized at the same value as new anodes and at trifling cost.

The Prest-O-Lite Company, Inc., estimates that more than a ton a year of scrap anodes can be used in its plating department.

The Course in High Temperature Measurements at Purdue University

BY ERVIN S. FERRY

Head of the Department of Physics.

Some half-dozen years ago the Department of Physics of Purdue University commenced the organization of a course in high-temperature measurements. The lack of standardization of equipment, as well as the lack of a text book or laboratory manual, necessitated a large amount of work premilinary to the admission of students. Much of this preliminary work was done by Dr. G. A. Shook, now of the University of Michigan. Since the departure of Dr. Shook the laboratory work of the course has been under the charge of Instructor J. R. Collins. As the course has emerged from the pioneer stage and now forms part of the required work of the students in our school of chemical engineering, it has been thought that a brief description would not be without interest to readers of *Metallurgical and Chemical Engineering.*

The course occupies one hour of lecture and five hours of laboratory work per week for one-half year. The lectures begin with a consideration of the ideal gas, the thermodynamic and the black-body temperature scales. Then follows a consideration of thermoelectric and resistance pyrometry. The methods of making the "cold-junction correction" as well as the practical means employed to diminish the magnitude of the error are discussed in some detail. The laws of radiation are taken up and discussed with especial reference to optical and radiation pyrometry. The methods of calibrating and using all the standard types of pyrometers are studied, as well as the availability of the various types for particular duties.

The furnace equipment includes three 20-kw tube furnaces, each connected to a separate transformer and switchboard (Fig. 1), a number of smaller electric

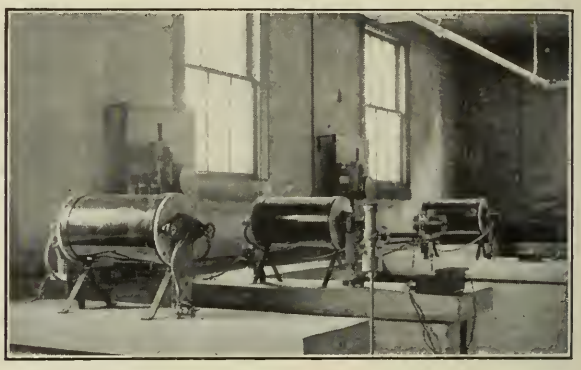

FIG. 1—TUBE FURNACES

furnaces, and a battery of five gas furnaces for 1-gal. crucibles (Fig. 2). Through the courtesy of the professor of practical mechanics our students also use the large oil furnaces belonging to that department. The laboratory maintains a Lummer-Kurlbaum "black-body," which, however, is no longer entrusted to student use.

The instrument equipment includes several types of thermoelectric pyrometers; resistance pyrometers having various types of bridges and potentiometers; radiation pyrometers according to Fery and Thwing; together with optical pyrometers according to Le Chatelier, Fery, Shore, Wanner and Holborn-Kurlbaum.

The list of experiments for the present year includes the ten determinations outlined below, followed by prac-

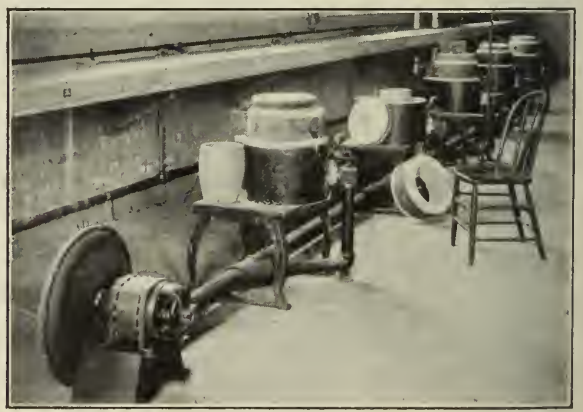

FIG. 2—GAS FURNACES

tical temperature determinations under shop conditions in the tempering room of the department of practical mechanics.

1. *Calibration of a Platinum-Rhodioplatinum Thermoelectric Pyrometer.*—The empirical curve is constructed by coördinating the known freezing points of five metals

or salts with the corresponding pyrometer indications. The equation of this curve is computed and the curve extrapolated.

2. *Construction and Test of a Base Metal Thermoelectric Couple.*—The two wires are wound with asbestos, coated with fireproof insulating material, the "fire end" fused, the wires annealed and tested for inhomogeneity. The calibration is made by comparison with a standardized platinum-rhodioplatinum couple. To exercise the student in making "cold-junction corrections" the cold junction of the standard thermoelement is maintained at a temperature different from that at which it was calibrated. The calibration curve of the standardized thermoelement is computed for the particular temperature of the cold junction at the time of the experiment. From this curve and the readings obtained from the base metal pyrometer the calibration curve of the latter is constructed. The ordinary approximate shop methods of correcting for the cold junction temperature are compared with the more precise method.

3. *Determination of the Transformation Points of a Specimen of Steel.*—For this experiment a device has been developed that will permit the location of not only the decalescent and incalescent points, but also the points of less marked absorption or evolution of heat.

4. *Calibration of a Resistance Thermometer.*—Both potentiometer and bridge indicators are used. From the indications at three known boiling points is computed the relation between temperature and resistance. From this equation the calibration curve is constructed.

5. *The Direct Calibration of a Pyrometer by Means of a "Black-Body" and a Standardized Thermoelement.*—The Fery lens radiation pyrometer, the Fery mirror radiation pyrometer, the Fery spiral radiation pyrometer, the Thwing radiation pyrometer and the Shore pyroscope are calibrated by a step-by-step direct comparison with a standardized thermoelement.

6. *Calibration of a Le Chatelier Optical Pyrometer.*—From the theory of the instrument and the observation of a "black body" at one known temperature a complete calibration curve is constructed. This is compared with the curve obtained by a step-by-step comparison of the optical pyrometer readings with the thermoelectric pyrometer readings of a "black-body" at a series of temperatures.

7. *Calibration of a Wanner Optical Pyrometer.* — A calibration curve is constructed based on the reading obtained when directed toward a "black-body" at one known temperature, and this curve is compared with the calibration curve obtained from observations on a body at a series of known temperatures.

8. *Calibration of a Holborn-Kurlbaum Optical Pyrometer.*—From the observations on a body at three known temperatures the equation of the calibration curve is computed. The curve obtained from this equation is compared with the calibration curve obtained from a series of known temperatures.

9. *The Determination of the Relation Between the Luminous Intensity and the Temperature of an Incandescent Lamp Filament.*—In this experiment a curve is obtained coördinating the temperature of the filament and the current traversing it, and also a curve coördinating candle power and current. From these two curves the required curve showing the relation between candle power and temperature is constructed.

10. *Calibration of a Fery Absorption Pyrometer.*—From the readings obtained when directed toward a "black-body" at two known temperatures the equation of the calibration curve can be found. The curve obtained by means of this equation is compared with one obtained from observations of a body at a series of known temperatures.

As in the other laboratory courses of the department of physics at Purdue University, before a student begins an experiment in this course he must write an analysis of the experiment which shall include the derivation of all equations used, the method of making the computations and an outline of the laboratory procedure. After completing the required observations he tabulates the data, makes the necessary computations, constructs his curves, and writes the laboratory report.

The analysis, the experiment, the computation and the report are all done under class-room conditions, without book, notes or any other assistance than that which may be given by the supervising instructor. This practice results in efficient preparation on the part of the student and a low laboratory maintenance cost on the part of the department.

A New Diaphragm Pump

The Colorado Iron Works Company of Denver, Col., has brought out a diaphragm pump which is felt to

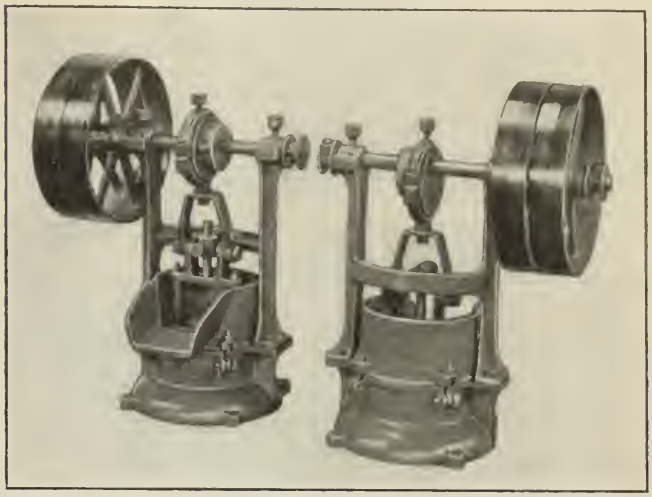

FIG. 1—NEW TYPE OF DIAPHRAGM PUMP

meet the requirements of handling slime in cyanide plants and similar work, and at the same time offers important advantages in the matter of convenience. The pump is illustrated in Figs. 1 and 2.

In ordinary power-driven diaphragm pumps, the power is applied through a rocking motion which causes

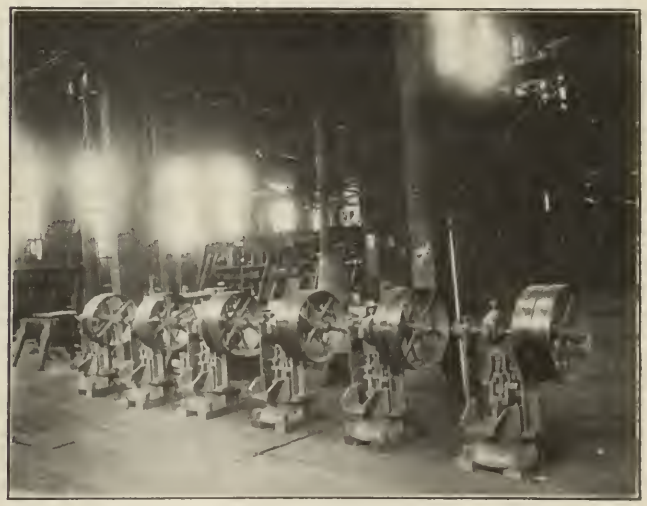

FIG. 2—DIAPHRAGM PUMPS ON ASSEMBLING FLOOR

rapid deterioration and failure of the diaphragm. In the pump under consideration this disadvantage is overcome by the use of an eccentric and cross-head working

in a guide. While this greatly increases the life of the diaphragm, yet to facilitate its replacement without disturbing the driving mechanism, the pitcher spout portion which holds the diaphragm in place can be raised for removal of the ruptured diaphragm and insertion of the new one. Hook bolts are here used to eliminate all possibility of dropping them or their nuts, possibly into a tank full of pulp.

Recognizing the advantage of a pump which will deliver the material at a uniform rate, this one is fitted with adjustable eccentrics such as used on jigs, whereby the length of stroke can be adjusted within a wide range to suit the desired volume, without changing the speed.

The pump is made with 3-in. and 4-in. suction, uses standard diaphragms and can be had with either side or bottom suction. While being a suction pump and consequently subject to limitations as to lift imposed by altitude and the density of pulp, it nevertheless has sufficient lift for most applications, and where it applies it offers probably the most satisfactory means obtainable.

British Producer-Gas and Ammonia-Recovery Plant

London *Engineering* of June 4, 1915, contains an interesting description of the producer-gas and ammonia-recovery plant developed by Mr. Arthur H. Lymn of

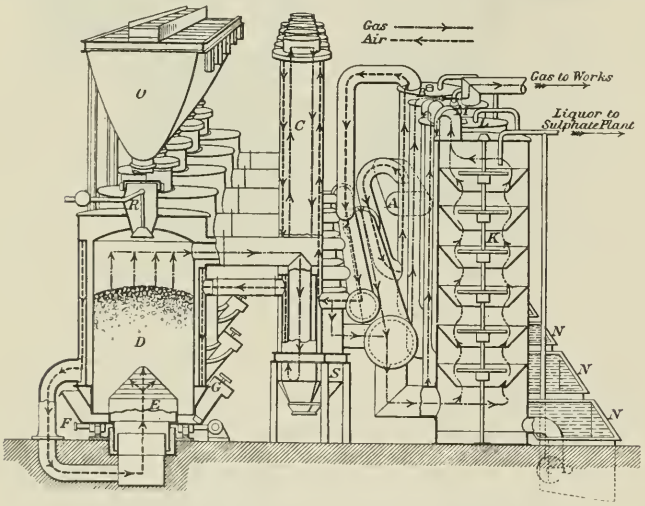

FIG. 1—DIAGRAM OF CYCLE OF OPERATIONS

Sanctuary House, Tothillstreet, Westminster. Although of British origin, the Lymn system has had some of its most important applications in Germany. During the two years immediately preceding the war, contracts for Lymn plants having a total value of about $500,000 were secured in Germany.

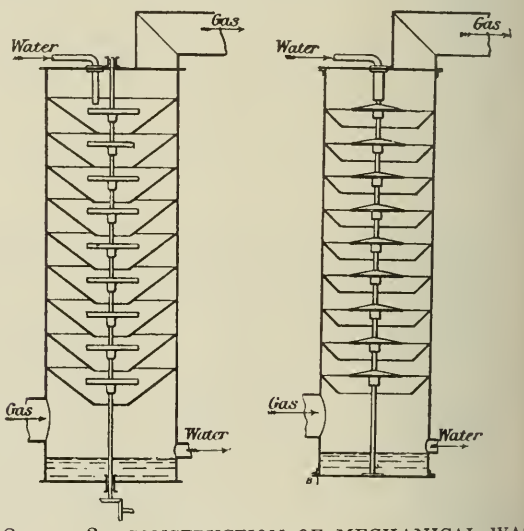
A perspective diagrammatic sketch of a Lymn plant is given in Fig. 1. In a general way it is based upon the Mond process, the essential patents of which have expired. The Lymn apparatus, however, has many features peculiar to itself, and in connection with these various advantages are claimed, as, for instance, low first cost, smallness of space occupied, and simplicity of operation. The plant is automatically regulated, and is capable of using a large range of fuels. It is stated that by-products can be profitably recovered in units as small as 500 horsepower. The special features of the Lymn producer and recovery plant are largely concerned with the ammonia-absorption, gas-washing, gas-cooling and air-saturating arrangements, the common high and bulky towers having been replaced by a novel system of vertical washers, in which the washing of the gas is chiefly brought about by its own momentum.

The cycle of operations, about which there is little novel, will best be followed by reference to Fig. 1, where D is the gas-producer, E the grate and F the water seal. This seal allows ashes to be removed from the grate by the apparatus G without interfering with the working of the producer. This operation is performed automatically or manually, depending on whether the grate is mechanical or non-mechanical. Above the producer there is an overhead fuel banker O, feeding to a charging-hopper R.

In Fig. 1 the heavy dotted lines represent the path of the air, and the dot-and-dash lines the path of the gas. The arrows on these lines indicate the direction of flow at various points. It will be seen that the air and steam blast enters the fuel in the producer through the grate; before dealing with this point in the cycle, however, it will be well to trace back the air stream to its point of origin at the blower A.

The blower is of the Roots, or some such type. The air from the blower first passes through the air-saturating apparatus B, in which it is brought into intimate contact with hot water and becomes saturated with steam. The water is heated during the cooling of the gas at a later point of the cycle. The saturating apparatus B will be described in detail later. From the saturating apparatus the air passes to the superheater C, in which it is superheated by the hot gases from the producer. The air and gases pass through the superheater in opposite directions. From the superheater the air and steam mixture may pass through the jacket of the producer, through the grate, and into the fuel bed. It is further heated in passing round the producer through the jacket.

We may now deal with the path of the gases, which as they leave the producer carry with them the ammonia and other constituents, which are afterwards recovered as by-products. The hot gases first pass to the superheater, where, in heating the stream of air and steam, they part with much of their heat, which is thus



FIGS. 2 AND 3—CONSTRUCTION OF MECHANICAL WASHER AND COOLER

recovered and returned to the producer. From the superheater the gases pass through a dust-separating apparatus S to the ammonia-absorber K. In this absorber the gases are brought into intimate contact with an atomised solution of sulphate of ammonia containing a small excess of sulphuric acid. The acid dissolves the ammonia in the gases, and the solution passing to the bottom of the absorber enters the tanks N. From the absorber the gases pass to the gas-cooler L, which is

an apparatus of the same type as the absorber. Here they are brought into intimate contact with cold water. This gas-cooler works in a cycle with the air-saturator, B, which has already been referred to in connection with the path of the air. The water first passes through the gas-cooler, thus cooling the gas and at the same time itself becoming heated. It then travels to the saturator, and saturating the air, is itself in turn cooled, and is then ready for a further passage through the gas cooler.

By the use of this cycle it is clear that a large amount of heat, which would otherwise be wasted, is recovered from the gas and returned to the producer as steam. On leaving the gas-cooler L, the gases pass to a second cooler M, where they are again brought in contact with cold water. Leaving this they are sufficiently clean and cool for firing boilers or furnaces, but if they are to be entering at the bottom, passes up through the finely-divided spray and is cooled, or, in the case of the absorber, has the ammonia it is carrying dissolved out. This type of mechanical washer or cooler is not novel, but Mr. Lymn is believed to have been the first to apply it to producer-recovery plants. Originally he designed his coolers on traditional lines, but on watching their operation he came to the conclusion that the momentum of the gas was a more important agent in the mechanical mixing than the rotation of the discs. Accordingly, he cut away a considerable part of the collecting cones to give the gas more play, and finally he was able to handle the gas from 90 to 100 tons of coal in a cooler which was traditionally designed to handle the gas from 45 to 50 tons.

This work ultimately led to the type of construction shown in Fig. 3. In this it will be seen that the holes

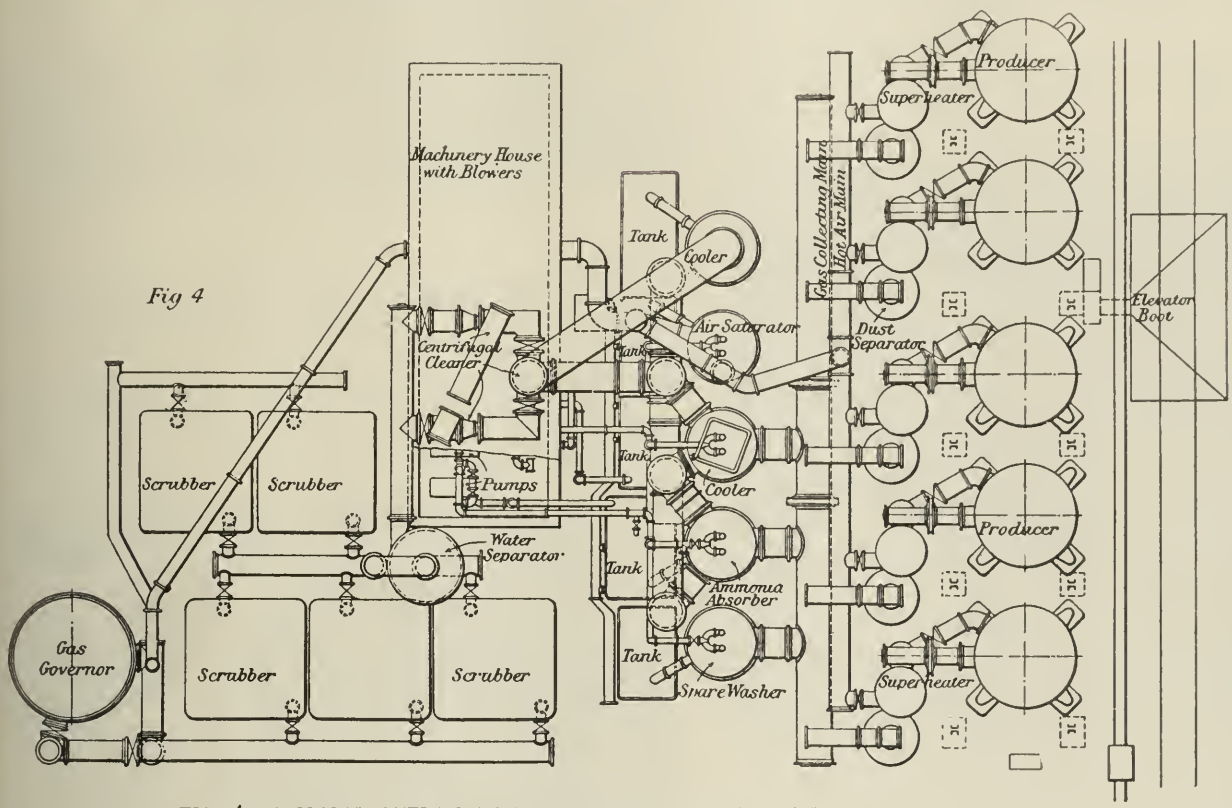


FIG. 4—GENERAL OUTLAY OF PRODUCER-GAS AND AMMONIA-RECOVERY PLANT

sed in gas engines they have still to be treated for he removal of tar. This process is carried out in centrifugal cleaners and dry scrubbers of the usual type. he sulphate of ammonia is recovered by evaporation f the solution collected from the ammonia-absorber by he tanks N. The solution is circulated through these nks and through the absorber until it is very concenated, when but little evaporation is required for ystallizing out the solid salt.

The design of the saturator B, the absorber K, and e gas-coolers L and M undoubtedly forms one of the ost interesting features of this plant. It is indicated some extent in Fig. 1, but may be more clearly exained by reference to Figs. 2 and 3. Referring first Fig. 2, it will be seen that the arrangement consists a vertical cylindrical chamber, containing a series of verted truncated cones. Up to the middle of the amber a shaft runs, carrying a number of discs. The aft is rotated by gearing at the bottom end. The ter enters the cooler at the top, and falling onto the st rotating disc is sprayed onto the surrounding ne. From this it falls onto the next disc, to be rayed to the succeeding cone, and so on. The gas, in the bottom of the cones are of considerably larger diameter than the discs, so that if no gas is passing water entering the top falls straight to the bottom. So important has the effect of the momentum of the gas proved to be in this form of cooler that in the design shown in Fig. 3 it has been found possible to do away with the rotation of the discs altogether, and plants have now been in successful operation for more than two years with fixed discs. The importance of these improvements, which have doubled the capacity of the coolers, and at the same time simplified them, is obvious. The capital outlay is largely reduced and space is saved. Coolers of the type shown in Fig. 3 can be built to deal with gas from 10,000 cu. ft. an hour to 1,300,000 cu. ft. an hour in a single unit. It should, perhaps, be said, as will probably be obvious, that the dimensioning of these coolers is not altogether a simple matter, and that they are designed empirically from data built up from practical experience.

In connection with other parts of the gear it may be said that considerable pains have been taken to apply to these ammonia-recovery plants the mechanical agitation of the fuel and ash zones of the producer, as well

as mechanical ash removal, which have been so widely applied to ordinary gas-producers in Germany. The producer is based on the principle which has been so largely utilized for hot-gas producers, and involves a rotary grate and mechanical ash removal somewhat on the lines introduced by Kerpely of Vienna, and others. Adapting a hot-gas producer for ammonia-recovery conditions, Mr. Lymn has naturally found material modifications necessary, owing to the greatly increased volume of air and steam, the deeper fuel-bed, the necessity for superheating the blast of air and steam, etc. An interesting point in connection with this plant is that it contains no lead parts. Steel is used for the ammonia-absorbing apparatus. In a plant which has been in operation in Germany for four years, and which contains no lead whatever, no corrosion has been found. A plan showing the general lay-out of a Lymn plant is given in Fig. 4. The functions of the various parts will be followed in connection with the sketch of the method of operation we have already given.

Among the various plants in operation in Continental Europe, *Engineering* mentions one belonging to the Badische Anilin und Soda-Fabrik at Ludwigshafen, and another belonging to the German government at Heinitz, and a plant of six producers built for firing steel furnaces at the Barop Steel Works.

In Table I the actual operating results are given for a Lymn plant over two periods of four weeks each.

TABLE I—OPERATING RESULTS OF POWER-GAS PLANT (LYMN SYSTEM), DRIVING LARGE GAS-ENGINES AND FIRING FURNACES

This plant was designed to gasify 45 to 50 tons of coal per 24 hours. It has since been extended, and is now gasifying about 80 tons, and is driving four 1300-hp gas-engine electric sets, and also firing four furnaces. The coal in use is smalls, through a ¾ in. sieve, and ordinary brown-coal briquets. Average price, 12 to 13 marks ($3 to $3.25) per ton.

FIRST PERIOD, BETWEEN NOVEMBER 20 AND DECEMBER 22, 1912 (FOUR WEEKS)

	Total	Average per day of 24 Hours	General Average
Coal consumption of the gas plant	1806 tons	64.6 tons	0.72 kg. per kw-hr.
Power produced (kw-hr.)	1,889,740 kw-hours	.....	2812 kw-hours per hour
Yield of sulphate of ammonia	49.11 tons	1.76 tons	27.1 kg. per ton of coal
Yield of tar (containing water)	189.7 tons	6.78 tons	105 kg. per ton of coal
25 per cent of total gas produced is used for firing furnaces.			

Average heat value of the gases, 1380 calories per cubic meter (155 B.t.u. per cubic foot).
Tar contained in the gas (average), 0.04 gram tar per cubic meter.
The auxiliary machines (excluding blowers) consumed regularly 71 kw.
Including 10 per cent depreciation, the gas costs per kw-hour work out at 0.55 pfennig (0.138 cent).

SECOND PERIOD, BETWEEN JANUARY 27 AND FEBRUARY 23, 1913 (FOUR WEEKS)

	Total	Average per Day of 24 Hours	General Average
Coal consumption of the gas plant	1967 tons	70.2 tons	0.78 kg. per kw-hr.
Power produced (kw-hr.)	1,899,600 kw-hr.	.....	2830 kw-hours per hour
Yield of sulphate of ammonia	54,300 kg.	1.94 tons	27.6 kg. per ton of coal
Yield of tar (containing water)	231,700 kg.	8.27 tons	117 kg. per ton of coal
25 per cent of total gas produced is used for firing furnaces.			

Average heat value of the gases, 1370 calories per cubic meter (154 B.t.u. per cubic foot).
Tar contained in the gas (average), 0.057 gram per cubic meter.
The auxiliary machine (excluding blowers) consumed regularly 78 kw.
Including 10 per cent depreciation, the gas costs per kw-hour work out at 0.56 pfennig (0.14 cent).

NOTES

1. Nitrogen contained in the coal (average), 0.8 per cent.
2. Heating value of the coal, 6000 kg. cal. per kg. (10,400 B.t.u. per lb.).
3. The nitrogen efficiency during these two periods was 70 per cent. It is frequently 75 per cent.

The periods are not specially selected. It will be noted that in spite of the low nitrogen content of the coal and its high price the cost of gas per kilowatt-hour worked out at only 0.14 cent.

There is one point in connection with this branch of industry which deserves considerable attention. The amount of steam generally used by these plants is about 2½ tons for every tone of coal gasified. Of this amounts up to two-fifths, or 1 ton per ton of coal gasified, is recovered from the heat of the gases in a modern plant. This steam is recovered during the gas-cooling and air-saturating cycle. The remainder has to be raised either by means of direct coal-fired boilers or in some other way. Needless to say, the employment of special coal-fired boilers involves a considerable charge on the operating costs of the plant, and the alternative of utilizing waste heat from gas engines, furnaces, etc., to raise such steam offers considerable attractions. In the plant referred to in Table I, which has been in operation for four years, the whole of the steam is raised in this way. There are four boilers, each attached to a 1300-hp gas engine. They raise 2 lb. to 2½ lb. of steam per hoursepower-hour. The steam produced is quite 25 per cent in excess of that required for the gasification of the coal. Corrosion is sometimes mentioned as a difficulty in connection with this form of application, but in Mr. Lymn's opinion the matter is purely one of properly dimensioning the boilers. The plant in question has been in day and night operation for four years without any trouble from this cause. It is stated that this plant was the first in existence absolutely self-contained in the matter of steam supplies.

Exhibits at the San Francisco Exposition

Carborundum Exhibit

Prominent among the exhibits in the Palace of Machinery is the display of The Carborundum Company, Niagara Falls, N. Y. The accompanying illustrations give some idea of the attractiveness of the display,

FIG. 1—CARBORUNDUM EXHIBIT

embodying a grand idea of broad industrial education.

In brief the plan of the exhibit is to show the varied uses to which carborundum products are put, to show the wide variety of materials and products in their crude or unfinished state and after they had been cut, ground or finished with carborundum products. The result has been a wonderful collection gathered from manufacturing plants, not only in this country, but from South America, England, India, New Zealand, Australia and other foreign countries. The collection embraces materials and products ranging from tooth picks to flooring, from flour mill rolls to needles, from steel shafts to watch dials, from semi-precious stones to shrapnel shells and malleable castings, and also includes samples of marble, onyx and granite, pearl, cut

and engraved glass, sueded skins and boots and shoes. In the grinding, shaping and finishing of every piece of the show, carborundum products have played their important part, and in each case the particular carborundum product which did the work is shown.

FIG. 2—CARBORUNDUM FOUNTAIN

To display the hundreds of products, a space of about 1400 square feet was necessary. The materials are shown in full glass show cases (Fig. 1). In the center of the exhibit is a fountain (Fig. 2), built of irregular masses of iridescent carborundum crystals, over which real water plays, splashing into a marble basin, the coping for which was moulded with carborundum wheels. The fountain is twelve feet high and is strikingly beautiful.

Cork Exhibit—Heat-Insulating Materials

Industrial education is also the keynote of the joint display of the Armstrong Cork Company and the Armstrong Cork & Insulation Company of Pittsburgh, Pa.

FIG. 3—HEAT-TREATING FURNACE INSULATED WITH NONPAREIL BRICK. MODEL AT SAN FRANCISCO EXPOSITION

The exhibit is situated at the corner of Sixth Street and Avenue A in the Palace of Manufactures and occupies a space 26 by 40 ft. No attempt whatever was made to have a "big" display. Emphasis rather has been placed on perfection of detail. The pavilion itself reflects this idea.

Entering it from the Sixth Street side, the first thing that attracts the visitor's attention is the display of corks and cork specialties. Here may be seen pieces of "virgin cork," "second stripping bark," and a number of specimens of the third and subsequent strippings (cork being really the outer bark of a species of evergreen oak which flourishes only in the Spanish Peninsula, Southern France and Northern Africa). Some of the sheets are of exceptional size, others of unusual thickness. A cross-section of a cork tree is also on display, showing the dense, heavy wood of the trunk, the thin inner bark—which is the seat of the growing processes, and the thick outer coating of cork.

Attractively arranged in ninety-five glass jars are corks of every kind and description and for any kind of service. In a show case are exhibited an amazing array of cork specialties.

Of greatest interest to our readers, however, will be the exhibit of heat-insulating materials. All of these articles exhibited, except one, are by-products of cork

FIG. 4—MUFFLE FURNACE INSULATED WITH NONPAREIL BRICK. MODEL AT SAN FRANCISCO EXPOSITION

—manufacture either solely, or in part, from cork waste. The one exception is "nonpareil" high-pressure covering for steam lines and other heated surfaces, which is composed of diatomaceous earth (kieselguhr) and asbestos.

The most important of this group of products is nonpareil corkboard, for insulating cold-storage warehouses, ice factories, packing plants, breweries, dairies, creameries, fish freezers, fur storage vaults, refrigerators, etc. The principal steps in this manufacture are shown by suitable specimens, and few visitors are not surprised to learn that the particles of cork waste are held together solely by the natural gum or rosin which is brought out by the manufacturing process.

Of somewhat similar interest is the display of nonpareil cork pipe covering for brine, ammonia and drinking water lines. Some idea of its commercial importance may be gathered from the fact that this product is manufactured in more than 1500 different shapes, sizes and grades.

The exhibit of nonpareil insulating brick, which adjoins that of cork covering, is an unusual demonstra-

tion of how modern science produces new articles by combining two or more substances long well known. These insulating brick—so light that they float on water—are composed of diatomaceous earth mixed with ground cork, molded into brick form and then fired. The cork is burned out entirely, leaving the brick extremely porous in texture and a light terra cotta in color. A series of nine models, complete in every detail, show how the brick are installed in boiler settings, bread baking ovens, heat treating furnaces, hot blast mains, brick kilns, etc., to save fuel. Their remarkable heat-insulating efficiency, moreover, is demonstrated by an electrically-heated furnace, which is maintained constantly at a temperature of 1000° F.

But the most interesting feature of the display of heat insulation is a cross-section of a typical cold storage plant, built to scale and complete in every respect. In this model, which is 7 ft. 4 in. wide and 7 ft. high, the commercial installation and use of the entire line of nonpareil heat insulating materials are effectively demonstrated. For example, the boiler is insulated with miniature nonpareil insulating brick, the steam lines and feed water heater are covered with nonpareil high-pressure covering, the brine and ammonia pipes are covered with nonpareil cork covering, while the brine cooler, ammonia accumulator and fore-cooler are insulated with nonpareil cork lagging. The second, third and fourth stories of the model include an ice freezing tank, ice storage, and meat, butter, fruit and egg storage rooms—all insulated with nonpareil corkboard. Miniature tubs of butter, barrels of fruit, crates of eggs and sides of meat add a finishing touch of reality to the whole structure.

A motor-driven fan a few yards away, which serves to demonstrate the sound, and vibration absorbing value of nonpareil cork machinery isolation is the next thing that usually catches the attention of the visitor. This material is used under fans, motors, pumps, printing presses and other machinery to deaden noise and diminish vibration.

Other exhibits are cork paving brick (a combination of finely ground cork and asphalt), cork tilings for museums, libraries, etc., and the linoleum department, powdered cork being the basic ingredient of linoleum.

Mining Exhibits

The Mines and Metallurgy Departmental Jury of the Panama-Pacific Exhibition has adopted unanimously the following resolution:

"*Resolved*, That the Mines and Metallurgy Group Jury of the International Jury of Awards of the Panama-Pacific International Exposition desires to convey to the administration of the exposition and to the exhibitors in the Mines Department an expression of its high appreciation of the service which has been rendered to the mining industry and of the stimulus which has been given to the wise development of the world's mineral resources by the exhibit in this department. The jury heartily congratulates the chief of the department of mines and metallurgy, Prof. Charles E. van Barneveld, on the great success of the exhibit.

"Taken collectively, the exhibit displays a remarkable development in the method of presenting the mining industry for the general revise and education of the public. This development is not due so much to improvements in the individual methods of display, but rather to the adoption of a new point of view of planning and arranging the exhibit materials as a whole. The fundamental thought running through the entire exhibit is to set forth in a vivid and forceful manner the tremendous utility of our mineral resources. A systematic collection of the ores of the various metals and non-metals forms but the first step in a series of exhibits which demonstrate the basic importance of the mineral industry to civilization. The great variety of products derived from our mineral deposits shows in the most impressive manner the fundamental dependence of our industries upon the mineral supply.

"The results show great achievements in establishing step by step the interdependence of mining and manufacturing, with special emphasis placed on the paramount necessity of safeguarding human life and conserving human energy. The results have greatly increased the popularity of the mining department and have made the building a rendezvous for the public as well as for the specialist.

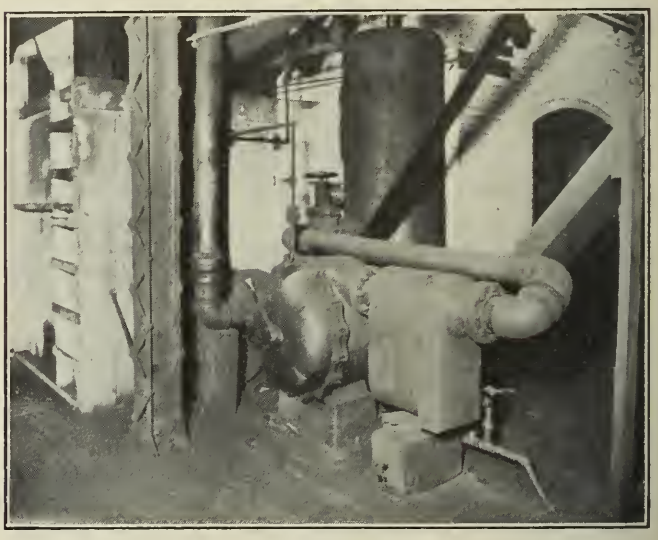
"In general, the mining industry is so clearly depicted as to make this jury cordially urge the visiting public to profit by the educational opportunities offered by this department."

* * *

The International Jury of Awards, Panama-Pacific International Exposition, has voted to give a medal of honor to the publications of the McGraw Publishing Company, Inc., which include METALLURGICAL AND CHEMICAL ENGINEERING. This is the highest award granted a publishing company. The principal basis of the award is the general excellence and superiority of these publications.

Air Compressor

The accompanying illustration shows an illustration of an air compressor at work in the plant of the Nungesser Carbon & Battery Co., of Cleveland, Ohio. This air compressor has been in continuous use for over a year without giving any trouble since or putting the



AIR COMPRESSOR

company to any expense for repairs. It operates over its rated capacity. It is belt driven from a line shaft and takes 43 hp. It operates ten 6-inch air cylinders with 12-inch strokes at 20 pounds pressure per square inch. It also operates other auxiliary air for other purposes around the plant. As its continuous service is all-important for the main purpose for which it is used, since a shut-down would require stopping a considerable portion of the plant, the fact that it is running continuously without adjustment and with its original high efficiency, attaches considerable interest to its design.

The principle of this air compressor which was designed and built by the Nash Engineering Company, of South Norwalk, Conn., is radically different from every other device on the market for compressing air. Its only moving part is a rotor mounted on a shaft, well supported by bearings, and it is arranged to spin freely in an elliptical casing. The pump is filled with water. Power is applied to the end of the shaft, causing the rotor to revolve, which in turn carries the water around with it.

The water, in addition to turning with the rotor, follows the surrounding casing, due to centrifugal force.

As the hub and blades of the rotor are round, and the casing elliptical, it follows that a portion of the water alternately receeds from and reenters the rotor. When the water goes out of the rotor air is drawn in through ports cut in the sides of the casing. When the water is pushed back into the rotor, the water acting as a piston, compresses and delivers the air through the outlet ports.

The water stays at the level of the outlet ports and is used continuously. A small quantity of water is supplied to the compressor to absorb the heat of compression. This water enters at atmospheric pressure and is discharged with the air into a separator, which removes all entrained moisture from the air. The air is thus thoroughly washed of all dust and dirt and contains no oil, which is an advantage where clean air is desired.

There are no valves, gears, connecting rods or moving vanes. The bearings are very large and are relieved of side strains, due to the fact that compression takes place simultaneously on opposite sides of the rotor.

The delivery from these compressors is free from pulsation, therefore no receiver is required. The efficiency is high and the only attention they require is that they are occasionally lubricated and supplied with water.

American-Made Porcelain Ware for Chemical Laboratories

New in the list of manufacturers of high-grade laboratory porcelain ware, but old and well known as a manufacturer of earthenware and porcelain (cooking utensils, etc.), is the Guernsey Earthenware Company of

PLANT OF THE GUERNSEY EARTHENWARE COMPANY

Cambridge, Ohio. It would be wrong, however, to assume that this company went into the manufacture of laboratory porcelain ware as a result of the European war, since, under the direction of its president and general manager, Mr. Charles S. Casey, it had been engaged in experimental work for two years preparing to place upon the American market a laboratory ware in every way equal to that of the imported article.

The clays which go into the makeup of Guernsey ware are both foreign and domestic, and it was the selection of these clays and various tests on various combinations of clays which occupied considerable attention during the experimental period. The result of these experiments has been entirely satisfactory, as all tests have shown that the porcelain is equal to any made in the world, as the company's guarantee reads.

The original pieces manufactured were crucibles, casseroles, evaporating dishes, mortars and pestles, Petri dishes. The demand for these pieces has already reached 2000 per day, and the factory is now being arranged to greatly increase the output both in variety and number, so that it will occupy a space of 200 x 420 feet. Additional ware which will soon be offered comprise beakers, porcelain plates, Rose crucibles, Gooch crucibles, funnels, spatulas, spoons, perforated plates, combustion boats.

The Non-Ferrous Metal Market

The past month has been one of unusual activity in the non-ferrous metal markets. With the exception of tin, which stands in about the same position as a month ago, the metals command higher prices. A good volume of business has been transacted. Lead has experienced a decided rise, the demand being for ammunition purposes and export. Spelter has continued its unprecedented and spectacular rise, and the climax seems to have been reached.

Copper.—Electrolytic copper has risen steadily to 20 cents per pound, New York, due to the development of an active buying movement on the part of manufacturers of brass for ammunition purposes. Lake copper sold by the Calumet & Hecla company has maintained a price of 23 cents, but there is a tendency on the part of consumers to substitute electrolytic for Lake at these prices, and the differential is diminishing.

Tin.—A lull was experienced in this market during the latter part of May, but increased transactions early in June restored a firmer tone. The metal is quoted at about 40 cents, New York.

Lead.—An advance began late in May, due to large inquiry from ammunition makers, and the price was set at 4.30 cents, New York, by the A. S. & R. Co. Later the advances became a matter of daily occurrence and reached nearly 7 cents. A large business was transacted before the market began to decline.

Spelter.—June spelter reached the record price of 25 cents, St. Louis, on June 9, and about the same time the demand began to diminish. The galvanizing trade is practically out of the market at these prices, and other consumers have shown a disposition to withhold for the time being. The fluctuations in price have been rapid and wide, and an accurate quotation is difficult.

Other Metals.—Aluminium has been active and strong, and the price has risen to 27 to 29 cents, New York. Antimony continues strong, with a range in prices from 35 cents for ordinary brands to 48 cents for Cookson's. The latter is largely nominal. Quicksilver has again risen, small lots bringing $100 per flask of 75 lb., and larger orders $85. The price at San Francisco is somewhat lower, ranging from $75 to $85.

Personal

Mr. **George O. Bradley**, consulting mechanical engineer for the Utah Copper Co., has been retained to design and supervise the construction of the 8000-ton Alaska Juneau mill. Mr. Bradley designed the new mill for the Alaska Gastineau company.

Mr. **Sidney Cornell** is now efficiency engineer of the Remington Arms & Ammunition Co. at Bridgeport, Conn.

Mr. **Russell T. Cornell**, engineer of mines, announces the removal of his office to 80 Maiden Lane, New York City. His new quarters adjoin those of Ricketts & Co., Inc., by whom he has been retained as associate mining and consulting engineer. His new association will not affect his status as an independent engineer.

Mr. F. M. De Beers, general manager of the Swenson Evaporator Company, of Chicago, was in New York in June and reported very lively activity in evaporator construction for various new chemical industries.

Mr. J. V. N. Dorr has returned to New York from Denver.

Mr. L. G. Eakins, former assistant manager of the Colorado department of the American Smelting & Refining Co., has been appointed general manager for Colorado, succeeding the late Franklin Guiterman. Mr. Eakins has also been appointed president of the Carbon Coal and Coke Co.

Prof. Albert J. Houle, of the department of mining and metallurgy, Michigan College of Mines, is spending part of the summer in Utah studying metallurgical processes.

Mr. Dorsey A. Lyon, of the Bureau of Mines, has returned to his station at Salt Lake City following a visit to the Joplin zinc and lead districts.

Mr. Ferdinand McCann is in charge of the erection of new milling plant at La Cotabambas Auraria mine, Peru.

Mr. Benjamin Magnus is returning to America and expects to be in New York by September, where his headquarters will be in care of H. M. Toch, 320 Fifth Avenue, New York City. Mr. Magnus went to Australia in 1907 to build the Electrolytic Refining and Smelting Company's Works at Port Kembla, N. S. W., for the refining of copper produced by Australian mines. In 1912 he became general manager of the Mount Morgan Gold Mining Co., Ltd., and designed the new smelter works and concentrator and reorganized the company's business generally. He also acted as consulting engineer to the Electrolytic Refining and Smelting Co., Ltd.

Mr. H. T. Matthew has been appointed Pacific Coast representative of the Society for Electrical Development. Mr. Matthew has with him the best wishes of many readers and friends of this journal of which he was the business manager for six years when it was still called Electrochemical & Metallurgical Industry.

Professor Arthur A. Noyes, of the Massachusetts Institute of Technology, is the recipient of the Willard Gibbs medal for 1915, awarded by the Chicago section of the American Chemical Society.

Mr. O. B. Perry, general manager for the Yukon Gold Co., has left New York on a trip of inspection of the company's properties in California and Alaska.

Mr. Charles H. Schmalz has been appointed manager of the Billings Foundry & Mfg. Co., of Billings, Mont. For the past six years Mr. Schmalz was master mechanic for the Anaconda Copper Mining Co., Boston, and Montana Reduction Department, Great Falls, Montana.

Mr. Arthur Putnam Scott, formerly with the Dominion Iron & Steel Company of Sydney, N. S., and with the General Electric Company, is now chief metallurgist of the Snyder Electric Furnace Company of Chicago. Mr. Scott contributed to this journal a most interesting article on "hard spots" (July and August, 1908, vol. VI, pages 281 and 323).

Mr. G. F. Streich is in charge of the zinc smelting plant at Bruce, Kansas, leased and operated by the Cherokee Zinc Co.

Mr. W. C. Tharp has been appointed district manager in charge of the Pittsburgh office of the Hoskins Mfg. Co. Mr. Tharp has been associated with the Republic Iron & Steel Company, the Scientific Materials Company, and the Metallurgical Testing Laboratory of Pittsburgh.

Mr. A. E. Wiggin has been appointed superintendent of concentration for the Anaconda Copper Mining Co., and will have charge of concentrating operations in Montana. Mr. Ralph Hayden has been appointed superintendent of the regrinding and flotation plants at the Washoe works, and will also have charge of the new slime plant on its completion. Mr. W. A. Estabrook retains the position of superintendent of the concentrator at Anaconda. Mr. C. R. Wraith has relieved Mr. E. S. Bardwell at the company's exhibit at the Exposition.

Obituary

Thomas Dyson West, iron foundry expert, died in June as a result of the injuries received when run down by an automobile near his home in Cleveland, Ohio. Mr. West was widely known in this country and abroad for his untiring efforts for the foundry industry, while his organizing and developing of the American Anti-Accident Society and the Sane Fourth Movement show the broad field which he endeavored to cover. Thomas D. West was born in Manchester, England, on August 31, 1851, his mother being a niece of Michael Faraday. He was brought to the United States by his parents when six months of age. At twelve years he began to work in a foundry and remained true to the foundry industry ever since. Mainly self-educated, he was from 1887 to 1909 organizer, vice-president, and general manager of the Thomas D. West Foundry Co., now Valley Mould & Iron Company, Sharpsville, Pa. In 1907 he organized the West Steel Casting Company of Cleveland, Ohio, of which he was chairman of the board and managing director at the time of his death. By his research work and by his writings he gained wide recognition as a foundry metallurgist. He was the originator of the use of standardized drillings, adopted by the U. S. Bureau of Standards in 1905. In 1905-6 he was president of the American Foundrymen's Association. He also was a member of the American Society of Mechanical Engineers, the American Society for Testing Materials, the American Association for the Advancement of Science, and the Cleveland Engineering Society. He was a prolific author. Of his books, "American Foundry Practice," which has reached its eleventh edition, is probably best known. He is survived by his widow, Mrs. Clara West, and three children, Dr. Thomas J. West of Honolulu, Mr. Ralph H. West, president of the West Steel Casting Company of Cleveland, and Mrs. William E. Ward of Cleveland.

Alain de Pierrefeu, engineer in charge of the metallurgical and industrial division of tests of the Illinois Steel Company, South Chicago, was killed in May in France. Educated in France and in the Lawrence Scientific School he entered service in the mills of the steel company in the lowest position seven years ago. He worked up through the laboratory section until he had charge of testing all kinds of special steel and various treatments of structural steel. He was an officer of the Seventeenth Infantry and left for the war last October. Letters to Langdon Pearse state that he was wounded about two months ago and had been obliged to leave the trenches on account of eye strain. His wife, a daughter of William Tudor, of Boston, is in Red Cross work abroad but the four children are with the grandparents in Boston.

Erratum.—The communication by Mr. Carlton G. Lutts on rapid analysis of bearing metals and high-copper content alloys, published in the June issue, page 346, contains a misprint in the second column under copper (B), where $Na_2S_2O_3$ (sodium thiosulphate) should read Na_2SO_3 (sodium sulphite).

Newspaper Chemistry

There was a man in our town
And he was wondrous wise,
He cracked petroleum odds and ends
With vim and enterprise.

He first cracked off some gasoline
And then some heavier bodies
Until he made a full, long list
Of Coal Oil Johnny's toddies.

And when he saw what he had done
With all his might and main
He curled them up, and into rings
He twisted every chain.

'Twas then the newspapers began—
And that's where chemistry
Can work all sorts of miracles
Most expeditiously.

The papers first took up benzol,
And, quoting Edison,
They made phenol by synthesis,
And dyestuffs, every one:

Alizarine and indigo
And all the coal-tar group
For dyes and photochemistry
They made in one fell swoop.

Then starting out with toluol
They made explosive stuffs
To smash the foes of Uncle Sam
In detonating puffs.

They made a neo-gasoline
For motor trucks and cars
So cheap that poor old Standard Oil
Was jolted full of jars.

And with this neo-gasoline
They ploughed the fertile fields,
And then, by using radium
They multiplied the yields.

Of wheat, potatoes, millet, corn
And rye and peas and beef;
They banished want and poverty
And hunger, past belief.

I wish I were a chemist of
The journalistic kind!
I'd take and go to work and make
A contract, drawn and signed

To furnish everything there is
And set the world agog;
And do it just as easy as
A-rollin' off a log.

—"E. H." in *The Percolator* of the New York Chemists' Club.

The spectroscopic analysis of steel has been investigated by the Bureau of Standards, at the request of the steel industry. It has been possible to show the presence of appreciable amounts of molybdenum, cobalt and vanadium in steels supposed to be free from these elements. No sample of iron has been found free from magnesium or copper. Silicon was not detected in electrolytic iron that had not been fused.

National Exposition of Chemical Industries

The arrangements of the National Exposition of Chemical Industries, to be held in the New Grand Central Palace, New York City, during the week of Sept. 20 to 25, 1915, are progressing very favorably. Almost one-half of the available space of the main floor has already been reserved by prospective exhibitors.

An auditorium will be provided with arrangements for slide pictures and moving pictures for special lectures by invited prominent speakers. In the evening this auditorium is to be used for meetings of the different chemical societies. The date of the meeting of the New York Section of the American Electrochemical Society has already been fixed for Tuesday, Sept. 21. Other evenings are to be reserved for the New York Section, as well as for the Industrial Section of the American Chemical Society, and for the American Institute of Chemical Engineers and for the New York Section of the Society of Chemical Industry.

The Bureau of Foreign and Domestic Commerce of the Department of Commerce, Washington, D. C., has expressed its hearty sympathy with the Exposition and is expected to arrange a noteworthy instructive exhibit in conjunction with the Geological Survey, the Bureau of Mines, the Bureau of Soils, the Forest Service, and other government bureaus.

The Exposition is being organized by Messrs. Charles F. Roth and Adriaan Nagelvoort, with offices at the New Grand Central Palace, Forty-sixth Street and Lexington Avenue, New York (telephone 6990 Murray Hill), with the co-operation of the International Exposition Company.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath, Anodes

226,616, April 20, 1880, Jacob Kleinhans, of New York, N. Y.

Relates to anodes for electroplating and describes shaping the anode with an oppositely bent hook at each end, so that a greater or less number of such anodes may be hooked together to increase or decrease the size of anode immersed in the electrolyte.

330,247, November 10, 1885, Henry Liepmann, of London, County of Middlesex, England.

Relates to anodes for electroplating and consists of a bundle of carbon rods, each having copper-plated ends, the assembled bundle being then copper-plated over the ends, or united by cast metal which enters the interstices between the rods. Instead of copper-plating, or cast metal caps, a plastic carbonaceous paste may be used to unite the rods, the paste then being carbonized, forming a solid composite carbon block. The compound electrodes thus made may be mounted between disks, forming a rotary drum for use in electrolytic apparatus.

450,105, April 7, 1891, Ernest Arthur LeSueur, of Ottawa, Canada, assignor of one-half to Charles N. Waite, of Newton, Massachusetts.

Relates to anodes for electrolytic cells, the anode consisting of a number of irregularly shaped pieces of gas-retort carbon, cut to an equal length, all united at one end by immersing in a shallow layer of molten lead, the lead on cooling gripping the several pieces of carbon and forming an anode having an extensive surface, and good electrical contact with each piece.

482,724, September 20, 1892, Thomas Craney, of Bay City, Michigan.

Relates to anodes for electrolytic cells, such as are used in the decomposition of sodium chlorid solutions. The anode consists of a nest of truncated cone-shaped tubular earthenware bodies, or the like, each having side projections by which they are supported upon and within each other, and leaving cylindrical spaces between each cone. The nest of cones is filled with lumps of conducting carbon, the cylindrical spaces also being filled with the same material and leaving the horizontal annular edge exposed to the electrolyte. Instead of separate cones, an earthenware tube with a perforated wall may be used. Instead of using lumps of carbon, a solid block of carbon may be used in the cones or tube, the spaces between the cones being filled with lumps of carbon which contact with the solid block. The cones may also be filled with a carbonizable mass of carbon and binder, and then baked to carbonize the binder.

508,091, November 7, 1893, Elisha Barton Cutten, of New York, N. Y.

Relates to contacts in anodes for batteries, and for electrolysis, and consists in cutting a tapered hole in the end of a rod or block of gas carbon, saturating the carbon surrounding the hole with paraffin, saturating a tapered carbon plug just fitting the hole, and having a projecting outer end, with paraffin, and then driving the plug tightly into the hole in the rod of carbon. A conducting wire is secured to the projecting end of the plug. It contains a reference to another application which is probably patent No. 510,899.

510,899, December 19, 1893, Elisha Barton Cutten, of New York, N. Y.

Relates to anodes for electrolytic cells, and refers to his copending application which became patent No. 508,091. The patent describes a method of testing the joints for resistance by passing a rather strong current through the electrode and measuring the fall of potential by a voltmeter. The joints are adjusted until all show the same fall of potential with the same current.

510,901, December 19, 1893, Elisha Barton Cutten, of New York, N. Y.

Relates to electrodes for voltaic cells and anodes for electrolytic cells, and refers to his copending application which became patent No. 508,091. The carbon electrode is secured to a glass cover by melting glass fragments or pouring molten glass around the joint between the electrode and cover, on the under side, or by melting the glass cover itself by a blow-pipe flame. The molten glass flows into the pores and cavities in the carbon, welding it to the cover, forming a gas-proof joint, and serving to suspend the carbon. Electrical connection is made with the electrode by a tapered carbon plug, as described in his earlier patent.

510,902, December 19, 1893, Elisha Barton Cutten, of New York, N. Y.

Relates to electrodes for voltaic cells and to anodes for electrolytic cells, and refers to his copending application which became patent No. 508,091. It describes securing the electrode to a stoneware cover by fusing glass fragments around the joint between the carbon and the underside of the cover, forming a gas-tight joint, and serving to suspend the electrode. Electrical contact is made with the electrode by means of a tapered carbon plug, as described in his earlier patent.

546,328, September 17, 1895, Carl Hoepfner, of Giessen, Germany.

Relates to an anode having a surface containing at least 10 per cent of silicon, which may consist of ferrosilicon or of pure silicon. The ferrosilicon may be formed by mixing iron and silicon powders with paraffin, the patent not stating how the alloying is effected. It states that the ferrosilicon may be deposited electrolytically. Or a solid electrode may be made in any suitable shape by casting ferrosilicon. The patent further states that pure silicon may be deposited upon an iron or nickel anode.

Book Reviews

Welding. Theory, Practice, Apparatus and Tests. By **Richard N. Hart,** B.S. Second edition, octavo, 210 pages, 127 illustrations; price, $2.50 net. New York and London: McGraw-Hill Book Company.

The practical art is advancing so rapidly that revision was made necessary by the great advances made, especially in arc-welding and oxy-acetylene systems. The divisions of the subject are ordinary welding, electric welding, hot-flame welding (autogenous welding), thermit welding and miscellaneous methods. It is a very satisfactory presentation of a most interesting and useful art.

Ferromangan als Desoxydationsmittel. von W. Rodenhauser. 15 x 23 cm., 127 pages, 49 illustrations. Price 7 marks (retail price in New York $2.35). Leipzig: Oskar Leiner.

Engineer Rodenhauser is well known to steel metallurgists for his work on the Roechling-Rodenhauser induction furnace. This timely book (dedicated to Mr. Roechling) is concerned principally with the latest improvement in manufacturing steel—the addition of molten ferromanganese. It describes the properties and function of ferromanganese, the various means for melting it, and the advantages resulting from adding it melted to the steel. The melting is described in detail as carried on in Rombach, Keller, Girod, Heroult, Nathusius and Roechling-Rodenhauser furnaces. We are sorry to see the Rennerfelt furnace omitted, for a good description of its usefulness for this very purpose was published by the Iron and Steel Institute last year. Notwithstanding this omission, it is a book which every steel maker ought to read.

Principes et Applications de L'Electrochimie. By O. **Dony-Henault, H. Gall** and **Ph.-A. Guye.** Large octavo, xxii + 686 pages, 183 illustrations; price 30 francs, in New York $6.00. Paris and Liége. Librarie Polytechnique, Ch. Beranger.

A splendid volume, containing treatises on the fundamental laws of electrochemistry by O. Dony-Hénault, the synthesis of nitric acid by Ph.-A. Guye, and the other applications of electrochemistry by O. Dony-Hénault and H. Gall. And yet, such is the present great extent of applied electrochemistry that each of the subjects must be spoken of as "briefly considered."

Mirabile dictu, here is a French book with a good analytical table of contents in front and satisfactory indexes of authors and subject matter at the back. What further proof could be needed that it is the best book in its field in the French language?

I Processi Termoelettrici della Siderurgia Moderna: Forni Elettrici. By Ing. **C. F. Bonini.** 15 x 23 cm., 607 pages, 174 illustrations. Price $12.50 lire. Milan: Ulrico Hoepli.

A beautifully printed and well-illustrated treatise on the electric furnaces used in the metallurgy of iron. Part I, in thirteen chapters (318 pages), deals with the principles of construction and operation of electric furnaces in general; it is well written. Part II, in five chapters (105 pages), treats of the direct production of steel from iron ore and the refining of steel; this part is not so thoroughly handled. Part III, in six chapters (170 pages), concerns the production of cast iron and ferro-alloys; it is quite satisfactory.

Any engineer reading Italian and interested in electro-metallurgy or electric furnaces will find it a useful book.

Metallurgical and Chemical Engineering

The Coming Exposition of Chemical Industries

The curious individual who said that an exposition of chemical industries was a self-contradictory conception because chemical industries were secretive by nature, will find himself hopelessly behind the times when the National Exposition of Chemical Industries opens in New York City on Sept. 20. The commercial success of the exposition seems assured by the generous response of the industry and reversely great benefit can accrue from the exposition to the industry. As the exposition is primarily technical, it is an excellent idea to facilitate and insure the presence of chemists and engineers by arranging meetings of the various chemical societies in connection with the exhibition. In presenting in visible form—and wherever possible, in form of working models—the latest advances in machinery design, construction, and operation, the exposition can fulfill a distinct function of its own. It should be suggestive and encourage exchange of critical ideas and prove another connecting link between various classes of chemists and engineers.

More indirect, though by no means negligible will be the effect of the exposition on the industry by reason of the very fact that the general public will be largely attracted. To procure public recognition for chemistry, the public must be made to realize what chemistry is. No amount of lecturing will do this so well as a direct appeal to the senses. Chemical industry must be visualized by exhibits, working models, moving pictures. This is what the exposition will do. And the logical consequence will be a storage of appreciative good will that must be of immense value in future for the industry not only in connection with financial investments in the industry, but in connection with tariff and other legislation.

Bessemer and Open-Hearth Steel

Despite the astonishing increase in open-hearth steel making capacity in recent years, and a slight decrease in Bessemer steel making capacity, due to the abandonment of at least one large plant and the adaptation of some Bessemer blowing capacity to the duplex process, there is to-day what is described in steel market parlance as a "scarcity" of open-hearth steel. One can purchase Bessemer billets or sheet bars at a lower price than open-hearth billets or sheet bars. Buyers of finished steel who have exhibited a preference for open-hearth steel are in many cases being asked whether a substitution of Bessemer will be permitted. The trade reports state that practically the entire open-hearth capacity is in operation, but only 70 or 75 per cent of the Bessemer.

Sellers of steel insist that in many cases the prefer-

ence buyers express for open-hearth steel is not founded upon adequate knowledge, and that indeed there are numerous buyers who "would never know the difference" if Bessemer steel were substituted for open-hearth. Some sellers of steel actually wax impatient over the attitude of buyers in this connection, but it is in point to observe that in a measure the seller is himself responsible for the condition which now disturbs him. In periods of market dullness the seller who has both Bessemer and open-hearth steel to offer is quite prone to put the open-hearth in the front, thus fostering a habit on the part of the buyer to take open-hearth steel. The position of the seller at such a time has, perhaps, not been entirely altruistic. While we would not undertake to make an authoritative comparison, plant for plant, between the cost of making Bessemer and open-hearth steel respectively, it is a fact attested by the experience of numerous buyers that in the recent period of market stagnation they were able to buy open-hearth billets and sheet bars at a slightly lower average price than Bessemer steel of the same description, and the experience suggests that the maker who conducted both operations found the open-hearth process the cheaper. It may be unfortunate from the seller's standpoint that the buyer will not change his habits to suit the circumstances, but the preference expressed for open-hearth steel can hardly be described as a case of pure pig-headedness on the part of a buyer who would experience difficulty in distinguishing the one class of steel from the other. It can hardly be doubted that Bessemer steel could properly be used more widely than it is. In most cases of employment of merchant bars, pipe and wire no distinction is made, or could be made, by the ultimate consumer.

Patent Office Procedure

Elsewhere in this issue we publish a concise statement on United States patent procedure, viewed from the standpoint of a metallurgical engineer who wishes to remain anonymous though his name is well known from his connection with one of the most celebrated metallurgical patent suits of recent times. The statement is not only critical but constructive. Without committing this journal to every proposal made in the statement we may say that it presents admirably various phases of the situation that are well worthy of serious consideration. In the development of our patent law and practice the original object has been almost defeated. Our patent system was devised to foster the inventive genius; to give equal opportunity to all without regard to material wealth; to protect intellectual property among poor and rich alike.

Unfortunately our patent practice does not vest in the Patent Office the right or duty to pass finally on the validity of a patent when that validity is challenged after the patent is issued. That duty is left to our courts which, incidentally, are ill adapted to the work. The result is that an advantage is given to those who have the power of wealth to prosecute suits, while those less favored in this regard may find their rights abridged. Finally, the whole industry suffers from the uncertainty of the outcome; progress is delayed and the public grows restless under a system which obviously works injustice.

The idea of publishing applications for patents so that all who believe their rights would be abridged by the granting of such patents may challenge their issue is a procedure that has simplified matters in the German Patent Office. If a challenge is offered, it need require only a brief hearing or a demonstration to enable the officials to decide whether the application shall be granted or denied. Such would be the function of the Patent Court suggested by our contributor.

The United States is prodigal in granting patent monopolies. Issued at the rate of about 100,000 per year at a cost for "maintenance and operation" of something like $25 per issue, it is obvious that a wholly inadequate sum is spent to enable the Patent Office to discharge its full duty to the public. Many of the patents granted are inconsequential, and others are in the nature of improvements that would naturally occur to the active mind of anyone engaged in a given line of industry. And yet each is a monopoly that can be made the basis of an injunction to restrain the holder of a like monopoly from exercising the presumptive rights which he obtained from the same source.

With the subject of patent practice receiving so much attention at the hands of competent and experienced thinkers, and with the public conscience quickened to the necessity of establishing conditions under which business and industry can develop normally and unhampered, the time should not be far distant when reform will be accomplished.

Engineering or Legal English?

From a power contract drawn by one of the large power companies at Niagara Falls:

> "The word 'furnish,' when used in this agreement in reference to electric energy, is to be understood to mean readiness and ability . . . to furnish . . . electric energy at the agreed rate."

The Steel Industry and the War

The steel industry of the United States is now almost fully employed. Reports are that substantially all the open-hearth capacity is engaged, and 70 to 75 per cent of the Bessemer capacity, making an average for the industry of not far from 90 per cent. The condition is in striking contrast with that obtaining last December, when operations reached a particularly and unprecedentedly low ebb, at not more than about 35 per cent of capacity.

There is a disposition in some quarters to attribute the present steel-making activity, or at least a great part of it, to demand occasioned by the European war. Such a belief will hardly bear close investigation. It must be recognized, in the first place, that the breaking out of the war caused a great decrease in industrial activity in the United States, while as conditions became better understood there was a reaction. A part of the demand for steel that has been experienced since

Jan. 1 represents simply demand that ought to have been expressed in the closing months of 1914. The fact is worthy of consideration in this connection that an improvement in the steel market occurred in June and July, 1914, and that at the time many reputable observers expressed strong hopes that the improvement then noted represented the beginning of a general movement toward real prosperity. The breaking out of the war suddenly arrested this improvement, but it does not follow that the movement could not be resumed at a later time.

A great deal of the present demand for steel can be traced to ordinary domestic consumers. Freight car orders definitely placed after the war started, and up to the beginning of last May, made a total of only 15,000. In the past three months railroads in the United States have placed orders for about 35,000 freight cars, representing a rate seven times as great. In the three months the French and Russian governments have placed orders in the United States for 21,000 cars. These may be regarded as war orders, but they represent only 30 per cent of the total freight-car buying since the war started. As another illustration of domestic demand it may be noted that while the American motor-car industry has been stimulated by war orders, it is well known that the deliveries of cars to domestic buyers during the season just ended have broken all records, and the automobile industry is entering a new season in expectation of a still larger demand. The export demand may be important, but the domestic demand is in itself making an excellent record. As another illustration it may be mentioned that in April and May, as the agricultural implement industry reached the close of its regular manufacturing season, it was found that the production had been less than it should have been. There was a speeding up at the last moment, and the intention is to make a much larger output in the season now being entered upon. The case of the agricultural implement trade is of particular interest, because it has suffered very seriously in the export direction, the exports in the last fiscal year having been less than one-third as heavy as in the preceding fiscal year.

Illustrations of this sort could be multiplied, showing in detail that the domestic demand for steel has very materially increased. The export movement it is necessary to discuss under two heads, the exports to belligerents and the exports to neutrals. The exports to belligerents, again, must be subdivided into two classes, material required for war purposes, and material required because former sources of supply are shut off. British imports of blooms, billets, sheet bars and wire rods from the United States, according to the June returns of the Board of Trade, are at the rate of over 650,000 tons a year. In chief part this movement represents the shutting off of imports hitherto drawn from Belgium and Germany, but the total imports are somewhat larger than they were a year ago. There are other exports of this character to belligerents, including wire rods to France, nails to both England and France, and scrap and pig iron to Italy.

Of the exports of regular steel-mill products to belligerents only a relatively small proportion can be distinguished as intended for war purposes. By far the largest items are steel bars for the manufacture of shells, and barb wire. In May we exported of the former 37,260 tons and of the latter 18,182 tons, and some portion at least of the tonnage went to neutral countries, but even the total tonnage represents but a trifle more than 2 per cent of our steel-making capacity. As to the steel involved in shells which are manufactured in this country and then exported there are no statistics, but it is evident that the tonnage cannot be more than a very few per cent of our total steel output.

The war would throw a very large tonnage of steel demand from neutral countries to the United States, if the demand existed, but unfortunately no large demand has thus far developed. During three or four years prior to the war the combined exports of the great iron and steel exporting countries, Germany, England, the United States, and Belgium, named in the order of their importance, and excluding exports to each other, averaged very nearly if not quite 10,000,000 tons a year. The only exporting countries now are England and the United States. The British exports to neutral and non-producing countries are now at the rate of about 2,500,000 tons a year, while the similar exports of the United States may be estimated at not more than 1,500,000 tons, making total exports to neutral and non-producing countries of not to exceed 4,000,000 tons, when formerly there was demand for 10,000,000 tons. It must now be mentioned that we include in the British exports just mentioned the exports to India and British colonies, and these exports really amount to fully one-half of the total. There is reason to believe that if the demand increases over the rate of 4,000,000 tons the lion's share of the increase will fall to the United States, since Great Britain does not seem to be in position to accept more business. That is for the future, but there are much greater prospects of our export trade increasing in this direction than of its increasing in the matter of war material. The possible demand from neutral countries covers practically all classes of steel products, while the demand from the belligerents is confined largely to relatively few commodities.

While only rough estimates can be made, it would appear that while our steel exports to neutral countries are at the rate of about 1,500,000 tons a year, our exports to the belligerents of steel in all forms, including that used in the manufacture of shells, motor trucks, railroad rolling stock, etc., do not exceed 2,000,000 tons, or possibly 2,500,000 tons at the very outside. Inasmuch as the present finished steel capacity is in the neighborhood of 27,000,000 or 28,000,000 tons a year, our actual production being at the rate of nearly 25,000,000 tons a year, it is evident that our total steel exports, even including the exports to neutral countries, do not account for any very large part of the present manufacturing activity. The actual consumption of steel in the United States is by far the chief cause of the steel trade's prosperity.

Needed Changes in the Patent System

To the Editor of Metallurgical & Chemical Engineering:

Sir:—The experience of our nation with business monopolies has been such as to lead us to place, through our legislative bodies, certain restraints upon the forms and operation of monopolistic enterprises. While we have been following out this policy, endeavoring to re-establish the conditions under which business can have its most normal development, we have overlooked the fact that our Government is annually, through the machinery of the Patent Office, creating thousands of ill-defined monopolies over which no control is retained by the Government, and which are so created that they are in many instances a decided handicap to the development of industry.

The fundamental assumption upon which patents are issued is that the granting of a temporary monopoly in the control of an improved process or apparatus will stimulate the work of invention and the development of new processes and forms of apparatus by making it possible for the inventor to get an adequate profit through the temporary monopoly of his invention, and that the public will profit by this system through the increase in improved processes and apparatus, and the final free use of the same as divulged in the Letters Patent which are granted to the inventor.

NATURAL EVOLUTION OF ARTS AND INDUSTRIES

The development of any art or industry is a gradual evolution, each step of which is made possible by work which has been done before, and each step, in advance of which is, to a considerable extent a natural evolution of what has preceded it. Innumerable instances of practically simultaneous inventions of processes or apparatus, and of practically simultaneous discovery of scientific truths, have demonstrated that many, if not most, of the advances in industry and science would be made by one individual if not by another, because the development of the art or science has brought it to such a state that the next steps to be taken are so much a matter of necessity that they will be taken by any one of a number of those who are confronted with a problem.

It has been a commonly accepted belief that invention partakes somewhat of the nature of inspiration; but a study of the history of the development of any of our arts will show that a great part of the steps forward which have been made, have been the logical result of that which has been done before, and have not involved any high degree of inventive ingenuity or any long period of research. There are, however, many new processes and forms of apparatus which are the result of the application of highly developed inventive capacity to the solution of difficult problems through long and expensive periods of research work.

A patent is a monopoly granted in derogation of one of the most fundamental and valuable rights of mankind, the right of each individual to use for his own profit all of the information which he may possess. This right is of such vast importance that if it is abridged the greatest care should be used to protect, not only the inventor whose work is to be stimulated by the patent system, but the rights of the public, which are definitely restricted by every patent which is granted.

The law, as now enacted and administered, places unnecessary obstacles in the way of the development of industry, as the Patent Office, the chief function of which is to determine whether or not inventors are entitled to patents for their alleged inventions, does not finally determine that matter. A United States patent is not considered to have any established validity until it has been made the subject of litigation which has passed through all of our courts up to the highest tribunal of the land. No technical expert nor legal adviser nor body of experts or advisers can foretell what the courts will consider a patent to cover; or whether or not, on being made a matter of contest, a patent will be held to be valid. To determine the scope of a patent, and whether or not it is valid, requires a contest extending through several years' time and involving enormous expenses. Thomas A. Edison is credited with the statement that an American patent is nothing more than an introduction to the United States Supreme Court. This is practically true, and anyone who has had occasion to be introduced to that exclusive body will realize that the introduction involves a degree of expense which cannot be borne by the type of men who actually advance industry by their inventions.

The effect of this method of dealing with patents is to greatly discourage inventors; to seriously handicap or debar those who have inventive capacity from its profitable employment; to delay the adoption of inventions of proven merit, and to generally and unnecessarily interfere with the development of industry.

SUGGESTION FOR GREATER PATENT OFFICE

The whole subject of the validity of patents and patent rights should be dealt with by one compact organization, which could well be built around our present Patent Office. All matters dealing with the granting of patents, the status and control of patents, and the litigation relating to patents should fall within the province of this greater Patent Office.

This office could well consist of three departments: a department attending to those matters concerned with the granting of patents; a permanent patent court, before the branches of which all patent litigation should be disposed of; and a department or commission having power to establish the conditions under which monopolies resulting from the granting of patents shall be exercised.

The Patent Office should be more adequately housed than it is at the present time, and adequate provision should be made for all of its activities. The library should be made absolutely complete, and its contents should be made easily available for all of the needs of the Patent Office staff, and for such of the public as choose to make use of it. Laboratories should be provided in which the inventor should be made to demonstrate the proven workability of his invention, if it be demonstrable without large or elaborate installations. These laboratories should also be available for the demonstrations necessary in illustrating the inventions involved in patent litigation.

The patent law and practice should be so modified that every application for patent should be published, and that opportunity should be given to all who consider that they possess rights which will be abridged by the granting of this patent to set forth their rights through simple and expeditious procedure, accompanied by an absolute minimum of red tape.

As previously stated, no patent should be granted for

anything but a complete and workable invention; and no patent should be granted for improvements which must be the natural outcome of the application of reasonable engineering ability and skill to the solution of engineering problems. A patent should be made much more difficult to obtain, but much more easy to defend when once obtained.

All litigation relating to the validity of patents should be heard by special courts forming an integral part of the Patent Office. These courts should be given discretionary power as to what issues should be heard before them, and what evidence should be entertained, so that it should be impossible for patents and the patent courts to be made a means by which inventors or the public could be unnecessarily harassed.

It should be possible for anyone to institute proceedings to determine the validity of a patent, so that this matter might be determined without the necessity of first infringing the alleged rights of the patent and running the possible risk of being assessed damages for such infringement.

All litigation relating to the validity of patents should be heard before courts consisting of at least two members of the Patent Office's regular judicial staff, who, by training and experience, are particularly conversant with the branch of industry to which the patent litigation pertains, sitting with at least one other member of the regular judicial staff of the Patent Office who has had special training and experience in the patent law.

ADJUDICATION WITHOUT APPEAL

It appears to a layman that there should be no possibility of appeal from the decision of this court. The whole theory of appeal involves the assumption that it is possible, when a case has been once passed upon by a court, to find a more competent court to hear it again, and so on through the series of courts to which appeal may be taken. No court which is not competent to give a final decision upon a case should be allowed to try it at all; and when the court which is competent to give a decision in the case has once passed upon it, that case and the issues involved therein should be forever closed.

If this assumption is not well taken, and it is necessary to provide for the possibility of appeal of cases from the court of first instance, it could be provided that a court of appeal, also a regular part of the Patent Office, and constituted of experts in technical matters and patent law, should have power to order, upon proper showing of necessity for doing so, a review of questions involving the interpretation of patent law, by a court consisting of all the regular law judges of the department sitting *en banc*, from whose decision no further appeal could be taken, and which could also under conditions warranting such action, provide for the review of questions of fact before judges especially selected by it from the regular judicial staff, whose decision should be final. But special stress should be laid by the law upon the fact that great injustice is done by delay in disposing of patent litigation.

All procedure before the patent courts should be so simple that the poorest inventor could, if necessary, defend his own case unaided. When advisable, sections of the patent courts should hold their hearings in other cities than Washington, D. C.

As it is possible for the owner of a patent to place unnecessary obstacles in the way of the development of arts and industries, by withholding improved processes or apparatus from use; by making extortionate charges for the use of patented processes or apparatus, or by monopolizing improvements perfected by others, as a consequence of possessing earlier patents covering improved inventions, provision should be made for revoking patents not put to successful use within a reasonable length of time, and for determining the charges that may be made for use of patented inventions and the types of contracts under which they may be disposed of.

TAXATION OF PATENTS

Several foreign governments regularly tax patents. It is probable that public interest would be served if our Government should charge an annual license fee for every patent for each year of its life after two years from the date of issue, and forfeit all patents for which this annual fee is not promptly paid.

If it is impossible, during the first two or three years after a patent is granted, to establish its value to such an extent that the inventor can afford to pay an annual license fee or tax to keep his rights alive, the patent should be allowed to lapse and the rights of the public should be no longer abridged by it.

These annual fees would not have to be large to furnish adequate funds to support the organization herein outlined and provide ample revenue so that such salaries could be paid as to command and retain the services of the ablest type of men.

The judicial staff should be so large that all matters coming before it should be finally disposed of within six months at the most from the time actions are commenced.

Long periods of uncertainty as to the rights of the inventor and the public are so prejudicial to the development of industry that they should not be tolerated by a business-like nation. Public business should be dispatched with the promptness and thoroughness demanded in private business.

If the modifications of law and practice herein suggested should be adopted, all of the rights of the inventor and of the public could be adequately protected; invention would be stimulated, as inventors would realize that if their inventions were truly patentable, they would obtain patents therefor which could be cheaply defended; and progress in the development of the arts and industries would not be retarded through the great expense and long periods of waiting now required to determine whether or not patents which have been granted by the United States Government convey any defendable rights..

AN ENGINEER.

A Modified Iron-Carbon Diagram

To the Editor of Metallurgical & Chemical Engineering:

SIR:—In my work with the Chinese students during the past four years a constant effort has been necessary to simplify and clarify problems, especially of a practical nature, owing to the fact that the Chinese methods of education in the past have not been given to practical lines but more to the training of the memory.

Further, when we consider the fact that the peculiarly rigid and inelastic form of the language does not allow of its being readily adapted to technical expressions or terms, and that the student has first to learn a foreign language which is fundamentally different from his own, both in methods of writing, construction and expression, it stands to reason that not only is it necessary to use the simplest expressions and clearest explanations possible, but also carefully to avoid the least possibility of confusion in the presentation of ideas or practical facts.

Among other things we have, for instance, the study of metallography in relation to the alloys, more especially that of iron-carbon, in the study of the metallurgy of iron and steel.

Of course, we all know that there are some very mate-

rial differences between authorities regarding some of the points included in the equilibrium diagram and some of them have led to rather puzzling questions from the students.

As we endeavor to make our work on iron and steel as thorough as possible it became quite necessary to take up these differences and if possible, to harmonize them so as to relieve the minds of the students of any confusion or distrust as to accuracy.

The text books used are Stoughton's "Metallurgy of Iron and Steel," and Hofman's "General Metallurgy," with references to Sauveur's "Metallography of Iron and Steel," Howe's "Iron, Steel and Other Alloys," and Tiemann's "Iron and Steel" for definitions.

A metallographic laboratory has recently been equipped with apparatus for grinding, polishing, etching and photographing as well as for recording recalescence curves for the better study of metallography in general as well as in special work.

As Sauveur is taken as a guide in the metallography, and Stoughton as a text book in the metallurgy of iron and steel, I soon came up against these disagreements of statements and it became necessary to harmonize them, as stated before, or to leave one authority discredited.

BOUNDARY BETWEEN CAST IRON AND STEEL

The first point to be considered was that of the location of the boundary line between steels and cast iron. On page 6 of Stoughton, second edition, 1911, he says,

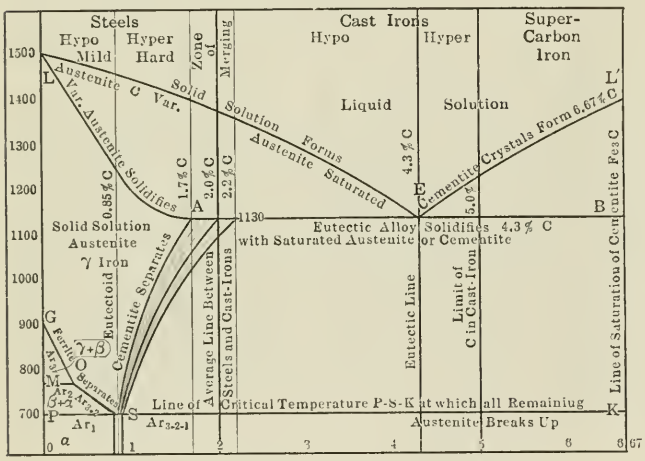

FIG. 1—MODIFIED IRON-CARBON DIAGRAM

"Cast iron generically is iron containing so much carbon or its equivalent that it is not malleable at any temperature. * * * The committee[1] recommends drawing the line between cast iron and steel at 2.20 per cent carbon for the reason that this appears from the results of Carpenter and Keeling to be the critical percentage of carbon corresponding to point *a* in the diagrams of Roberts-Austen and Roozeboom."

Again (*ibid.*), "It is because of this difference in the freezing of the alloys that the line *XY* (at 2.2 per cent) is arbitrarily considered as the dividing line between steel and cast iron."

Howe, in his "Iron, Steel and Other Alloys," second edition, 1906, page 170, says, "Fortunately there is one criterion which may be adopted for discriminating between all the various classes of steel on one hand and those of cast iron on the other, a criterion which we may apply to all future varieties of iron when we seek to decide whether they ought to be called steel or cast iron. This criterion is malleableness in at least some one range of temperature; we may adopt it because such malleableness is probably the only important specific property which all steels of to-day have and all cast irons of to-day lack, if we except the special product known as 'malleable cast iron.' * * * Cast iron, iron containing so much carbon or its equivalent as not to be malleable at any temperature, * * * the dividing line between steel and cast iron may, for the present, be put arbitrarily at 2 per cent of carbon." Again (*ibid.*) on page 195, "In this work the dividing line between cast iron and steel has been arbitrarily drawn at 2 per cent of carbon, in rough accordance with commercial usage."

Sauveur, in his "Metallography of Iron and Steel," first edition, 1912, Lesson XIX, pages 5-6-8, says, "It will be evident that, starting from carbonless iron, as the carbon increases, at first low-carbon steel is produced and then in succession medium high-carbon steel, high-carbon steel and finally white cast iron, each metal passing gradually into the next without any sharp line of demarcation between them. It is logical to base the distinction between high-carbon steel and white cast iron upon the malleability of the former and the non-malleability of the latter and this is altogether a question of carbon content. The dividing line may be drawn somewhat arbitrarily at 2 per cent carbon. *As a matter of fact steels are very seldom manufactured containing more than* 1.75 *per cent carbon while white cast iron rarely contains less than* 2.25 *per cent carbon. Between the steel series, therefore, and the white cast-iron series there is a natural gap, the existence of which generally removes any doubt as to the nature of the metal under examination.* Again if the process of manufacture be known there need be no doubt as to the classification of any highly carburized iron alloy; if made in the blast furnace from the reduction of iron ore, it is cast iron, while if it is the product of refining cast iron, * * * or of the remelting under oxidizing conditions of iron or steel scrap, with or without cast iron, * * * or of the carburizing of wrought iron, * * * or of the carburizing and melting of wrought iron, it is steel. * * *

"The portions of the diagram corresponding respectively to the steel series and to the cast-iron series have also been indicated, leaving two groups of alloys unrepresented by industrial products, namely, those containing between 1.70 per cent and 2.25 per cent carbon and those containing more than 5 per cent carbon. * * * (Footnote:) Again some unimportant products are offered for sale under the name of semisteel which may contain between 1.75 and 2.5 per cent of total carbon entirely combined, forming, therefore, a sort of connecting link between the steel and the cast-iron series. They are frequently obtained by remelting cast iron in cupola furnaces in the presence of considerable iron or steel scrap. Washed metal likewise may contain between 1.75 and 2.5 per cent of total carbon entirely combined, but this is a semi-finished product resulting from a partial refining only of cast iron."

Tiemann, in his "Iron and Steel," first edition, 1910, on page 44, under "Cast Iron," says, "It contains a considerable proportion of carbon (say 2.2 per cent) up to about 7 per cent—usually from about 2.5 to 4 per cent, and variable percentages of other substances, such as silicon, manganese, phosphorus, sulphur, etc. It is hard and brittle and cannot be rolled or forged at any temperature." And again on page 318 under "Steel," "That form of iron produced in a fluid condition and hence practically free from slag (difference from wrought iron) which contains less than about 2.2 per cent of carbon—as a rule less than 1.5 per cent (difference from cast iron)."

Now comparing the above there must be some rea-

[1]Committee on the Uniform Nomenclature of Iron and Steel of the International Association for Testing Materials.

sonable explanation for this rather broad difference and in reading the quotation from Sauveur it is very fair to assume that he has met the point especially where he says, on page 5 of Lesson XIX, "As a matter of fact steels are very seldom manufactured containing more than 1.75 per cent carbon, etc.," quoted above.

From this it can be assumed that the circumstances under which the product is made will govern the character, i.e., under some conditions it will meet the definition for steel taken from the report of March 31, 1906, of the Committee on the Uniform Nomenclature of Iron and Steel as quoted above, and under some other conditions of manufacture will meet the definition for cast iron, even though the carbon content may be the same, and that all combined.

As a result I have drawn the lines *A-S* in Fig. 1, so as to cover the zone between these two amounts and have called it "The Zone of Merging." This extends from 1.7 per cent on the one extreme to 2.2 per cent on the other, with an intermediate line at 2 per cent as an average.

LOCATION OF EUTECTOID LINE

The next point was that of the location of the eutectoid line. Stoughton, on page 292, under "Eutectoid," says, "The alloy containing 0.9 per cent carbon is known as the 'eutectoid alloy'." Again, on page 303 (*ibid.*), "The practiced eye can usually tell; but a chemical analysis readily distinguishes, since steel with less than 0.8 per cent carbon will have excess ferrite, and that with more than 0.9 per cent will have excess cementite."

Sauveur, in Lesson V, page 4, under "High-Carbon Steel," says, "Since the introduction of increasing amounts of carbon in steel results in the formation of a correspondingly increasing proportion of pearlite and a decreasing proportion of ferrite, a degree of carburization must necessarily be reached, when the whole mass will be made up of pearlite, the ferrite having finally disappeared. This critical point in the structure of steel is attained when *the metal contains somewhere between* 0.8 *and* 0.9 *per cent of carbon, exceptionally pure steel requiring the larger proportion of carbon and impure steel the smaller for the complete disappearance of ferrite.*"

Again (*ibid.*), on the same page, under "Eutectoid Steel," "Steel containing less than 0.85 per cent of carbon, *or thereabout,* and in which, therefore, some free ferrite is present, is called 'hypo-eutectoid,' while steel more highly carburized than eutectoid steel is called 'hyper-eutectoid'." Again (*ibid.*), on page 9 of the same lesson, he demonstrates the theoretical percentage of carbon in "pearlite" as being 0.834.

Tiemann, on page 185, under "Pearlite," says, "A eutectoid of cementite and crystallized iron formed by slow cooling past Ar_1. * * * It should be regarded as a variable mixture, for in structural steels containing between 0.5 and 1 per cent manganese, the carbon in pearlite varies between 0.6 and 0.9 per cent, and in some tool steels, according to the method of treatment, the pearlite accompanied by free cementite may contain 1 per cent carbon."

From these authorities we may assume that the eutectoid, depending on varying conditions, may ordinarily lie anywhere between 0.8 and 0.9 per cent carbon and have a general average of 0.85 per cent in accordance with the statement of Professor Sauveur. This I have assumed in my diagram, making the eutectoid area extend from 0.8 to 0.9 per cent, in accordance with the above.

The liquidus line from *L* to *E* has been assumed as being slightly curved, following Carpenter and Keeling's equilibrium diagram shown on page 18 of Lesson XXIII of Sauveur.

The solidus line from *L* to *A* has been made in accordance with Rosenhain, as explained on page 20 of Lesson XXIII of Sauveur.

A limiting line has been placed at 5 per cent carbon as the limit of carbon usually in commercial irons, according to Sauveur's statement from page 8 of Lesson XIX as quoted above, from the fact that these irons seldom carry more than 5 per cent carbon. Those carrying more than this amount I have designated as super-carbon irons, in order to have some distinguishing term.

The Western Metallurgical Field

Two Historical Notes on Flotation

With the rapidly increasing use of the oil-flotation process of concentration, and the consequent investigation of various processes and search of the literature on the subject, it is interesting to note some of the earlier work. It will be found true in many instances that various investigators observed certain effects that are now well known, but which may have been passed over at the time without a full realization of their value and importance.

Flotation by means of a stiff froth produced by violent agitation of an ore pulp to which oil has been added, is now one of the most common forms of the process. An interesting early reference* to the froth or foam effect is to be found in the *California Journal of Technology* for November, 1903, in an article by Messrs. W. F. Copeland, Drury Butler and James H. Wise. The authors presented some experiments on the Elmore process of oil concentration, which at that time was comparatively new. After describing their experimental work on a variety of ores, they close the article with this interesting reference:

"**Foam Effect.**—The foam effect is produced by a violent agitation, especially in acid or salt solutions. This throws the oil into a froth, which is heavily charged with air or other gases. This gas, of course, gives a greatly increased buoyant force. The oil in this condition assumes a certain load of mineral and holds it in a very stable condition. The charge does not settle and overload on standing as in the case of the lake effect. The foam effect is best adapted for light, flaky minerals, such as molybdenite."

In contrast to the stiff froth or foam formed by violent agitation, there has come into prominence more recently a process making use of a light and less coherent froth, produced by the introduction of air or gas through a porous medium; so that it enters the pulp in a finely divided condition. This effects a gaseous flotation of mineral particles. The froth thus produced breaks down more readily than some of the stiffer froths produced by violent mechanical agitation, and this feature is an advantage in many respects, particularly when the floated concentrate contains two minerals, say lead and zinc sulphides, which are to be separated on tables.

The principles of this method were described by T. J. Hoover and Minerals Separation, Ltd., when in 1910 they secured British patent No. 10,929, based on this method of flotation. But as far as known they did not secure patent in the United States. A quotation from the specification is instructive.

"According to this invention the method of introducing air or other gas into an ore pulp for the purpose of effecting flotation of certain particles consists in bringing the ore pulp into contact with a porous medium

*Compare also the report on the flotation suit in July issue, page 409.

through which air or other gas is caused to pass. Thus according to one method the pulp is introduced into a vessel having one or more porous walls through which air or other gas can be caused to pass.

"The porous media employed according to this invention may consist of plates of porous ceramic material, porous bricks, coke, or felt or other fibrous material suitably supported.

"The gas which is caused to pass through the porous medium into the ore pulp may be air or furnace gases, or it may be a gas produced chemically such as carbonic acid liberated from a carbonate or the gas may be produced electrolytically, or the gas which is passed through the porous medium may act both as selective agent and as frothing agent; a gas such as formaldehyde or carbon bisulphide vapor can be thus employed. The introduction of the gas through the porous medium may be effected either by pressure or by suction."

Metallurgy of Low-Grade and Complex Ores of Utah

In spite of the wonderful advance made in handling economically the low-grade and complex ores of Utah, as instanced by the work of the Utah Copper Company and others, a varied problem still remains to be solved. Utah's eminence as a mining State lies mainly in her large supply of low and medium-grade ores, some of which are quite complex and require careful metallurgical treatment. Fortunately the problem is being attacked in a systematic manner by a co-operative arrangement between the University of Utah and the U. S. Bureau of Mines. A preliminary report on the situation is embodied in Technical paper No. 90 of the Bureau of Mines, by Messrs. Lyon, Bradford, Arentz, Ralston and Larson. A careful survey of the mineral resources of the State has been made, resulting in a classification of the various types of ores. Some of these are being treated, but not in the most economic manner. Suggestions are made for improvements in treatment that will return a larger net profit to the owner.

Among processes having a possible application to Utah ores, the following are mentioned: For lead carbonates carrying silver; the Murex process, combining oil selection and magnetic separation; sulphidizing and flotation, converting the oxidized minerals to sulphides by hydrogen sulphide and then floating; electrostatic separation, after first coating the particles by the sulphidizing process.

For oxidized copper ores carrying gold and silver: Chloridizing and leaching; sulphidizing and flotation; leaching with ammonia-cyanide solution, according to the Mosher-Ludlow process; leaching with hypochlorous acid, according to the Slater process.

For oxidized zinc ores, occasionally carrying gold and silver: Igneous concentration, producing zinc oxide for pigment or further reduction; leaching with ammonium carbonate solution; leaching with sulphur dioxide solution, as proposed and tested at Swansea, Wales; leaching with acid solution, and electrolytic precipitation of zinc.

For oxidized zinc-lead ores, occasionally carrying gold and silver: The bisulphite process just mentioned, dissolving the zinc and smelting the lead residue; leaching with ammonium carbonate solution; sulphidizing and flotation, separating lead from zinc, the latter not being affected.

For oxidized ores of zinc and copper, carrying gold and silver: Leaching with ammonium carbonate solution and separating by electrolysis; the bisulphite process; leaching with acid solution and electrolytic precipitation; igneous concentration, recovering zinc oxide and smelting the copper residue.

Utah has an abundant supply of raw materials that can serve as reagents for carrying on many of these processes. An unlimited supply of salt is at hand, associated with mirabilite (Na_2SO_4), from which numerous reagents can be prepared. Sulphuric acid could be produced at smelting plants, and sponge iron for use as a precipitant can be prepared from many iron ores in the State. Coal and coke are readily obtained, and acid-resisting hydrocarbons for vat lining exist in large quantities. In short the State offers a wonderful field for the investigation of the problem that has been so ably presented in the preliminary report.

Workmen's Compensation Insurance in Colorado

Since the adoption of workmen's compensation insurance in Colorado at the last general election, the State industrial commission has been engaged in settling premium rates for various lines of industry. The rates that should apply to the mining and metallurgical industries have been the subject of much concern, for it was felt that such rates might easily be made oppressive, inasmuch as the mining industry cannot add the cost of such insurance to the price of metals and thus distribute the burden among consumers. Rates have now been settled, however, and the industrial commission has notified private insurance companies that it will approve the following premium rates per $100 of payroll: For underground employees in metalliferous mines, $3.75; for surface workers at mines of the same class, $2.39. Where employers supply medical and hospital service in accordance with the law, 25 per cent of the rate will be cut off. Previous to the action by the industrial commission, private companies had filed an average rate of $3.85 per $100 of payroll. The rates approved by the industrial commission will probably induce most mining companies to take their compensation insurance with the State fund. In the case of coal companies a rate of $6 per $100 of payroll has been approved. The larger coal companies may form a mutual insurance company to carry their compensation insurance.

Increased Valuation of Joplin Output

According to the Joplin *News-Herald* the value of zinc and lead ores produced and shipped from the Joplin district for the first half of 1915 is $11,303,654, as compared with $7,620,268 for the first half of 1912, which was the previous banner year. The aggregate production for 1912 was valued at $18,043,379, but this will be exceeded this year if the mean weekly valuation reaches $260,000. Of late the weekly valuation has been averaging $500,000, so that from present indications the value for 1915 will break all records. Comparative figures for the first half years 1912 and 1915 are given below:

	Shipments		Values	
	1912. Lb.	1915. Lb.	1912.	1915.
Blende	253,681,839	276,290,830	$6,203,554	$9,772,546
Calamine	16,016,160	22,470,472	241,678	479,964
Lead	51,993,604	42,753,990	1,175,036	1,101,144

Company Reports

The ninth annual report of the **Buffalo Mines, Ltd.**, Cobalt, Ontario, Canada, covers the yearly period ended April 30, 1915. The low price of silver, the high cost of supplies and the shortage of power combined to make unfavorable conditions for production and marketing during this period. The concentrating mill and cyanide plant were closed for four months, and subsequent operations were on three-fourths time, so that the report really covers little more than six months' production. The financial statement shows net income of $79,690. A dividend of $50,000 was paid. The total surplus is

$379,968. The concentrating mill treated 51,667 tons of ore averaging 19.5 oz. silver. The recovery by concentration was 72.22 per cent. The cyanide plant treated 8385 tons of slime averaging 9.86 oz. silver, recovering 82.26 per cent. The amalgamation plant and refinery treated 4925 lb. of high-grade ore, 163,865 lb. of jig concentrate, 547,010 lb. of table concentrate and 3600 lb. of metallics from the low-grade mill, and 11,967 lb. of precipitate from the cyanide mill, all containing 409,525 oz. of silver. The total recovery from the plant was 442,299 oz. silver, the excess being process silver from ores previously treated. The total production for the year was 822,791 oz. of silver. Ore reserves are estimated at 42,000 tons that will average 20 oz. per ton. The plant for cyaniding sand tailing has not been built as present conditions do not warrant the expenditure. Recovery of mercury from the amalgamation residues amounted to 41,850 lb.

The annual report of the **McKinley-Darragh-Savage Mines**, Cobalt, Ontario, Canada, for the year 1914, shows a production of 1,396,540 oz. of silver, of which 1,159,154 oz. came from the McKinley and the balance from the Savage. The total silver shipped to Jan. 1, 1915, from these mines is 14,123,525 oz. Ore reserves are estimated at 68,011 tons, containing 2,132,820 oz. of silver. A brief statement of milling operations is given below.

	Tons treated	Oz. silver per ton	Oz. silver per ton tailings	Percentage extraction
McKinley ore	45,098	24.10	3.54	85.14
Savage ore	21,656	13.37	4.85	64.13

The cost of milling McKinley ore is given as $1.442 per ton milled, and for Savage ore, $0.714.

Beaver Consolidated Mines, Ltd., experienced the same difficulties in 1914 that befell the other companies operating in the Cobalt district. The outbreak of the war caused a cessation of operations, and the mill was closed for two weeks in August. The shortage of power and the low price of silver have also had an adverse effect. The mill treated 26,724 tons of ore, recovering 415,708 oz. of silver in concentrates. Earnings amounted to $158,465. The cost of silver production was $21.54 per ounce. One dividend of $60,000 was paid.

The **Calumet & Arizona Mining Co.**, in common with other copper companies, curtailed production 50 per cent last August. The output for the year 1914 was as follows:

	Pounds copper	Ounces gold	Ounces silver
Domestic ores	49,992,909	19,745	573,606
Purchased ores	2,675,020	4,377	348,537
Totals	52,667,929	24,122	922,143

The net cost of refined copper, crediting value of precious metals, was 9.19 cents per pound. Operating cost at the smelter was reduced 35 cents per ton as compared with the cost in 1913. The blast furnaces treated 403,269 dry tons of ore and 31,299 tons of slag and by-products. The reverberatories handled 238,095 tons of charge. The roasters treated 209,138 wet tons, the average sulphur content of the ore being 27.5 per cent, and of the calcines 9 per cent. The converters produced 32,059 tons of blister copper, and treated 24,823 tons of silicious material. The New Cornelia Copper Company was acquired during the year, and a large amount of experimental work was done on a treatment process. A hydrometallurgical scheme was tested in a 1-ton plant for six months, and later in a 40-ton plant. In the 1-ton plant an extraction of 80.07 per cent was obtained. Copper was precipitated electrolytically at the rate of 0.982 lb. per kilowatt-hour. All the acid necessary was regenerated except a deficiency of 1.4 lb., 100 per cent acid per pound of copper. The report states that the process has been worked out and that future changes will be in detail only. It is understood, however, that flotation has since been adopted.

The Iron and Steel Market

Throughout the iron and steel markets there was decided improvement in July, despite the fact that usually July ushers in a "summer dullness" for the trade. In the steel trade proper the closing days of June witnessed a very material increase in the volume of shipping orders booked, due in considerable part to the fact that in certain commodities there were relatively low-priced contracts that expired June 30, and if specifications were not furnished the tonnages would be canceled. Instead of the activity decreasing in July, however, it increased. The increased demand has been well distributed. The freight car builders, who had booked large orders in May and June, totaling about 50,000 cars for the two months, began to specify freely for the steel required. The agricultural implement trade began to specify against its new manufacturing season. The automobile trade began active preparations for its new season. Export demand increased, for both war and peace materials.

Perhaps the most important influence of all, by a long range view, was the fact that in certain finished steel products the mills began to fall somewhat behind in deliveries. For many months buyers of all products had been in the habit of depending upon very prompt mill shipments, even in the case of orders calling for a wide variety of sizes and descriptions of material. In normally active times, buyers, both jobbers and manufacturing consumers, must carry stocks, for the mills make up their rolling schedules weeks in advance, making as long runs as possible on a size, and thus avoiding frequent roll changes. When orders are scarce they are naturally very accommodating. When the delivery period lengthens from two or three days, or a week, to four or six weeks, as has lately been the case with many commodities, the buyer at once begins to order more material, so as to accumulate a stock. The procedure is well known in the steel trade, and it is recognized that if at any time the mills fall somewhat behind in deliveries demand will take care of itself for quite a period. This extra demand is now being experienced.

Approximately 100 per cent of the open-hearth steel making capacity was engaged during July, and between 70 and 75 per cent of the Bessemer capacity. Open-hearth steel promptly became "scarce," open-hearth billets and sheet bars commanding a premium over Bessemer, as has always been the case in recent years in periods of activity. Steel production at the close of July was at a rate between 85 and 90 per cent of capacity, against about 70 per cent in April and not over about 35 per cent last December.

Our review a month ago noted that in striking contrast with conditions obtaining in the steel market proper the related markets in coke, scrap and pig iron were dull and relatively soft. This anomaly has now disappeared, more activity being shown in these lines, with an advancing tendency in prices. Connellsville furnace coke, which had practically gone begging at $1.75 on contracts for the second half of the year, stiffened to $1.75 for the third quarter and to $2 for the half year, while spot coke, easy in June at $1.50, advanced to about $1.70. Scrap has been more active in all markets. Just after the middle of July heavy melting steel delivered at Pittsburgh mills advanced from $11.75 to $12.75.

Pig Iron

The total pig iron turnover in July was not large, as pig iron sales go, but the volume of business on the whole was considerably larger than in June or May, all markets showing a stiffening tendency, while some ad-

vanced. A development of the month was the withdrawal of the low prices the lake front furnaces had been making in territory normally tributary to other pig iron making districts. Cleveland pig iron had been sold even in West Virginia, and there had been free offerings in Pittsburgh territory in competition with nearby and valley furnaces. The most spectacular transaction was that by which the Cleveland Furnace Company sold about 40,000 tons of basic pig iron to the Youngstown Sheet & Tube Company at not over $13, delivered, this being the first time in history that lake front pig iron was sold to the Mahoning Valley. Not so very many years ago valley pig iron was shipped to Cleveland. Conditions changed after this sale and the valley furnaces resumed sway in the territory usually regarded as their own, and their prices advanced slightly. The Republic Iron & Steel Company bought 16,000 tons of Bessemer pig iron at $14, valley furnace. We quote No. 2 foundry, delivered Philadelphia, $14.25 to $14.50; f.o.b. furnace, Buffalo, $12.50 to $13; delivered Cleveland, $13.50; f.o.b. furnace, Chicago, $13 to $13.50; f.o.b. Birmingham, $9.75 to $10; at valley furnaces, 95c. higher, delivered Pittsburgh; Bessemer, $14 to $14.25; basic, $13; No. 2 foundry, $12.75 to $13; malleable, $12.75 to $13; gray forge, $12.50 to $12.75.

Steel

Market prices on billets and sheet bars advanced sharply during July, not so much by reason of heavy demand in the market as because of heavier specifying by consumers on regular contracts, greatly reducing the tonnage the producers were able to offer in the open market. Subsidiaries of the United States Steel Corporation bought a total of nearly 150,000 tons of billets and sheet bars from mills in eastern and western Pennsylvania, Ohio, and even from one mill in Kentucky, cleaning up all the relatively cheap steel. The market scarcity is only of open-hearth, but Bessemer steel producers have not hesitated to mark up their quotations also, assuming that the market would pay within 50 cents or $1 as much for Bessemer as for open-hearth steel. The market is excited, and it is possible more would have to be paid than quotations here named: Bessemer billets, $21; Bessemer sheet bars, $21.50; open-hearth billets, $22; open-hearth sheet bars, $22.50, f.o.b. maker's mill, Youngstown. There is practically no steel offered by Pittsburgh mills, and the market, delivered Pittsburgh, is quotable $1 per ton over the Youngstown market. Rods are $26, Pittsburgh, and in poor supply.

Finished Steel

The large steel mills had been quoting 1.20c. on bars, plates and shapes for prompt shipment, and 1.25c. on third quarter contracts. At the close of June they withdrew the 1.20c. quotation, according to program, but there remained small mills ready to sell plates at 1.15c. or 1.20c., shapes and bars being fairly well established at the quotation of the large mills. About the middle of July the majority of the large mills withdrew the 1.25c. quotation, naming 1.30c. for any delivery, and this price became established, at least as to bars, while the smaller mills firmed up to 1.25c. on plates. Steel boiler tubes were advanced July 16 by one point or about $2 a ton. While the leading wire interest on June 30 reaffirmed its $1.60 price on nails, sales continued to be made at $1.55. At the same time it advanced painted and galvanized barb wire $2 a ton above the former official figure, and on account of the heavy demand for export this advance held quite well.

Current quotations are as follows for ordinary deliveries, f.o.b. Pittsburgh, unless otherwise noted:

Rails, standard sections, 1.25c. for Bessemer, 1.31c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.25c. to 1.30c.

Shapes, 1.25c. to 1.30c.

Steel bars and bands, 1.30c., base; hoops, 1.30c., base.

Iron bars, 1.20c. to 1.25c., Pittsburgh; 1.30c., Philadelphia; 1.20c., Chicago.

Sheets, blue annealed, 10-gage, 1.35c.; black, 28-gage, 1.75c. to 1.80c.; galvanized, 28-gage, 4.50c.; painted corrugated, 28-gage, 1.90c. to 1.95c.; galvanized corrugated, 28-gage, 4.55c.

Tin plate, $3.10 to $3.20 for 100-lb. coke.

Steel pipe, ¾ to 3-in., black, 79 per cent off list; galvanized, 57½ per cent off list.

Steel boiler tubes (less than carloads), 3½ to 4½-in., 72 per cent off list.

Structural rivets, 1.50c.; boiler rivets, 1.60c.

Railroad spikes, 1.40c. to 1.45c.

The Non-Ferrous Metal Market

No changes of marked importance have occurred in the non-ferrous metal market during the past month. Fluctuations in price have been small. Spelter and lead have declined from the previous high prices; tin has receded a little but copper remains firm.

Copper.—This market has been active and producers have been able to maintain their prices. Small daily fluctuations in price have not been permanent. Demand for brass making continues good, and this business is said to be larger than ever before. Electrolytic copper at New York is quoted at 19.45@19.65 cents.

Tin.—The metal has been plentiful and the price has receded slightly during the month. Buyers seem well stocked and demand has slackened. July tin at New York is quoted at about 38 cents.

Lead.—The high price of 7 cents in June was not long maintained, and the principal producer gradually reduced the price until it reached 5.75 early in July. This price has since been practically maintained, although smaller dealers have offered concessions. The metal is quoted at 5.60@5.75 cents, New York, and 5.50@5.60 cents, St. Louis.

Spelter.—The demand for this metal is stimulating construction of new reduction works and the rejuvenation of some old ones. Good business is reported both domestic and foreign. London quotations continue nominal and a wide variation still exists in domestic prices. At St. Louis the latest quotations are 19.75@21.75 cents.

Other Metals.—The market for aluminium has improved and prices have risen, the New York quotation being 32@33 cents. Antimony continues scarce with high prices, special brands being nominal. Quotations range from 37½ to 52½ cents for different grades. Quicksilver is strong with a good demand. The price for large lots is $94 per flask of 75 lb., New York, and $90@$95 in San Francisco. Smaller quantities bring up to $100 per flask.

Production of Radium by the Bureau of Mines

In a statement issued by Secretary of the Interior Franklin K. Lane in Washington on July 27, it is announced that the production of radium from Colorado carnotite ores by the Bureau of Mines, in connection with the National Radium Institute, has passed the experimental stage in its new process and is now on a successful manufacturing basis. He also declared that the statements made to Congress concerning the ability of the Bureau of Mines to produce radium at a greatly decreased cost over other processes had actually been accomplished and that the costs were even less than predicted.

"The cost of one gram of radium metal produced in the form of bromide during March, April and May of the present year was $36,050, I am informed by Dr. Charles L. Parsons, in charge of the radium investigations of the bureau. This includes the cost of ore, insurance, repairs, amortization allowance for plant and equipment, cost of Bureau of Mines co-operation, and all expenses incident to the production of high grade radium bromide. When you consider that radium has been selling for $120,000 and $160,000 a gram, you will see just what the Bureau of Mines has accomplished along these lines."

"The cost of producing radium in the small experimental plant during the first few months of the Bureau's activities was somewhat higher but not enough to seriously affect the final average.

"The public, however, should not infer that this low cost of production necessarily means an immediate drop in the selling price of radium. The National Radium Institute was fortunate in securing through the Crucible Steel Company the right to mine ten claims of carnotite ores belonging to them and this was practically the only ore available at the time. Since then new deposits have been opened but these are closely held and according to the best judgment of the experts employed by the Bureau of Mines, the Colorado and Utah fields, which are much richer in radium-bearing ores than any others known, will supply ore for a few years only at the rate of production that obtained when the European war closed down the mines. The demand for radium will also increase rapidly, for the two or three surgeons who have a sufficient amount of this element to entitle them to speak from experience are obtaining results in the cure of cancer that are increasingly encouraging as their knowledge of its application improves. A few more reports like that presented to the American Medical Association at its recent San Francisco meeting and the medical profession as a whole will be convinced of its efficacy. Under all the circumstances that have come to my knowledge it does seem to me that it behooves the Government to make some arrangement whereby these deposits, so unique in their extent and their richness, may be conserved in the truest sense for our people, by extracting the radium from the ores where it now lies useless and putting it to work for the eradication of cancer in the hospitals of the Army and Navy and the Public Health Service.

"The ten carnotite claims being operated at Long Park, Colorado, by the National Radium Institute have already produced over 796 tons of ore averaging above 2 per cent uranium oxide. The cost of ore delivered at the radium plant in Denver has averaged $81.30 per ton. This included 15 per cent royalty, salary of Bureau of Mines employees, amortization of camp and equipment and all expenses incident to the mining, transportation, grinding and sampling of the ore.

"A concentrating plant for low-grade ores has been erected at the mines and is successfully recovering material formerly wasted. Grinding and sampling machinery has been installed at Denver and a radium extraction plant erected in the same city. The radium plant has now a capacity of three tons of ore per day, having been more than doubled in size since last February. Before that time the plant had been run more or less on an experimental scale although regularly producing radium since June, 1914. To July 1, slightly over 3 grams of radium metal had been obtained in the form of radium barium sulphate containing over 1 milligram of radium to the kilogram of sulphates. The conversion of the sulphates into chlorides and the purification of the radium therefrom is easily accomplished, and with very small loss of material. Unfortunately, however, special acid-proof enamelware, obtainable only in France, has not been delivered of sufficient capacity to handle the crystalization of the full plant production, so that a little less than half the output, or to be exact, 1304 milligrams of radium element have been delivered to the two hospitals connected with the National Radium Institute. The radium remaining can be crystalized at any time from neutral solution in apparatus already installed, but the greater rapidity and efficiency of production of this very valuable material by the methods used have decided the Bureau of Mines to await the completion of apparatus now being built before pushing the chloride crystallization to full capacity.

"The average radium extraction of all ore mined by the National Radium Institute has been over 85 per cent of the amount present in the ore as determined by actual measurement. The amount present in the ore has been found in fact to be essentially the same as the theoretical amount required by the uranium-radium ratio. The extraction figures for the last five carloads of carnotite treated has shown a recovery of over 90 per cent in each case.

"A bulletin giving details of mining, concentration and methods of extraction is being prepared by the Bureau of Mines and will be issued early in the fall."

Columbia University Establishes a Separate Department of Chemical Engineering

Courses leading to the degree of Chemical Engineer have been offered in the Department of Chemistry of Columbia University for the past ten years but, in recognition of the rapidly increasing importance of those industries based upon the applications of chemistry, and the consequent demand for men specially trained in the fundamental engineering practices as applied to the problems of industrial chemistry, the trustees of Columbia University have established a separate department of chemical engineering which will be placed upon the same plane of importance in the Columbia Graduate Engineering School as mining, civil, electrical and mechanical engineering.

The demand for graduates to fill important positions in the rapidly developing industries of the United States has brought an ever-increasing number of students to study chemical engineering at Columbia, the registration in this subject having reached a total of eighty-one during the past year.

The new chemical engineering laboratories which were recently installed, where the students are taught to use engineering methods and engineering appliances in the study and development of chemical industry, will be provided with still further equipment during the coming summer. In these laboratories research may be conducted on such a scale as to establish dependable engineering data to serve as a basis for intelligent and accurate process design. They are equipped with apparatus to illustrate the fundamental operations of chemical and electrochemical processes, and the student learns by actual contact to apply the fundamental scientific principles to industrial problems. It was here that Dr. Rittman carried on, as a graduate student, his work in the direction of obtaining gasoline, benzol and toluol from residual oils.

The fields in the chemical industry which have been most seriously affected by the European war and in which, in many cases, the supply of European products has been entirely cut off, might be enumerated as follows:

Coal-tar dyes for use in the textile industry; synthetic drugs from which many of our most improved pharmaceutical products are made; synthetic tanning materials for use in tanning our high-grade leathers;

barium compounds; magnesium compounds and a large line of similar high-grade chemicals; chemical and decorated glassware; ferromanganese used extensively in the metallurgical industries; potash and air nitrate for use in fertilizers.

The sudden demand for many of these products has greatly stimulated the activity among chemical manufacturers. In many cases it is necessary first to develop the raw material supplies, as for example for the manufacture of coal-tar dyes, where we are required to obtain a large quantity of benzol, phenol, toluol, etc. The demand for these materials is being met rapidly by the installation of large plants for the recovery of these heretofore wasted products from coke oven gases. Such concerns as the United States Steel Corporation, Lackawanna Steel Company and other large coke producers both in the United States and Canada are now recovering these products. Similar activity obtains in other fields; for example, on account of large demands for explosives, the production of sulphuric and nitric acids is being enormously increased. Entirely aside from these abnormal developments, forced upon the chemical industry by the war, it should be noted that chemical processes are being established in other fields.

Co-operation in Chemical Export Trade to South America

In the Federal Trade Commission hearings, held in Boston in June, on Co-operation in Foreign Trade, some interesting remarks were made with request to the possibility of chemical export trade to South America. We quote from *National Foreign Trade* (Vol. I, No. 3):

Mr. **Henry Howard,** vice-president Merrimac Chemical Company and Chairman, Executive Committee, Manufacturing Chemists' Association, Boston, Mass., said:

"Our association is made up almost entirely of small manufacturers. When the war broke out, it seemed to our committee an especially good time to investigate the opportunities in South American trade in chemicals, as the German supply was being cut off.

"The first thing we ran up against was that, under the law, it was doubtful if we could form a combination to investigate and comprehensively push our export trade in South America. Eminent counsel advised us it was not safe to do it. Hardly more than three members of the association are large enough to send representatives to South America, and I question if any of them are large enough to send representatives to more than one or two countries. In our own case, there are only three articles we manufacture that would find a market in South America. We could not afford to send a representative because the cost would more than eat up any profit we might get, but we could join in an export association made up of other members of our association, or other manufacturers outside, and contribute toward the maintenance of an efficient staff in all the leading countries, because the expense, apportioned among forty or fifty manufacturers, would be insignificant.

"The great advantage of such an association is that we would be in a position to meet European competition, in foreign trade, where going singly we would not. European business is thoroughly organized and intelligently managed. Even if some of us went individually, we would be afraid, as soon as the war was over, that we would be killed out individually. The foreigners would think twice before starting a fight to eliminate the entire association."

Mr. **A. H. Weed,** secretary and counsel Manufacturing Chemists' Association, Boston, Mass., said:

"The association, upon request from Washington, prepared a tentative form of a bill necessary to permit the kind of co-operation contemplated. The bill is premised upon the idea that the law should give the absolute and unqualified right to American manufacturers to co-operate for export trade. The effect of such co-operation, whether it be by agreement, combination or association, is to be found primarily in the foreign markets where such agreements, combinations or associations are to be carried out. If the laws of the foreign country permit such co-operation and if our foreign competitors are all acting in combination, within these foreign markets, we should have the right to meet that competition on equal terms. In other words, our anti-trust laws should have no extra territorial effect.

"On the other hand, to prevent any abuses which might result from such co-operative movements, any retroactive effect which a combination might have to restrain trade in the United States, the bill has a provision granting power to the Federal Trade Commission, similar to the power which it now possesses, to restrain unfair methods of competition, under Sec. 5 of the existing law. The proposed bill, therefore, defines export trade on the one hand and 'trade within the United States' on the other."

Possibility of Extra Session of Congress and the Tariff

An important report is in circulation in Washington to the effect that President Wilson is likely to make an announcement shortly which will have great interest in connection with the tariff. This is taken into consideration at the National Capital under the influence of ideas that are reaching there from the business and financial centers of the country concerning what the attitude of the United States is to be after the war in Europe has ended.

Economists in Washington are now giving much attention to the steps that it will be necessary for the United States to take after the war has ended. In these the question of a protective tariff largely figures. Reports reaching Washington from all over the United States are to the effect that business men will be glad to see a readjustment of tariffs. It is especially obvious that the very large sums of money which are now being invested and about to be invested in the creation of new chemical industries (which will make the United States economically and industrially far more independent of other countries than it ever has been), will simply be wasted if these new industries are not to be protected by a suitable tariff and accessory measures.

Senators and other tariff makers now in Washington believe that the early fall would furnish a suitable opportunity to discuss these matters and plan ahead. For that reason there is apparently a growing advocacy of the plan to have Congress reassemble around Oct. 1. This idea obtains support from many Senators and Representatives who are obliged to come to Washington in September to place their children in school, as well as from those who are anxious to begin as early as possible upon the fight as to whether or not there shall be a great increase in the military preparedness of the United States, sure to come this winter.

Again, some Senators and Representatives are urging an early session of Congress because of the fact that almost all of the important questions at the coming session will furnish material upon which the 1916 political fight is to be waged and because the national political conventions meet in the summer of 1916, by which time, they hope Congress will have completed all of its labors. Thus, they advocate an early start this fall.

Cyanidation of Low-Grade Sulphide Ores in Colorado—II

BY H. C. PARMELEE

Caribou, Boulder County

In the early history of Colorado mining, Caribou was a well known camp in Boulder County, springing into prominence about 1869 and continuing active with a wonderful production of silver until 1893. In 1888 the famous Caribou mine was closed as a result of litigation, and the camp went into a decline which culminated in 1893 with the fall in the price of silver.[1] Through this combination of circumstances, but particularly on account of the slump in the silver market, Caribou suffered the fate which overcame other silver mining camps in Colorado. It was gradually deserted, the mines filled with water, fire devastated a once populous camp, and Caribou became a place of only historical interest.

The silver production credited to Boulder County, from 1869 to 1893 came mainly from the Caribou, Poorman and other mines, all located in a restricted area at Caribou. In round numbers, the annual silver output of the county began with 3500 oz. in 1869, rose to 348,000 oz. in 1879, dropped to 250,000 oz. in 1893, and finally slumped to 75,000 oz. in 1894. Aside from the known production of some unusually large nuggets of silver, the richness of the ore is attested by the early records which show profitable operation under a mining cost of $17 per ton, and transportation and treatment charges of $45, or a total of $62 per ton. Raymond[2] states that in 1869, 26 tons of Caribou ore shipped to the Hill smelter at Black Hawk had a gross assay value in silver of $3,217, and that in 1870, 425 tons shipped to the same place had a gross silver value of $73,772. For the treatment of low-grade material, say 60-oz. silver ore, which would not stand the cost of shipment, there was erected a lixiviation mill at Nederland, four miles from Caribou.

It can be readily appreciated that at the time the Caribou and Poorman mines were worked, a vast quantity of what was then low-grade ore was left unmined, used as stope filling or thrown on the dump. It will also be apparent that, due to the progress in metallurgy in 30 years, such an abandoned property might now become a source of profit if properly sampled and tested, and equipped with a suitable treatment plant. This possibility having been brought to the attention of Mr. Henry P. Lowe, he undertook first the sampling of the dumps, and later, after getting encouraging results from this work, the unwatering and sampling of the mines. The Cariman Mining & Milling Co. was organized and a modern concentrating and cyaniding mill was built.

The dumps were carefully and systematically sampled through trenches and shafts, large lots of material being crushed, automatically sampled and assayed. Later these same lots were used as the basis of concentration and cyaniding tests, so that a safe foundation was laid for any subsequent work that might be justified by the results obtained. The original tests were checked by an independent engineer who practically confirmed the first results. In many of its aspects the problem here presented recalls that which confronted the engineers for Stratton's Independence in sampling and testing that dump. The latter project was greater in magnitude and the valuable metal was gold instead of silver, but similar principles were involved, and, strangely enough, similar treatment was ultimately adopted at both mines, viz., concentration and cyanidation.

The sampling of the Caribou dumps showed an average silver content of from 7 to 8 oz. per ton. The gold value varied from 40 to 70 cents per ton. The quantity of ore in the dumps was estimated at 135,000 tons. The tests indicated a total extraction of 85 per cent, of which 35 per cent was by concentration and 50 per cent by cyanidation. Flotation was not considered as a possible means of treatment on account of the prohibitive royalty demanded. The unwatering and sampling of the mines revealed the possibility of securing a large tonnage of ore from filled stopes and low-grade

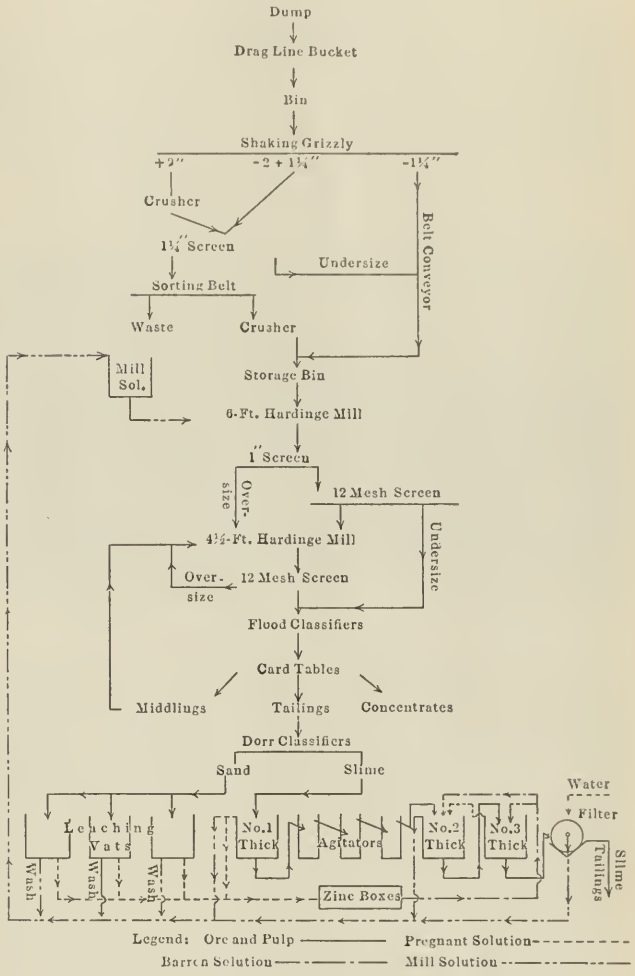

FIG. 1—FLOW SHEET CARIMAN MILL

veins that would average 15 oz. silver per ton. The final result of the sampling and testing which was carried on over a period of nearly two years, was the construction of a modern concentrating and cyaniding mill of 125 tons daily capacity, which has been in operation for over six months.

Cyanidation of Silver Ores at the Cariman Mill

The silver in Caribou ore occurs both native and as sulphide. Galena is present in small quantity, and occasionally chalcopyrite occurs. The gangue is granitic and exceedingly hard.

The ore is conveyed from the dump to bins at the coarse-crushing and sorting department by means of a drag-line bucket fitted with manganese-steel teeth. This method of reclaiming the dump has proved effective and economical, the cost averaging 4 cents per ton. From the bins the ore is fed over a shaking grizzly, with bars spaced two inches apart and below them a steel

[1]The price of an ounce of silver in 1869 was $1.32; in 1879, $1.12; 1890, $1.05; 1893, $0.78.

[2]Raymond, R. W., "Mineral Resources West of the Rocky Mountains."

plate punched with 1¼ in. round holes. The grizzly yields three products, as shown in the flow-sheet, Fig. 1. The size minus 1¼ in. is conveyed directly to the bins above the Hardinge mills. The largest size is crushed, combined with the medium size and screened through a trommel with 1¼-in. holes. The oversize from this screening operation is hand-sorted, sufficient barren granite being removed to raise the value of the mill feed from 25 per cent to 30 per cent above the gross value of the dump. Up to this point the ore is crushed dry, but beginning with the regrinding, mill solution is added. Lime also is added to the feed of the first Hardinge mill.

Hardinge conical mills have been selected for the medium and fine grinding. The first mill is 6 ft. in diameter, lined with manganese-steel ribbed plates and charged with 5-in. manganese-steel balls. The second and smaller mill is 4½ ft. in diameter, fitted with similar lining and charged with 3, 2 and 1-in balls. On account of the hardness of the ore, pebbles have not been found efficient grinders for the smaller mill.

Experience with Britannia Lining

The so-called Britannia lining, made of short pieces of rail set on end and embedded in cement, was originally furnished with one of the Hardinge mills. The lining failed after a very short run and was reset according to specifications with a strong cement mixture. After allowing ample time for the cement to set and dry the mill was again put in commission, but the lining lasted for only a few hours. The impact of the heavy balls loosened the rails and in a short time the lining was entirely broken up. Considering the time required to put this type of lining in place and allow it to set and dry, together with the very short service obtained, the experience with it was wholly unsatisfactory. Manganese-steel linings have since been used with satisfactory results.

The maximum size of feed to the first Hardinge mill is 1¼ in. The product is screened as shown in the flow-sheet, and the unground portion treated in the second mill. Twelve-mesh is the maximum size of the final product, and at this size concentration begins. There are no new features of importance in the concentrator. The pulp is hydraulically classified in Flood classifiers and distributed to Card tables. The concentrate is a finished product and is shipped to the smelter. A small amount of middling is returned to the second Hardinge mill, and the balance of the pulp, sand and slime tailing, is sent to the cyanide department.

About 35 per cent of the silver in the ore is recovered in a concentrate containing 100 oz. silver and 0.50 oz. gold per ton, with 5 per cent of lead.

Separate Treatment of Sand and Slime

The tailings from the concentrating tables flow to a duplex Dorr classifier where a separation is made between sand and slime, the dividing point being 100-mesh. The two products are about equal as to tonnage. The sand is elevated to a distributor and charged into leaching vats. Percolation begins as soon as a substantial layer of sand has formed on the filter-bottom, and continues while the vat is filling. The average rate of filling is 2.6 tons per hour, so that a 135-ton vat is under percolation for about 55 hours. During this period the solution is strengthened to 2.5 lb. KCN per ton. When the vat is full, mill solution at a strength of 1.7 lb. is turned on for about 100 hours. This is followed by a water wash for from 20 to 30 hours, according to the time available before the vat is required for a new charge. The pregnant solution obtained while filling the vat and during the wash with mill solution all flows to the clarifier and thence to precipitation. The water wash flows to the mill-solution sump. Sluicing requires from 8 to 10 hours on a 135-ton vat. An automatic sand sample is taken while the vat is filling. As the distributor revolves, the stream issuing from the longest arm passes over a slotted pipe connected with a sample box, so that with each revolution of the distributor a small quantity of the pulp is cut out.

A change made in the discharge gates on the sand vats has removed some difficulties formerly encountered. Originally the gates were of the usual type, hinged at one side and locked in place by wedges. At times the wedges would break. Again, it was necessary to have a movable launder in order to open and close the doors. The movable launder was responsible for sand spills, and at times a heavy tonnage would overflow before it was noticed. In order to obviate these troubles the doors have been tapped and threaded to receive a 6-in. plug or a 6-in. diameter pipe of suitable length to reach a permanent launder. To discharge a vat the plug is removed and replaced by the pipe which is screwed in loosely by hand. In replacing the plug it is necessary only to screw it in as tightly as may be required to avoid leakage, and if this cannot be done by hand a few turns with a wrench will suffice.

Continuous Counter-Current Decantation

The slime treatment is clearly shown in the flow-sheet. Decantation and agitation are continuous through a series of one Door thickener followed by three Dorr agitators and two Dorr thickeners. A Portland revolving filter is placed at the end of the system to recover cyanide. The overflow of No. 1 Dorr thickener is diverted either to the mill-solution sump or to the clarifier for precipitation, according to requirements. Enough of this overflow is added to the pregnant solution from the sand vats to keep the clarifying leaves submerged, and to furnish a constant supply for the zinc boxes.

The transfer of pulp from the thickeners is accomplished by means of Colorado Iron Works diaphragm pumps, which were illustrated and described in our last issue. The length of stroke of these pumps is regulated by adjusting an eccentric. At the Cariman mill the pumps are set for maximum stroke, and the quantity of pulp actually lifted is then controlled by means of an air-cock which admits air to the pump suction. No difficulty is found in thickening the slime pulp to 50 per cent moisture, and this is the standard usually maintained. Tests are made three times per shift by taking a measured quantity of slime from the discharge of the diaphragm pumps and suspending it on an ordinary spring balance with dial and indicator. A scale indicating per cent moisture, calculated from slime tables, is placed on the dial so that the moisture content is read directly.

The strength of cyanide solution is raised to 3 lb. per ton at No. 1 agitator. The agitators are run in series and the transfer of pulp is effected by gravity through adjustable transfer pipes.[3] The period of agitation is from 36 to 40 hours. On account of the sandy nature of the slime, it being ground to only minus 100-mesh, difficulty was experienced at first in keeping the transfer pipes open and pulp flowing freely. At times sand accumulated in the pipes and restricted the flow until the tanks overflowed. This has been entirely overcome by introducing compressed air through a ⅜-in. line into the transfer pipes, producing, in effect, a small air-lift. The connection between the air line and the transfer pipe is flexible so that the position of the

[3]See this journal, Jan., 1915, page 13

latter can still be adjusted as required. The quantity of air used is negligible.

The principle of impoverishing slime by decantation before filtering is now generally recognized as good practice. At the Cariman mill the function of the Portland filter is the recovery of chemicals in solution and the dewatering of the slime tailing. Dissolved silver in the slime is practically removed in the decantation process and the value of chemicals remaining in the slime pulp is greater than that of recoverable silver. A typical group of assays of filter head and tailing samples is as follows: Filter head, unwashed, 0.64 oz. silver per ton; filter head, washed, 0.34; filter tailing, unwashed, 0.42. This indicates a loss of dissolved silver of but 0.08 oz. per ton. The mechanical loss of cyanide at the filter is 0.18 lb. per ton of solution discharged in a pulp of 35 per cent moisture. Water is added as a wash in sufficient amount to balance the moisture lost in the discharged slime.

The pulp in the filter tank is kept in suspension by means of compressed air introduced from four jets spaced equidistant along the bottom edge of the tank. Once in 24 hours these jets are opened, one at a time, until all the settled slime is in suspension. The airlifts usually provided to keep the pulp in circulation have not been sufficient to prevent settlement in this particular case. They had the effect of merely pulling holes through the settled slime without disintegrating it.

The daily control of the work in the slime department requires the assay of the following pulps and solutions: Washed slime head, overflow from all thickeners, filtered solution from pulp in No. 3 agitator, washed pulp from No. 3 agitator, unwashed and washed pulp from underflow of No. 3 thickener, which constitutes the filter head; filter effluent, and unwashed filter tailing.

Precipitation and Refining

The pregnant solution from the sand vats and a varying portion of the overflow of No. 1 thickener is clarified through filter leaves under vacuum. The clarifier solution is pumped to a constant-head tank from which the zinc boxes are fed. Solution is precipitated at the rate of 1.8 tons per ton of ore. The head solution assays from 1.5 to 1.75 oz. silver per ton, and the tailing solution from 0.02 to 0.05 oz. No lead acetate is used or other special treatment given. A clean-up is made once in ten days, and a precipitate obtained assaying from 15,000 to 18,000 oz. silver and 50 oz. gold per ton.

Up to the present time no means for acid treatment have been provided, and the precipitate is given merely a light roast in a Case muffle roasting furnace. It is then fluxed and melted in a Case tilting crucible furnace. Both furnaces have gravity oil feed and air blowers, and give excellent satisfaction. A further description of the tilting furnace and burner appears elsewhere in this issue.

On account of the current high prices for chemicals, several fluxes have been tested to secure one that would prove efficient and economical. The one finally adopted contains the following materials in parts by weight: Soda, 5; borax, 3.5; silica, 1.5; manganese dioxide, 1. This has been used at the rate of 75 lb. per 100 lb. of precipitate. Manganese dioxide was selected in place of nitre, as the respective prices of the two chemicals at Denver is now about 10 cents and 20 cents per pound.

Power and Labor

Electric power is one of the modern conveniences that make possible the operation of such isolated mills as the Cariman. Situated at an altitude of over 10,000 feet and two miles from the railroad, the cost of coal delivered at the mill would be prohibitive in milling low-grade ore. Under present conditions electric power is available for all operations, and the only need for fuel is to heat the mill in winter. All motors are of ample size for the work required, as follows: Drag-line bucket, 20 hp.; belt conveyor, 5; coarse crushers, 35; Hardinge mills, 75; concentrator, 10; wet elevator, compressor and all cyanide machinery, 50.

The mill is designed to require the minimum amount of labor. All coarse crushing is done on one shift, requiring one man on reclaiming the dump and one at the crushers. In the mill there is one man per shift at the Hardinge mills, concentrator and in the cyanide department. Wages range from $3 to $4 per day.

Miscellaneous Data

The mill solution contains 1.7 lb. KCN per ton, with protective alkalinity of 2 lb. CaO. The latter may vary between 1.8 and 2.2, but outside of these limits the settlement of slime in the thickeners is seriously affected. At the sand vats the solution is strengthened to 2.5 lb. KCN, and at No. 1 agitator to 3 lb. The consumption of cyanide is 1 lb. per ton of ore, and occurs almost entirely at the agitators. The mechanical loss of cyanide in leaching is from 4 to 6 lb. per vat of 135 tons. At the filter the mechanical loss is 0.18 lb. KCN per ton of solution. The lime consumption is five lb. per ton of ore. Mine water is used throughout the mill, and solutions are kept at normal mill temperature, about 55 deg. Fahr. in winter and 65 deg. Fahr. in summer.

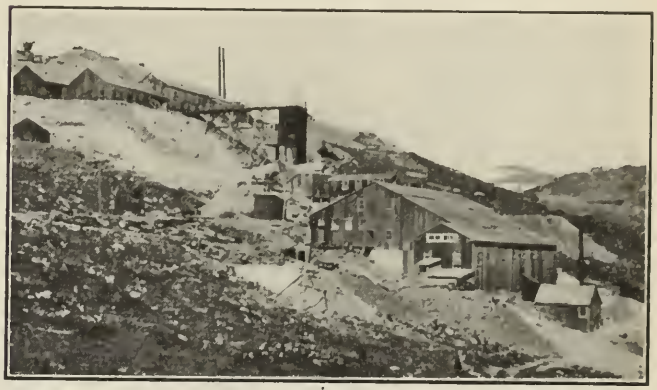

FIG. 2—CARIMAN MILL, CARIBOU, COLO.

The figures for the month of June show an average mill feed of only 4.8 oz. silver per ton. This was unusually low, due to the necessity of removing a lean part of the dump in preparation for some construction work. The concentrators recover 35 per cent. The average assay of the sand product was 2.1 oz. silver, of which 71.4 per cent was recovered. The average assay of the slime was 1.2 oz. silver, and the extraction 78.3 per cent. This amounts to a gross extraction of 85.8 per cent, or 4.12 oz. silver per ton. The total milling cost is estimated at $1.72 per ton.

The mine is now being equipped for production next winter, it being the intention to treat the dump ore only in summer. When all arrangements now planned are in working order it should be possible to maintain an average mill feed of 7 to 8-oz. ore from the dump and 15-oz. ore from the mine. The entire project affords an excellent example of revival in an old mining district, due wholly to improved methods of metallurgy and facilities for economic operation.

To Mr. Henry P. Lowe, and members of his staff, we are indebted for the data here given and for many courtesies extended in the preparation of these notes.

The Effect of High Ignition-Voltages on the Accuracy of Bomb Calorimeter Determinations

BY EDWARD J. DITTUS

In the determination of calorific values with the bomb calorimeter it is necessary to ignite the weighed portion of the substance in an atmosphere of oxygen, under pressure, by melting a small piece of iron wire (approximately 0.01 gram) with an electric current. A small calorific increment results, due to the passage of the current. It is contended that high voltages enhance this increment.

In order to determine the value of this source of error, several experiments were made with the apparatus shown in Fig. 1 and under conditions indicated.

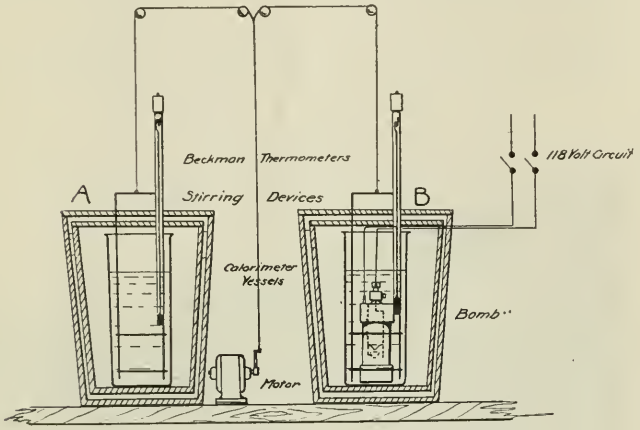

FIG. 1—APPARATUS FOR CALORIMETRY

Calorimeter A was used only as a blank to determine the variation of the temperature of the water contained, due to changes in room temperature. Calorimeter B was prepared as for a combustion, but no combustible material was introduced. No. 34 Brown & Sharpe gage iron wire was used to connect the two terminals, and the bomb contained oxygen under a pressure of 20 atmospheres. The terminals were connected to a 118-volt direct-current circuit. The two stirring devices were operated by the same motor, and the two Beckman differential thermometers were identical.

Before beginning an experiment the two thermometers were adjusted, as nearly as possible, to read the same. The difference in the reading was taken as a constant because the temperature range was in all cases very small, and the error from this source, therefore, small.

The same quantity of water (1500 grams) was used in each calorimeter, and in all experiments it was allowed to stand at least two hours in order to obtain temperature equilibrium. It was impossible to obtain the same temperature of the water in both calorimeters. Temperature readings were, therefore, made in each calorimeter until the difference was constant, and this difference assumed constant for all subsequent readings.

In making an experiment, a temperature reading was taken on each calorimeter, and immediately thereafter the 118-volt circuit was momentarily closed. Temperature readings were then taken at fifteen to thirty second intervals for ten minutes.

Three experiments were thus made and the data recorded as shown in tabular and graphic form. In the tables, the column "Corrected Bomb Temperature" was computed by adding to the "Bomb Temperature" the sum of the difference in the initial readings of the two differential thermometers and the constant difference in the temperature of the water in the two calorimeters.

EXPERIMENT I

Weight of water in each calorimeter ..... 1500 g.

Initial difference in temperature of water	0.865° C.
Initial difference of Beckman thermometers	0.765° C.
Total difference	1.630° C.

EXPERIMENT 3 WITH BOMB CALORIMETER

TABLE IV

No. of Experiment	Difference in Temperature, Blank and Bomb	Resultant Error in Gram-Calories Using 1500g. Water and 0.5g. Coal	Percentage of Error on 1g. Coal on Assumed Basis of 7000 Gram-Calories
1	0.005	7.500	0.25
2	0.005	7.500	0.25
3	0.000	0.000	0 00
Average....	.....	.....	0.166

The above data lead to the conclusion that unless great accuracy is required the ignition voltage is not an important consideration. That is, in the determination of the calorific value of coal, oil, etc., an error of 0.2 per cent is permissible, and the ignition voltage need not be seriously regarded.

Metallurgical Laboratory,
Colorado School of Mines.

The new benzol plant of the Inland Steel Co. at Indiana Harbor is now practically completed. A similar plant is being installed by the U. S. Steel Corporation at the Gary works.

Silica-Graphite Paint.—A practice that is fast gaining adoption in progressive power plants is the use of paint for the inner surface of steam boiler drums. The paint is said to afford protection against pitting. Silica-graphite paint is used for this purpose and for a number of years the manufacturers of this paint have coated the steam drums of five B. & W. boilers developing 1800 hp. and as a result the drums are in almost perfect condition. Another instance, in a plant equipped with B. & W. boilers developing 8400 hp., the interiors of the drums were scalded, painted both above and below the water line and allowed 48 hours to dry thoroughly. This treatment was repeated every ten months, and not only did it stop pitting but where it had previously taken six men seven days to clean the drums of one boiler, two men now clean them in a day. This latter experience is quoted from a letter of the Chief Engineer of the New York Life Insurance Company, in the April issue of *Graphite*.

The Potash Situation

BY SAMUEL H. DOLBEAR

The pressing necessity of a source of potassium salts independent of the control of the German Kali Works has never been so apparent as now. The absolute embargo placed upon the export of potash in all forms by the German government has created a most serious situation for the potash consumer. Arbitrary treatment of American buyers by the German syndicate in the past has, it is true, created some little feeling, but heretofore the question has been largely that of price, while now the consumer finds himself unable to secure any part of his wants at any figure.

At least one source of potash in commercial quantities is now known to exist in the United States, at Searles Lake, San Bernardino County, California, and it is possible that the intensive search which has been conducted by the United States Geological Survey, the Bureau of Soils, and by private individuals may result in making known other deposits.

Proverbially, large bodies move slowly. The Searles Lake enterprise easily qualifies in such a class, and while the engineers and officials of this project are working intelligently and with as much speed as will secure ultimate results, no immediate production of potash in large quantities is expected. The problem of transportation has been solved by the construction of a branch railroad from Searles, on the Southern Pacific Railroad, to the new town of Trona, on the northwestern edge of Searles Lake. This work was done by the Trona Railway, a corporation financed by the American Trona Company, which is the operating concern. The California Trona Company continues as the owner of the property, which originally comprised about 250 placer locations of 160 acres each—a total area of approximately 40,000 acres.

The serious problem at Searles Lake is essentially a chemical one, involving the separation of potassium chloride from a solution containing also sodium carbonate, sodium chloride, sodium sulphate, sodium borate and other saline substances. The process worked out by John W. Hornsey, and for which an experimental unit designed to produce 5 tons of potash per day was built, has been abandoned as not practical. A new process has been developed by a New York engineer, which it is believed will successfully make this separation, but details of this new process have not been made public.

There is still some litigation with regard to the title to the company's claims. The California Trona Company filed application for patents on certain of its claims, and the granting of the patents has been protested by Victor Barndt. The reasons for the protest are unusual, being based on the following grounds: (1) Attempt to establish a monopoly; (2) failure of locators to make discovery; (3) that the locations were not made in good faith. The first claim hardly seems to deserve serious consideration for the reason that the presence of potash was not known to the locators when the claims were filed. Anent failure to make discovery, that is, of course, a matter to be determined by evidence. The third basis quickly resolves itself into the question of "What is 'good faith'?" The question in this case is really that of determining what is a sufficiently valuable consideration to constitute a valid transfer of title.

Aside from the work at Searles Lake, efforts have been directed along three other lines in the United States with a view toward securing a potash production: (1) From "vinasse" or refuse from a distillery in California; (2) from California kelp, and (3) from siliceous rocks in which potash occurs in an insoluble state.

During the past year the Pacific Chemical Company

commenced the construction of a plant at Agnew, Cal., on a site adjoining the distillery of the Western Grain & Sugar Products Company, and plans to use the refuse "vinasse" of the latter concern. No production has yet been made.

At Point Loma, San Diego County, Cal., the Kelp Products Company has built an experimental plant to extract potash from kelp. The plant is also designed to dry the kelp commercially for use as fertilizer. The kelp is harvested with a mower device which extends 6 ft. below the surface of the water. After being mowed the plants are carried by a conveyor into a barge. When loaded this is towed ashore to the company's wharf, on which has been placed a chopper. By means of a conveyor the plants are delivered from the barge into the chopper. From the chopper discharge the material is carried on another conveyor to a rotary tubular calciner in which a sufficient heat is maintained to thoroughly dry the chopped kelp. The dried product is then ground and sacked for shipment. According to the officials of the company, the dried product contains 15 per cent K_2O, 2 per cent N, and ½ per cent P_2O_5.

When it is desired to extract the soluble potash content from the kelp a different course is pursued. Under the patent which the company holds, a deglutinizing agent is fed into the chopper while the plants are chopped very fine. The juices are then pressed from the kelp and the residual pulp dried. The juices are then artificially evaporated and the salts allowed to crystallize.

A careful study of the chemistry of these kelps has been made under the direction of the College of Agriculture of the University of California. This institution has recently published a bulletin compiled by John S. Burd, entitled "The Economic Value of Pacific Coast Kelps."

The possibility of recovering potash from feldspar and feldspathic rocks has been very fully discussed by Messrs. Allerton S. Cushman and George W. Coggeshall in METALLURGICAL & CHEMICAL ENGINEERING in the issues of November, 1912, and February, 1915.

THE EUROPEAN SITUATION

Importations of potash into the United States were disturbed immediately upon the declaration of war in Europe, and months before Germany had established the absolute embargo, there existed what then seemed a critical shortage in supply. The extent of the interruption may be appreciated when it is known that in the fiscal year ending June 30, 1914, there was imported into the United States 1,066,929 tons of potash salts for fertilizers. Importations for the six months July 1, 1914, to Dec. 31, 1914, amounted to only 182,192 tons, as against 567,595 tons for the same period in 1913, thus leaving a shortage on Jan. 1, 1915, of 384,403 tons.

The turnover of the German Kali Syndicate in 1914 amounted to approximately 156,000,000 marks ($37,128,000), a decrease compared to 1913, when the amount was 192,000,000 marks ($45,696,000). In view of the rapid increase in production just prior to the war, it seems probable that had war not been declared the turnover for 1914 would have been about 210,000,000 marks ($49,980,000).

While authentic data regarding the present operations of the German Kali Works is not available, it is known that about one-half of its employees have gone to the front as soldiers. It is interesting to note that these men are being paid their usual wages while engaged in military duty.

There are two points of particular interest in the European potash situation at this time: the case of Alsace, and the prospect of securing a supply in Spain. In Alsace, so far as is now known, the deposits underlie an area of nearly 7 sq. miles. They range in thickness from 6 to 30 ft., and contain an estimated tonnage of 1,472,058,000 tons of potash salts. It is reported that explorations carried on in Baden, across the Rhine from the Alsatian mines, indicate the probable extension of the deposits into that section also. The future possession of Alsace is possibly now in doubt, and should the administration of that country pass out of German hands, potash from its mines might compete with the German product.

The presence of potash in the Provinces of Barcelona and Lerida in Spain has been known for several years, but only during the past year or two has general interest centered here as a possible competitor to the Strassfurth deposits. This possibility seems to have been appreciated by the German interests and much of the new fields had been taken up by them prior to the outbreak of war last year. Anticipating that German control might simply result in the complete shutting down of the mines, the Spanish government have prepared laws which require the constant operation of the deposits by those holding mining privileges. While investigations made so far seem to indicate that only enough potash may be found here to supply the demand in the Spanish markets alone, such investigations are far from complete, and sentiment in Spain does not seem to respond to the doctrine of conserving these resources for local use exclusively.

Aside from those concessions which have passed into the hands of German principals, others have been secured by French capital. All of the lands so far taken up are in a limited region along the Cardona River near the towns of Suria and Cardona. The claims do not go beyond Solsona on the north, and Tarrega, Servera and Manresa on the south. The Geological Survey of Spain is now conducting a careful investigation of this area, and while this research is being made all free lands have been reserved from entry. Under the new law, the government itself may undertake the exploitation of all minerals which can be utilized in the manufacture of fertilizers.

The American Consul General at Barcelona has reported that under the most favorable circumstances no production of potash could be made before the latter part of 1915, and that the development of these fields has been seriously affected by the present war.

OTHER FOREIGN SOURCES OF POTASH

The niter deposits of India, Chili and Africa furnish some potash salts, although the amounts produced are relatively small. About 10,000 tons is annually exported from India, while the Chilian production is about 20,000 tons. In Scotland, Norway and Japan small amounts of potash and iodine are extracted from kelp, and in Russia a small amount of potassium carbonate is made from the ashes of sunflower stalks. In Canada, potash is leached from wood ashes in the big lumber mills.

The development of a potash industry in Utah seems assured in the near future. The Mineral Products Co. has contracted for the construction of a tramway near Marysvale, Utah, for the purpose of transporting alunite to a treatment plant which is to be erected.

Ferromanganese Made at Niagara Falls.—The firm of E. J. Lavino & Company, Phila., Pa., has started the manufacture of 80 per cent ferromanganese at Niagara Falls, N. Y., and it is our understanding that they have made arrangements to supply the American trade with their future requirements. Since the war started, the supply of ferromanganese from Europe has been a source of worriment to the steel industry.

Possible Applications of Oxygen in Metallurgy

Oxygen Blast for the Iron Blast Furnace

Before the Mining and Metallurgical Society of America, Mr. **J. E. Johnson, Jr.**, discussed recently in an interesting manner some possible applications of cheap oxygen, especially in the metallurgy of iron (*Bulletin*, Vol. VIII, No. 2). In view of the fact that oxygen at lower and lower cost has become a commercial commodity in recent years, and that developments tending to reduce the cost of oxygen still further appear to be close to realization in the near future, Mr. Johnson's remarks are particularly timely and suggestive.

"One of the developments of the past five years has attracted less attention than it deserves, because its first steps were obscured by charlatanery and chicanery. I refer to the progress of separating air into its component oxygen and nitrogen on an industrial scale by distillation from liquid air, a process which is in actual operation at Niagara Falls, separating many thousand cubic feet of air per hour.

"Those who remember the ridiculous claims made for liquid air some sixteen years ago, and their subsequent utter collapse, are inclined to deny the commercial possibility of that operation, on theoretical grounds, but this is not correct. The theoretical power, figured on the basis outlined by Ostwald, the great apostle of physical chemistry, amounts to only 1 hp. per 6 cu. ft. of oxygen produced per minute. A modern 500-ton blast furnace needs 45,000 cu. ft. of air or 9000 cu. ft. of oxygen per minute, which would require, on the theoretical basis, 1500 hp. for its production, as against the 2500 hp. now necessary to blow the furnace.

"The best performance of any actual air separating operation to-day requires about seven times the theoretical amount of power, so we are still far from being able to replace existing methods on the power basis. Processes are under development, however, which promise to reduce this power requirement by one-half or two-thirds; in other words, we hope to produce oxygen at any efficiency of 50 per cent, based on theoretical power, and there is no fundamental reason why we should not do so. Even this, you will say, is no improvement over present conditions, and on the power basis alone that would be true. But this question cannot be decided on the power basis alone for two reasons: First, the heat consumption of the blast under present blast-furnace conditions is not limited to power alone. Second, the result in the furnace itself must be considered.

"In regard to the first point, it must be remembered that the blast must not only be compressed but it must be heated, and this operation requires about four times the heat required to supply power for compression; then there is the heating equipment which costs as much as the power plant, all of which would be saved by the use of oxygen. This brings us to the second point, the effect of oxygen in the furnace itself.

"In the furore which arose over the dry blast just ten years ago you may remember that a new theory of the blast furnace was brought out, which supplements the old theory in precisely the same way that the second law of thermodynamics supplements the first, and, curiously enough, is expressed by identically the same mathematical formula. This new theory rests on the fact that quantity of heat alone is not sufficient; the temperature at which it can be applied is just as important.

"We know as a matter of practical observation that a furnace will not operate properly unless the slag be raised to or above its free-running temperature, therefore that some of the heat required for the process must be supplied at or above that temperature. Since, under given conditions, the quantity of this heat bears a definite ratio to the total quantity, the first, which I call for convenience the 'hearth heat,' is just as important as the second. As a matter of fact, whichever quantity first falls below the requirements sets a limit to economy whether the other be present to excess or not, and in 95 per cent of the cases it is the quantity of hearth heat obtainable per pound of fuel which limits fuel economy.

"If we know the critical temperature it is easy to calculate this latter quantity for any given condition. I recently had occasion to calculate it for dry blast at 1000 deg. Fahr., and for a mixture of equal weights of oxygen and nitrogen (at atmospheric pressure) for different critical temperatures. The results are shown in Fig. 1. The critical temperature in ordinary coke practice is well established as about 2750 deg. Fahr., and you will see that at this temperature the hearth heat, with ordinary hot blast, is about 1600 B.t.u. per pound of coke, while with 50 per cent oxygen it is 2400 B.t.u., so that with 50 per cent oxygen blast an ore which now requires 2100 lb. of coke would require only

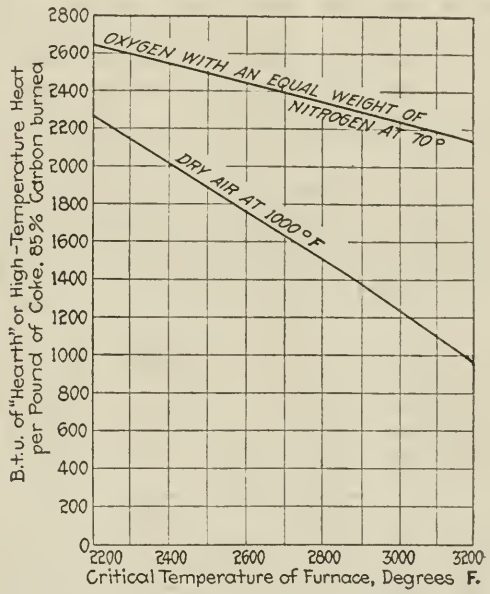

FIG. 1—DIAGRAM SHOWING HEARTH HEAT PER POUND OF COKE

Counting 85 per cent fixed C burnt in hearth, at different critical temperatures with blast of dry air at 1000 deg. Fahr., and with blast containing equal weights of oxygen and nitrogen.

1400 lb. While this is not the whole story, a very careful analysis, based on experimental data, indicates this result as entirely possible.

"This has an important effect on the consumption of power, for obviously it will require only 67 per cent as much oxygen to burn 1400 lb. of coke as it does to burn 2100 lb., and we therefore reduce our power consumption by 33 per cent to burn the same quantity of coke in each case.

"This is not all. The above computation assumed a blast containing 50 per cent oxygen, which may be obtained by mixing pure oxygen, on which our power calculations are based, with 1½ times its volume of air, which costs nothing; this reduces the pure oxygen which must be furnished to about 73 per cent. The product of these two percentages, 67 and 73, is about 49 per cent, and it thus looks as though power consumption by this suggested process might actually be less than at present, to say nothing of the saving of gas for heating the stoves. It becomes then a question merely whether the saving of 1000 lb. of fuel would pay fixed charges on the new investment; this is obviously a question of locality rather than of possibility for the present.

"There are, however, several other sides to the subject. One is the increasing leanness of the ores available; this may perhaps be best illustrated by the fact that when my father was called on to make an examination of the Chaplin mine in 1891 he found them throwing 56 per cent ore over the dump as rock. The effect of increasing the leanness on fuel consumption has already been felt, and is destined to be felt much more distinctly in the future. Ore of 52 per cent Fe produces about ½ ton of slag per ton of iron. Ore of 38 per cent Fe and 38 per cent silica produces 2.25 tons of slag, an increase of 1.75 tons, which at 0.4 ton coke per ton of slag produced means an increase of 0.7 ton in coke. In the same manner an ore with 25 per cent Fe, 48 per cent SiO_2, and 15 per cent Al_2O_3 would produce 5 tons slag per ton iron, which, at 0.4 ton of coke per ton of slag, would require 2 tons coke for slag alone, or nearly 3 tons in all.

"This would require 4.2 tons of coal per ton of iron, since to make 1 ton of coke takes 1.4 tons of coal, and the value of the by-products does not more than pay for coking.

"Moreover, we now use a large tonnage of ferromanganese and a considerable tonnage of ferrosilicon, which can be made only up to 15 per cent Si in the blast furnace; anything above this must be made in the electric furnace. In the case of ferromanganese, a heavy loss of manganese occurs because the bottom of the furnace is too cold and the top too hot. With both ferromanganese and ferrosilicon the consumption of coke is twice as much as with pig iron, though the heat requirements are but little greater. This is because the critical temperature at which the operation must be conducted is much higher. We can easily see by the chart that the critical temperature must be about 3300 deg. Fahr. to require this amount of coke, and that the available heat per pound of coke at this temperature, and with 50 per cent oxygen, is 2100 B.t.u., as against 800 B.t.u. with ordinary hot blast. In this case we may be sure that we could reduce the coke consumption to one-half with oxygen blast, and by reducing the volume and increasing the temperature of the slag we would cut down the slag loss of manganese; furthermore, the quick drop in temperature of the gases, due to their small volume, would prevent the volatilization of much of the manganese, which in present practice is being lost in that way.

"The critical temperature now attainable limits the production of ferrosilicon to those ferrosilicon brands containing 15 per cent or less Si, but a brief inspection of the chart will show that this will not be true when we use 50 per cent oxygen, and I confidently expect that we shall be able to make 50 per cent ferrosilicon in this way

"You may question the possibility of withstanding the high temperature produced by the combustion of incandescent carbon in oxygen, thinking that this will be a serious objection to the proposed process; no difficulty is to be anticipated on that score because we have no reason to expect any higher temperature with oxygen blast than we attain to-day. It must be remembered that the temperature of any combustion is determined by the total quantity of heat developed divided by the thermal capacity of the substances present. Theoretical combustion temperatures of the present blast furnace run up to 3500 deg. Fahr., but it is doubtful whether actual temperatures often exceed 2800 deg. or 2900 deg., because we charge the furnace with sufficient 'burden' to hold the temperature down to this point. With an oxygen blast, we should simply dampen the combustion with enough more burden to keep the temperature practically where it is now.

Other Applications

"The nitrogen discarded from the blast would be an asset of great value. Existing air distillation plants are run for the production of nitrogen for cyanamide, but the manufacture of ammonia by direct synthesis of hydrogen and nitrogen, without excessive power consumption, is an established fact; methods have also been developed for the production of hydrogen, both by partial liquefaction of water-gas or coke-oven gas, and by treatment of water-gas with lime. If this process be perfected we can obviously make about a pound of ammonia for every pound of iron, and at comparatively small expense. This would alter the fertilizer situation decidedly for the better.

"Many other dreams will be realized when we obtain really cheap oxygen. One of these is to obtain rich producer gas, containing a high percentage of the heating value of the coal, so that transmission of power and heat by gas generated at the coal mine will be not only feasible but profitable in many instances. To obtain water-gas by present methods, we must waste a large part of the heat value while 'blowing up' the producer, but having pure oxygen we could use a large quantity of steam with it continuously, thus producing a gas consisting wholly of hydrogen or hydrocarbons, and carbon monoxide, which would probably have a heat value of at least 500 B.t.u. per cubic foot and would afford a very high temperature of combustion because entirely free from nitrogen. By mixing a limited percentage of oxygen with city gas in the mains, its lighting power, applied to mantles, is enormously increased and it is not explosive.

"These are the phases of the subject with which I am most familiar. There are many others of almost equal importance, intimately connected with metallurgy and chemistry. Those who wish to be leaders in their particular branch of the profession would do well to ask themselves the question: 'What will probable developments in the production of cheap oxygen do for my field of chemistry or metallurgy?'"

Blue Vitriol.—Since June 1, 1915, the sale of copper sulphate, manufactured by the Nichols Copper Company, is handled exclusively by the General Chemical Co.

A preliminary report on the dye-stuff situation in the United States has been issued as Senate Document No. 952, Sixty-third Congress, and can be obtained free on application to the Senate Document Room, Washington, D. C.

Coal-tar products and the possibility of increasing their manufacture in the United States are considered in *Technical Paper* 89 recently issued by the Bureau of Mines, Washington. The paper contains also a chapter on coal-tar products used in explosives.

The production of chromium in the United States has increased since the war cut off European supplies. California is the chief source of chromium in this country. The production in 1913 was 255 long tons, and in 1914, 591 long tons. The gain in quantity was 131 per cent and in value 205 per cent.

The first ferromanganese furnace of the Noble Electric Steel Company at Heroult, Cal., was put in operation on June 3 and is reported to have produced a satisfactory cast of ferromanganese of 80 per cent grade, according to the British standard. This furnace has a capacity of 10 tons a day. Suitable ore, it is claimed, is supplied to the plant from mines in Mendocino County. The project is in the control of Mr. H. H. Noble, formerly president of the Northern California Power Company.

Vacuum Pans

Classifications, Principles, Tests

The paper by Prof. E. W. Kerr, assisted by J. F. Gunther and W. A. Rolston, on Performance Tests of Sugar-House Heating and Evaporating Apparatus, which forms Bulletin 149* of the Agricultural Experiment Station of the Louisiana State University and A. M. College, Baton Rouge, La., contains an interesting account of extensive vacuum-pan tests, made in large-scale sugar-house operation. A suggestive classification of vacuum pans is first given, with an explanation of the principles involved.

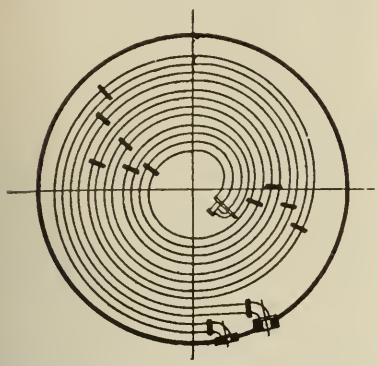

FIG. 1—COIL VACUUM PAN, DOUBLE COILS.

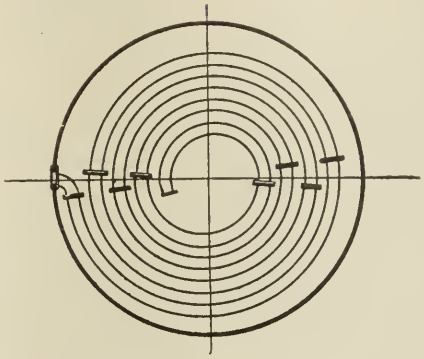

FIG. 2—COIL VACUUM PAN, SINGLE COIL

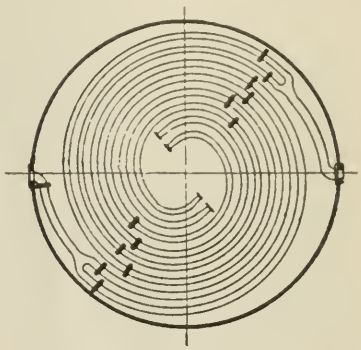

FIG. 3—COIL VACUUM PAN, QUADRUPLE COILS

Classification

There are two general types of vacuum pans (Figs. 1 to 9)—namely, calandria and coil pans. A calandria vacuum pan in the simplest form is practically of the same construction as a standard vertical-tube evaporator, except that the tubes are somewhat shorter and larger in diameter. There are several different arrangements of coil pans, a typical arrangement being shown in Fig. 4. Coil pans of this type may have single, double, triple or quadruple coils, as shown in Figs. 1 to 4 inclusive. Fig. 5 shows what may be called a manifold coil pan, there being an interior manifold for each set of coils, the steam entering the coils through the manifold and the condensation leaving from it. Fig. 6 shows another type which may be called the double manifold coil pan, steam entering the coils through one interior manifold and the condensation leaving them through another manifold.

Fig. 7 illustrates a plain calandria pan with two steam coils below the calandria. It will be noted that there is a central downtake as in standard evaporators, also a number of smaller downtakes nearer the circumference. Fig. 8 shows a calandria pan differing from the plain calandria pan shown in Fig. 7, mainly in the fact that the tube sheets are inclined. Fig. 9 illustrates another pan similar to that of Fig. 8 except that the tubes as well as the tube sheets are inclined. There are various other arrangements of calandria pans though those il-

*An abstract of the contents of this Bulletin is given in the Synopsis in this issue.

lustrated will serve to indicate the general principles involved in their design.

The factors which affect heat transmission and capacity in vacuum pans are in a general way similar to those in multiple evaporators. However, due to the difference in the arrangement and construction of the heating element, the methods necessary for meeting the requirements differ somewhat.

Principles Involved

TEMPERATURE FALL

In vacuum pans the temperature fall is generally much greater than in evaporators for the reason that the temperature difference between steam and liquid is not subdivided as in evaporators. In pans where live steam is used the pressure is usually 25 to 100 lb. gage, the average being in the neighborhood of 60 lb. gage, with a vacuum of 26 in. mercury. This would give an apparent temperature fall of 182 deg. This naturally results in a greater transmission of heat per unit of time and area than in evaporators. This applies especially to coil pans. In the case of calandria pans,

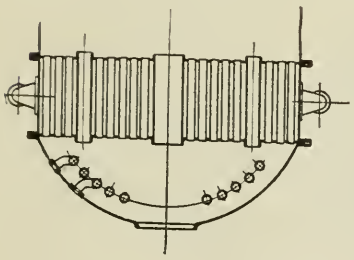

FIG. 7—CALANDRIA PAN.

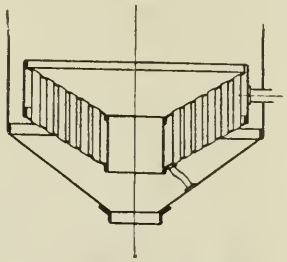

FIG. 8 — VACUUM PAN WITH INCLINED TUBE SHEETS

where more heating surface can be provided in a pan of given diameter than is possible with coils, exhaust steam can be and is often used instead of live steam. With exhaust steam the pressure will not be higher than about 10 lb. gage and the apparent temperature fall will be in the neighborhood of 100 deg. to 110 deg.

HYDROSTATIC HEAD

In vacuum pans the head is much greater than in evaporators. In a pan of average size the maximum head at the end of a strike is 12 ft. to 14 ft. above the lowest heating surface and a large part of the strike is boiled with average heads of 5 ft. to 8 ft. This, of course, results in a considerable increase of pressure and the temperature of boiling will be considerably higher than that corresponding to the vacuum in the pan. For this reason it is best to design vacuum pans with relatively large diameter and small height.

DENSITY AND PURITY OF THE LIQUID

In laboratory evaporator tests of Professor Kerr it was found that the density of the liquid also has a marked effect upon the rise in boiling temperature above the theoretical. For 70 deg. Brix, the rise about the theoretical was about 9.4 deg., with a vacuum of 25 in., referred to a barometer of 30 in. This curve was obtained with a sugar solution made up from a granulated white sugar, which was, therefore, practically pure—that is, with a purity of 100. The density of a strike varies from 50 deg. Brix at the beginning to about 95 deg. Brix at the end, so that the average Brix of a strike would be 70.

The purity of the liquid also affects the rise in temperature above the theoretical, the lower the purity the greater the rise. For Louisiana the purity of a strike of firsts will average something like 70, while for lower products the purity will be 60 or less. Sometimes a crystallizer strike will have a purity of considerably less than 50. In the tropics the purity will be somewhat higher than these, a purity of 80 for a strike of first being common.

Fig. 10 gives curves plotted from figures given by Classen showing the relation of purity to temperature rise. From this it is evident that due to the high density and low purity alone the temperature rise above the theoretical will be more than 25 deg. and in addition to this there is an added increase due to hydrostatic head, making a total rise of 30 deg. or more for the maximum condition.

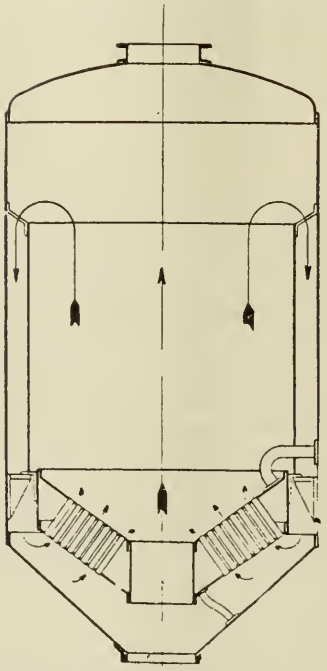

FIG. 9—EXPRESS PAN, INCLINED TUBES AND TUBE SHEETS.

THICKNESS AND MATERIAL OF THE HEATING TUBES OR COILS

As a usual thing, the diameter of coil in coil pans is 3½ in. or 4 in. The tubes in calandria pans also are usually 3½ in. to 4 in. in diameter. On account of the increased diameter, also on account of the more or less violent vibration incident to ebullition, the tubes are thicker than evaporator tubes, being usually in the neighborhood of 14 gage, corresponding to a thickness of approximately 1/12 in. This will cause some reduction in the heat transmission.

The heating surface in both coil and calandria pans is greater heat transmitting quality, but because of its ductility, which makes it easy to work. The latter is especially important in coil pans.

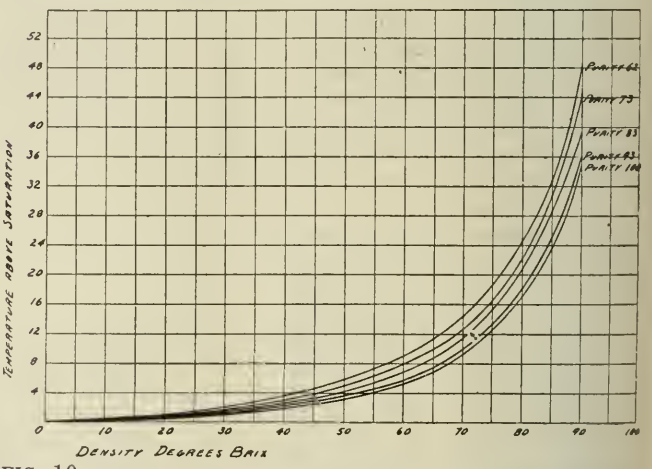

FIG. 10—EFFECT OF PURITY ON TEMPERATURE OF BOILING

VELOCITY OF CIRCULATION OF THE BOILING MASS

As in evaporators, rapid circulation is very beneficial as regards heat transmission. Much can be done in designing pans that will aid in bringing about good circulation.

In calandria pans the same general principles hold as with standard evaporators. Generally there is a central

downtake and in some cases additional downtakes, as shown in Fig. 7. The inclined tube sheets shown in Figs. 8 and 9 also aid in producing defined paths of circulation, the liquid passing upward through the tubes at the outside and in the annular space at the circumference and downward at the middle.

In order to further define the path of circulation above the calandria, the Express pan, Fig. 9, is provided with a cylindrical false shell, strengthened by pipes, *B*, which tends to give a circulation as shown by the arrows. The liquid inside of the false shell rising from the heating surface is of lower density than that between the false shell and the shell, due to the high temperature bubbles of vapor it contains. This causes the liquid to overflow from the interior to the exterior of the false shell. It is said there are two separate circulations as shown by the arrows.

In coil pans the path of circulation is likely not to be so positive or well defined as in calandria pans and for this reason the coefficient of heat transmission may be greater in calandria pans than in coil pans. The circulation is upward between coils and downward through the downtake at the center, the diameter of the downtake being equal to the minimum diameter of the coils. In a 10-ft. coil pan of standard construction the downtake will be in the neighborhood of 30 in. in diameter.

The space between coils in horizontal directions affects the circulation also. In placing the coils one above the other the space from bottom to top should be as straight as possible, otherwise the resistance to the flow of liquid in a vertical direction will be great and the rapidity of circulation reduced. The supports of the coils may also interfere with the circulation if they occupy too much room and are improperly arranged.

In some coil pans a circulation is induced mechanically by means of a revolving screw placed in the vertical axis of the pan.

VELOCITY OF STEAM

As in evaporators a rapid flow of steam on the heating surface will increase the coefficient of heat transmission. In calandria pans the same principles hold in regard to steam velocity and distribution as in standard effects. As vacuum pans seldom use steam of pressure below that of the atmosphere, pumps for removing the condensation are not required, hence the flow of steam toward a pump, which is common in evaporators, is missing in calandria pans. In coil pans the velocity of the steam is high at the end of the coil nearest the entrance and is practically zero at the other end, provided no steam is allowed to leave the coil, as would be the case when traps or automatic receiver pumps are used for removing the condensation. However, when adjustable check valves are used and they are left open too much, there will be some flow of steam from the coil, which will result in increased heat transmission, though this will be at the expense of economy.

AIR IN THE HEATING COMPARTMENT

The presence of air in the heating compartment has the same detrimental effect whether in vacuum pans or in evaporators. Air enters with the steam, and, as the steam condenses, it will accumulate unless it is promptly removed. On account of the relatively high pressure in the heating compartment of vacuum pans, the loss in temperature fall due to the presence of air is small as compared with evaporators where the pressures are in most cases below that of the atmosphere.

In calandria pans the methods of removing air are practically the same as for standard evaporators, vents being required. In connecting the pump or trap which removes the condensation from the calandria it is important to arrange the piping in such manner that air pockets will not be formed.

In coil pans the air is removed along with the condensation from the lower ends of the coils by different methods which will be described under the head of condensation.

Where traps are used, resulting in practically no steam velocity at the lower ends of the coils, there will be a tendency for air to accumulate and to vent this air numerous devices have been employed.

One requisite for the prevention of air pockets in coils or in the piping is that there should be a gradual incline downward where the pipe runs full of water. As air will rise in water, an air pocket will be formed at any high point unless the velocity is sufficient to sweep air bubbles along with the water.

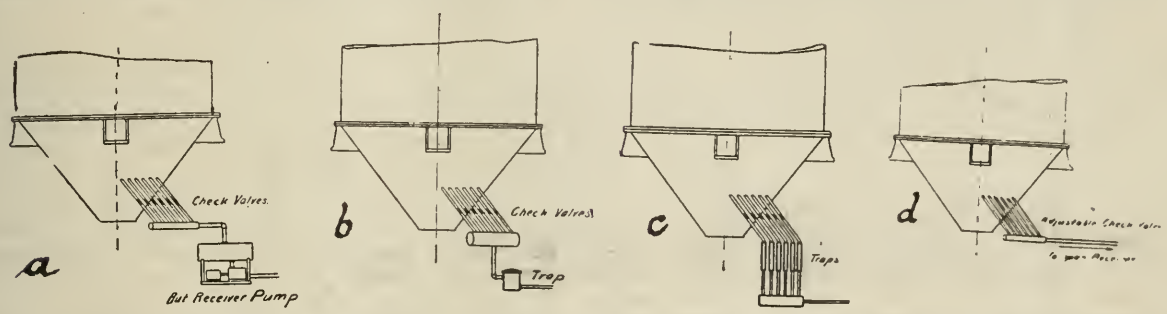

FIG. 11—DIFFERENT WAYS OF REMOVING CONDENSATION FROM VACUUM PANS; (*a*, BY AUTOMATIC RECEIVER PUMP; *b*, BY A SINGLE TRAP; *c*, WITH A TRAP FOR EACH COIL; *d*, WITH ADJUSTABLE CHECK VALVES)

CONDENSATION

As in all heating and evaporating apparatus vacuum pans must be promptly voided of the water of condensation or there will be a loss in the efficiency of the heating surface. The water of condensation may be removed from calandria vacuum pans by means of traps or automatic receiver pumps, either of which when properly installed and of the proper kind is satisfactory. The condensation from coil pans may be removed in a number of different ways as shown in Figs. 11, *a*, *b*, *c*, *d*.

Systems for handling condensation from heating and evaporating apparatus in sugar factories may be arranged according to two systems—namely, "closed" and "open." In the former the condensation is returned to the boiler as feed water without releasing the pressure —in other words, the boiler receives it at the temperature it had when leaving the pan or other apparatus. In the open system the water after leaving the pan or other apparatus is taken to an open receiver or hot well, from which it is pumped to the boiler. It is evident that as the pressure in the open receiver is that of the atmosphere, the temperature of the boiler feed taken from it cannot be higher than 212 deg. In vacuum pans the steam pressures are such that the temperature of the condensation may be 250 or more. When water with such high temperature is released in an open re-

ceiver a large amount of heat will pass off in the form of vapor when the pressure is released.

The arrangement shown in Fig 11a is well adapted for use with a closed system. The arrangement shown in Fig. 11b may also be used with a closed system, provided the trap is of the "return" type. In Fig. 11c separate traps are connected to the drain pipes for each coil, the traps being of the "non-return" type. In Fig 11d the removal of condensation is controlled by means of adjustable check valves. These valves are adjusted so that water but not steam will flow through. Evidently this arrangement could be used only with an open system.

On account of the occasional trouble due to the accumulation of air at different points in the system, to the disturbance caused by the mixing of condensation waters of different temperature, and to the fear that the feed pumps will not handle the water of very high temperature, there has been some objection to the use of closed systems. Practice, however, has shown that such systems are feasible and desirable, provided they are designed and arranged along rational lines. Often a closed system is lacking only in the need of equalizing or flash connections for ridding the system of air and vapors. The feed pumps will take water no matter how hot it is, if the pressure in the suction main is sufficient. Consider the water from a vacuum pan with a temperature of 280 deg. This high temperature is that corresponding to a pressure of 65 lb. gage and this pressure will certainly force the water into the pump, unless the pump happens to be too small for the work, so that it has to run at an abnormally high speed. In systems of this kind it is of great importance to have pumps of liberal size so that they can handle the water at slow speed.

Hot water mixing with cold water in a feed water heater is likely to cause pounding and unsteady action in general. For this reason it is better to mix them in a receiver of considerable volume with some vapor space in the upper part of it. The vapors forming in the top of the receiver may be released into the exhaust mains or into some heater where the heat from them may be utilized. To release these vapors into the atmosphere would, of course, make an open system of it.

Fig. 12 illustrates diagrammatically the feed water system used at the new Adeline sugar factory. There are four boiler feed pumps, three of which are of the automatic receiver type, the other without a receiver. There are two vacuum pans, the condensation from which is removed by two of these automatic receiver pumps. There are three raw juice heaters, though only two of them are in operation at one time, the third one being out for cleaning. One of these heaters operates with live steam and the other with exhaust steam. A large portion of the feed water naturally comes from these raw juice heaters. There are also two thin juice and two thick juice heaters, though only one of each is operated at one time under normal running conditions. Automatic receiver pump, number three, handles all of the condensation except that from the two vacuum pans. This includes condensation from the raw juice heaters, the thin juice heaters, the thick juice heaters, the steam engine separators, and the first bodies of the evaporators, also the drips from the high-pressure steam lines. Each of these different lines drain into a trap and the traps discharge through separate lines into the header above the receiver of pump number 3. The traps for the raw juice heaters are located on the ground floor below the level of the header, each trap having a live steam connection for discharging.

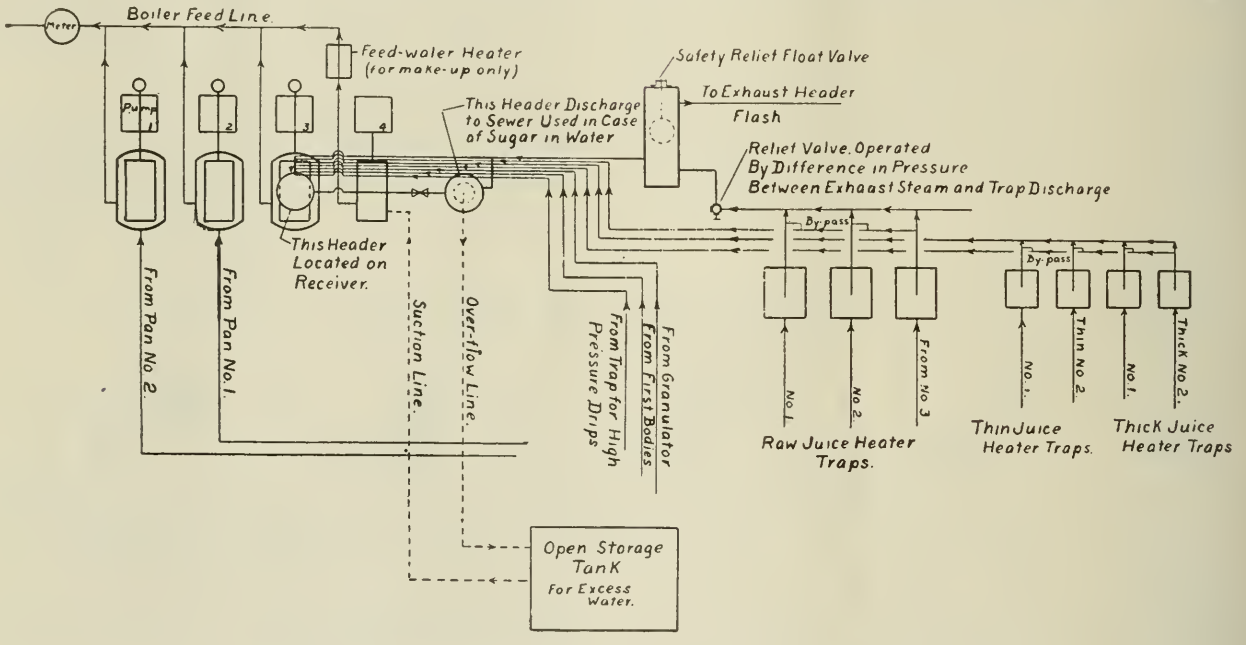

FIG. 12—SYSTEM FOR HANDLING CONDENSATION AT ADELINE SUGAR FACTORY

In order to provide for flash from the vapors coming from the condensation leaving the live steam raw juice heater a flash drum is provided as shown. The raw juice heaters are so connected that condensation from the exhaust heater can always be by-passed around the trap directly to the header. The condensation from the live steam heater passes through the relief valve into the flash drum and from there to the header, where it mixes with the condensation from other sources. From the top of this flash drum a flash connection is made to the exhaust steam mains. At one end of this drum there is an outlet with float-operated valve so that water cannot rise above a certain height in the drum. This prevents water from getting into the exhaust main. By means of this drum all disturbances of the kind mentioned above are prevented, the liberated flash being utilized along with the exhaust steam in the evaporators and other apparatus using exhaust steam. The make-up

feed water is handled by pump number 4, which draws from an open tank outside of the boiler room. The water in this tank is condensation coming from the second and third bodies of the evaporators. There is also an overflow into this tank from the header described above, which operates occasionally when the supply of condensation is greater than the boiler feed requirements at the time. This open tank in turn has an overflow into the sewer. The average temperature of feed water in this plant as found in a number of tests was about 216 deg. Fahr.

Fig. 13 shows another closed feed water system. In principle it is the same as that used at the Guanica Central in Porto Rico. In this case all of the condensation from different sources used for feed water is delivered to the boiler feed receiver, from which hand-controlled feed pumps deliver it to the boilers. The quadruple effects and the vacuum pans are situated some 40 ft. above the boiler feed receiver. From the top of the boiler feed receiver there is a vapor line connecting to the exhaust mains. In this line is a relief valve set at 15 lb. gage, so that there will be a pressure of 15 lb. gage in the receiver. The condensation from the vacuum pans is discharged by traps into an auxiliary closed receiver with a vapor connection to a feed water heater used for heating make-up feed water. The condensation is discharged by gravity into the boiler feed receiver. The condensation from live steam heaters is discharged by traps directly to the boiler feed receiver. As shown, the juice heaters using exhaust steam discharge their condensation by means of a trap to an open receiver. The pressure in the exhaust heaters is seldom much above atmospheric. The hot juice leaving the live steam juice heaters usually has a temperature of 220 deg.

On its way to the separators it is passed through eliminators, consisting in the main of closed drums with practically atmospheric pressure in them. The object of these eliminators is to remove and make possible the utilization of the heat in the juice above 212 deg. This heat passes off in vapors which mix with those from the auxiliary pan receiver and which are utilized in heating the feed water or in preheating juice just prior to the quadruple effects, also in heating scums in the mud tanks. This system works very satisfactorily, the average temperature of the boiler feed being about 227 deg. Fahr. There are no air locks and the system runs very smoothly.

The removal of condensation is also affected largely by the design of the vacuum pans themselves. The inclined tube sheets of Figs. 8 and 9 facilitate prompt drainage, the water being taken off from the lowest point. In large pans of this type there are generally three or four outlets.

In coil pans the length and diameter of the coil and its inclination to the horizontal has much to do with its drainage. With a coil of given diameter and steam pressure the amount of water that can flow out at its lower end is limited according to hydraulic law. Since the carrying-away capacity is proportional to the diameter, and the condensing power proportional to the length, the ratio of length to diameter is a controlling factor. It has often been stated that this ratio should not exceed 200.

Naturally a coil with steep inclination will drain better than a coil less steep—in fact, the steepness of the coil depends upon the length of coil in a pan of given size, a short coil giving a greater inclination than a long coil, equal drops considered. By reference to Figs. 1 to 4, inclusive, it can be readily seen that with a pan of given diameter a single coil would have approximately twice the length of a double coil, and four times the length of a quadruple coil, the angle of inclination being greatest in a quadruple, less in a double and least in a single coil. In pans of average size double coils are most common, quadruple coils being used in very large pans and single coils in very small pans.

Occasionally triple coils are used, branching on the inside in the manner similar to that shown in Figs. 1 to 4. Figs. 1, 2, 4 show two types of outlets for double coils. In the former there are two separate outlets—in other words, there would be a total of 12 outlets. In Fig. 1 the two coils are brought together with a single outlet so that there would be a total of six outlets. On general principles the double outlet arrangement is to be preferred. In the attempt to arrange for shorter coils the manifold coil pans shown in Figs. 5 and 6 have been designed. In Fig. 5 each manifold inside of the pan is divided into four

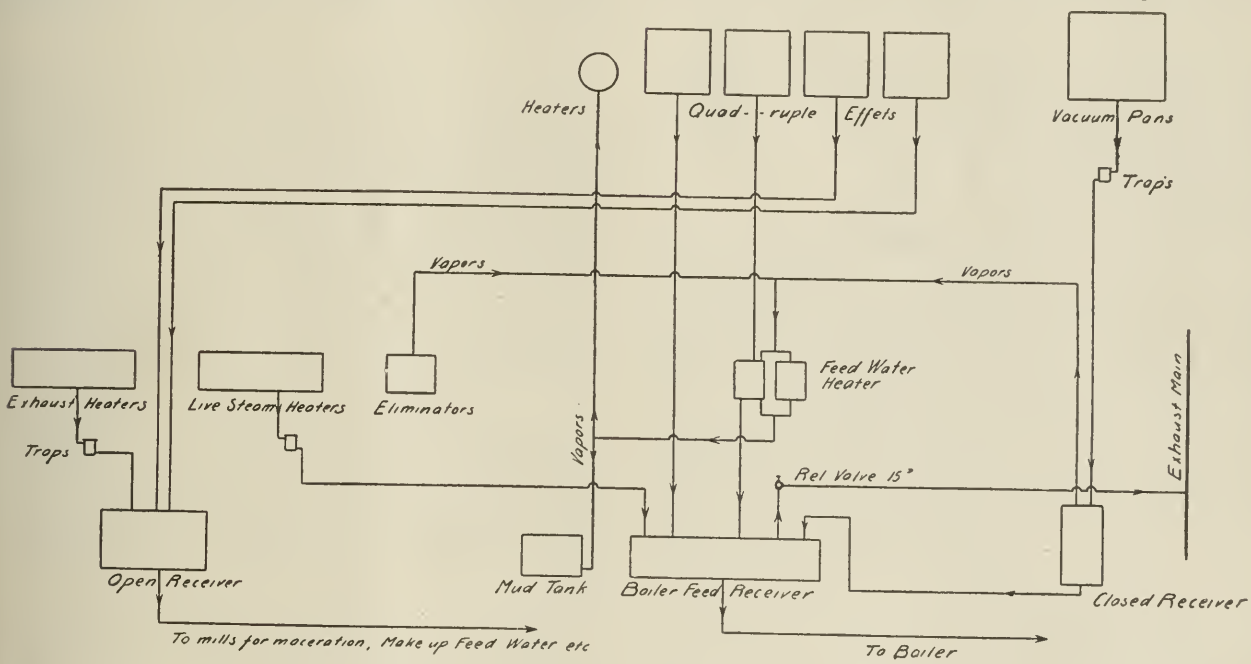

FIG. 13—SYSTEM FOR HANDLING CONDENSATION AT GUANICA CENTRAL

parts, so that steam makes a circuit through three coils, then two coils, then two circuits of one coil each, the condensation being led off from the lowest point of each manifold. As shown in Fig. 6, there is a steam manifold and a condensation manifold for each set of coils. The steam makes one circuit, no circuit being greater than the length of one coil.

DISTRIBUTION OF STEAM

Calandria vacuum pans differ from standard effects in that they seldom have circumferential distribution of steam. The steam is usually delivered directly to the tubes by the steam pipe which enters at one side. In very large pans the steam may enter in two pipes on opposite sides of the calandria. In coil pans the steam distribution depends entirely upon the location of the coils, the diameter of the coils and their distance apart. Naturally a better distribution can be obtained by making the coils small.

Some years ago a number of pans were built with two-inch coils, the spacing between coils being about two inches also. This was found to be an advantageous arrangement as regards heat transmission, but very objectionable as regards voiding the pan. With very stiff masscuite the pan could not be voided.

In modern coil pans in which the coils are usually 4 in. in diameter the spacing is generally about equal to the diameter of the coils—that is 3½ to 4 in.

FACTORS AFFECTING ECONOMY IN VACUUM PANS

The heat efficiency of vacuum pans depends altogether upon the loss due to radiation. However, the weight of steam required per unit weight of water evaporated is affected by the following factors:

Loss due to radiation.
Temperature of the syrup entering.
Pressure of the steam.
Temperature of condensed steam leaving.

In all vacuum pans the heating elements are surrounded by the boiling liquid which has a relatively low temperature—that is, the temperature corresponding to the vacuum under which the boiling takes place. The temperature drop from inside to outside is, therefore, small, hence the radiation loss should be small.

The amount of this loss will, of course, depend upon whether the radiation surfaces are covered with heat insulation or not and upon the kind of covering used. An approximate calculation of Professor Kerr shows 0.6 per cent loss for a 10 ft. coil pan boiling under normal conditions without covering, 0.15 per cent when entirely covered and 0.36 per cent with the cylindrical part of the shell covered, the dome and catch-all being uncovered. In each case the loss is based on the total heat delivered in the steam.

Naturally the radiation loss will be less for a strike of given size when it is boiled quickly than when boiled slowly. For this reason pans are usually less efficient from the heat standpoint when boiling low grade products than when boiling high grade products. Calandria pans with their greater amount of heating surface and more rapid circulation should be more efficient thermally than coil pans because of the shorter time required to boil.

The work of a vacuum pan consists of two parts—namely, heating the entering syrup up to the boiling point and evaporating. Naturally the lower the temperature of the syrup entering the more steam will be required for heating it up to the vaporization point.

The pressure of the steam and the vacuum affect the weight of steam required per pound of water evaporated due to the effect of latent heat. For example, assume a steam pressure of 60 lb. gage with corresponding latent heat of 899 and a vacuum of 26 in., with corresponding latent heat of 1026. In this case $1026 \div 899 = 1.085$ lb. of steam will be required to evaporate 1 lb. of water from the juice in addition to that required for heating. With high steam pressure a larger weight of steam would be required due to the reduced latent heat, and vice versa.

In calandria pans there may be a small loss in venting the incondensable gases, though this will be practically negligible. In coil pans there may be a considerable loss due to leakage of steam, especially where check valves are used and the steam is allowed to blow through to the atmosphere. Pan operators like to do this, because the current of steam thus set up in the coils results in increased heat transmission and capacity. It is evident, however, that this can be done only at the expense of economy. The same result may be brought about by leaky traps. It has been found in practice that much attention has to be given to traps to prevent the valves from leaking, especially if they are not of the best construction. Unfortunately, it is difficult to determine these leakage losses by tests for the reason that the steam thus lost cannot be measured, the steam consumption being determined by weighing the condensation. If the condensation is removed immediately after it forms, its temperature will be practically the same as that of the steam before it condenses. If it remains any length of time after condensing, its temperature will be reduced and this will result in decreased steam consumption for a given amount of evaporation.

Tests of Vacuum Pans

A very extended series of tests were made by Professor Kerr and his co-workers with a view of obtaining data regarding heat transmission and economy under regular operating conditions, for different types of pans, with varying grades of product. Twenty-three pans were tested in all. As to the arrangement and details of the tests the reader must be referred to the original publication. (An interesting account of a vacuum pan test of this kind with heat balance was given in an article specially written for this journal by Professor Kerr, in our issue of February, 1914, Vol. XII, p. 81.)

COEFFICIENT OF HEAT TRANSMISSION

The capacity of a given vacuum pan will depend upon the coefficient of heat transmission, the time the heating surface is on in per cent of the total time of boiling the strike and upon the temperature fall, the latter being affected materially by the increase of boiling temperature due to head and density, etc., which has been discussed.

The ability of the heating surface to transmit heat from steam to boiling liquid is directly proportional to the coefficient of heat transmission. It was calculated by dividing the total heat transmitted by the actual temperature difference and by the average time the total heating surface was working. The actual temperature fall was obtained by subtracting the temperature of boiling from the temperature of the steam.

In making the tests careful data were kept regarding the time when steam was turned on each coil, so that the actual time each coil was working could be estimated. The sum obtained by adding the time the coils operated, divided by the number of coils, gave the average time the total heating surface operated. This divided by the time of a strike and multiplied by 100 gave the actual time of the total heating surface in operation in per cent of the total time of the test. Evidently it would not be fair to charge the heating surface with the total time of the strike. The average time the total heating surface was on varied from 56 per cent to 83.9 per cent of the time of the strike, the average being 76 per cent.

This shows the great variation in capacity which may result from different methods of handling steam in the different coils as practiced by different sugar boilers.

Figures are given of the apparent and actual weight of water evaporated per square feet of heating surface per hour, the apparent weight being based on the total time of the strike in each case, and the actual weight on the actual average time the heating surface was working. The apparent weight of water evaporated varied between 6.48 and 20.35 lb. per sq. ft. per hour, the actual weight between 9.55 and 27.3 lb. But even the actual weights of water evaporated are not a fair unit for comparison because the steam pressure and the vacuum varied in the different tests. Thus, after all, in these tests the coefficient of heat transmission is the only fair and absolute measure of the heat-transmitting ability of the heating surface.

The figures for the coefficient of heat transmission (in B.t.u.'s transmitted per square foot of heating surface per hour per degree Fahrenheit difference in temperature of the two sides of the heating surface) varied in the different tests between 45 and 174.8. The average coefficient for the coil pans with straight strikes, omitting tests 19 and 20, is 110, varying from a minimum of 76.28 to a maximum of 174.8. The average time since cleaning was three days—in fact, in nearly all cases the heating surface may be considered to have been in fairly good condition. The best three tests on coil pans—namely, 21, 22 and 23—gave coefficients of 134.5, 124.3 and 174.8 respectively—in fact, these were much higher than the others and raised the average considerably. Without them, the average coefficient would have been 95. These three tests represent the three principal methods for removing condensate—namely, check valves with single trap, automatic receiver pump and adjustable check valves. The high coefficients obtained with these different arrangements show that either of them when properly installed and operated will give good results.

The highest coefficient, 174.8, was obtained with the shortest average length of coil—that is, with a ratio of 118. Doubtless this has much to do with the fine result obtained. Tests 21 and 22 also were made on pans with relatively short coils, which were well drained and in which the heating surface was clean. With so many varying conditions, the effect of some of which it was impossible to measure, it is impossible to form definite conclusions as to the varying results obtained in the different tests. The highest ratio of length to diameter of coil was 294. Although there is no definite relation between this ratio and the coefficient of heat transmission it is evident that the length of the coil had much to do with the variation of the coefficients obtained.

Tests 1, 2 and 3, giving heat transmission coefficients of 111, 88.3 and 45 respectively, were made with straight, mixed and crystallizer strikes with greatly varying purities and give some very conclusive and interesting data regarding the effect of varying kinds of product upon the coefficient, since these three tests were made upon the same pan and under conditions practically the same.

TEMPERATURE OF BOILING

The increase of boiling temperature due to hydrostatic head, density of liquid, and purity of liquid, has been discussed before. In these tests the temperature rise varied from a minimum of 11.9 to a maximum of 27.5 deg., the average being 19.7 deg. The minimum rise was obtained with the Express pan (Fig. 9), and the maximum with a 10-ft. coil pan. The average temperature rise in the three tests on the Express pan was only 12.9 deg., which is considerably less than that obtained in the coil pans. This is doubtless due to the reduced height of pan, also to the better circulation. At the beginning of a strike both the hydrostatic head and the density were smaller than at the end of the strike, there being a gradual increase from beginning to end. Naturally, therefore, the temperature rise of the boiling point increases toward the end of the strike.

Curves given in a diagram of the report show very clearly the effect of purity upon the temperature rise, the rise at the end of the test being 20.5 deg. for the straight strike, 27½ deg. for the mixed strike and 31 deg. for the crystallizer strike. The capacity of a pan decreases with the purity, not only because of the low coefficient of heat transmission, but because of the reduced temperature fall due to rise of the boiling point as well. In each of the curves there is a gradually increasing distance between the curve representing temperature of boiling and that representing temperature corresponding to vacuum.

COIL VS. CALANDRIA PANS

From the data given in the report it will be seen that the average coefficient of heat transmission in the Express pan tests was 40 per cent greater than the average coefficient in coil pans. The rise in temperature of boiling due to hydrostatic head, density and purity was also shown to be less in an Express pan than in the coil pans, which is also an advantage in that the smaller the temperature rise the greater the temperature fall for a given steam pressure. This means, of course, that there is a corresponding increase in capacity.

It may be well to state also that the amount of heating surface in the Express pan tested could be doubled by placing another calandria above the existing one. This, however, would require increasing the height of the pan.

The greater coefficient of heat transmission in the Express pan is doubtless due to the more rapid circulation and the more efficient removal of condensation, the latter being due partly to the sloping tube sheets and inclined tubes.

The test on the plain calandria pan shows a coefficient of only 58.38, which is very poor. This test was made with good syrup, but with steam having a pressure only slightly above that of the atmosphere. The reason for the very low coefficient is probably in the fact that the calandria was not properly voided of condensation. The condensation was removed by means of a steam pump; the outlet for condensation was 1½ in., though this was reduced to ¾ in. This is evidently too small. For these reasons the results of this test can not be taken as representative of the type.

RATE OF VAPOR FORMATION

Designers of vacuum pans and accessory apparatus frequently need information regarding the rate at which vapor is formed in vacuum pans during different intervals of time in the boiling of a strike. Such data are of especial value in calculating the dimensions of condensers and vapor pipes. Some tests were made with this problem in view.

At first thought it would seem that the rate of steam condensation would be sufficient for this purpose. It should be remembered, however, that part of the steam condensed is used for heating and a curve plotted with time against rate of steam condensation might not have the same shape, as one with time plotted against water vaporized.

In order to determine the weight of water evaporated during successive time intervals of a strike it was found necessary to measure the weight of the hot well water. This was done by means of a weir in connection with a Hook gage. Knowing the weight of water for each successive interval of time the heat delivered to it during that time could be determined from its initial and final temperatures. This, divided by the heat of vaporization corresponding to the vacuum in

the pan for that interval, gives the weight of water evaporated.

This method was carried out in one test and the result, plotted diagrammatically, shows that for all practical purposes it may be assumed that the rate of vapor formation is proportional to the rate of steam condensation. As the curve in question is practically a straight line, the rate of steam formation during successive intervals is practically the same as the average rate—in other words, the velocity of vapors in a coil pan may be assumed to be the same at all times during a strike.

HEAT BALANCE

Finally the steam consumption was measured in eight of the tests and the heat balance determined for the same tests. There is some uncertainty in the heat-balance calculations on account of the fact that the figures for specific heats of sugar solutions, used in the calculations, are uncertain. The total heat entering, minus the heat leaving in the condensed steam is termed the "available heat." The heat actually used in evaporation, divided by the available heat and multiplied by 100, is designated as efficiency.

The efficiency figures vary from 90.9 to 96.95 per cent, with the exception of one test in which it comes out as more than 100 per cent. The results of these tests do not show any difference in economy for coil and calandria pans.

It was thought that the temperature of the condensed steam leaving might be nearer that of the steam in calandria pans than in coil pans. Observations, however, seem to show practically no difference in this respect.

An average from three tests on the Express pan showed a temperature of condensate 15.3 deg. lower than that corresponding to the steam pressure. The average temperature of condensate from coil pans was 16 deg. less than that corresponding to the steam pressure and varying from 11.7 deg. to 21.3 deg.

Vanadium from Oxide to Steel

BY WARREN F. BLEECKER AND WALTER L. MORRISON

The ores from which ferrovanadium is produced and the processes of extracting the vanadium salts and oxides therefrom are so generally known that it is unnecessary to discuss them here. They are only of importance in determining the cost of raw oxides or vanadium salts and the cost in every case would be independent of the method of reduction.

The processes of making ferrovanadium from the raw salts and oxides are limited, and there are but two known reducing agents which may be used for the production of ferrovanadium on a commercial scale: aluminium and silicon.

Aluminium is the one most used and is the less desirable. Any process wherein aluminium is used as a reducing agent for vanadium is but a variation of the Goldschmidt thermit process.

When the aluminothermic process is carried on strictly as an exothermic reaction, there is one certain evil, and the choice of one of two others. First, the quantity of aluminium necessary for reduction is much greater than the theoretical amount. Secondly the recovery of vanadium will either be low or there will be found too much aluminium in the resulting alloy. A further objection to this process is that there is no opportunity for refining the alloy, in case there are objectionable elements present.

These difficulties may be done away with by carrying the reaction on in an electric furnace. The raw oxide or vanadate may even be partially reduced with carbon before the final treatment with aluminium and by properly treating the reduced alloy with slags, the refining may be carried to any required degree. It is, of course, understood that if the impurities are base metals there is no hope of removing them in the electric furnace.

The better process of making ferrovanadium is by reduction with silicon. Silicon may be had at a cost of about one-third that of aluminium and its theoretical oxygen value is higher by 25 per cent. In heat units the advantage is with aluminium.

The reaction between vanadium pentoxide and silicon is not quite self-propagating. In the electric furnace, however, the reaction is very brisk and very satisfactory.

As with aluminium, it is not possible to obtain at the same time and in one operation a high vanadium recovery, high silicon efficiency and a low silicon content in the resulting alloy. In two electric-furnace operations these three very desirable conditions may be had at a very small additional expense. We have never succeeded in doing this in one operation, although if an alloy containing 4 or 5 per cent of silicon were desired only one operation would be necessary.

In the commercial application of vanadium to steel there are several factors which determine the cost and to a large extent the cost of the contained vanadium in steel determines what classes of steels will stand the expense of the vanadium addition.

The important factors in determining the cost of vanadium per ton of steel is as follows:

The cost of the raw ore per pound of vanadium contained.

The cost of the raw oxide per pound recovered.

The grade and character of the raw oxide.

The cost of reduction per pound of vanadium recovered.

The efficiency of the reduction process.

The efficiency of the alloy added to steel.

In our present discussion we are not concerned with the first two items. They are of the utmost importance, but they are constant factors whatever the subsequent procedure.

The grade and character of the raw oxide is important, because, as will appear later, the presence of base metals, such as iron, will be a source of greater expense in one case than in the other.

The efficiency of the aluminium thermit process is known only to those who are using it on a large scale. The best we have been able to do under the most favorable conditions, and using a good grade of oxide, is around 70 per cent recovery. Under these conditions there will remain in the finished alloy between 1 and 2 per cent Al.

Using the electric furnace the efficiency may be raised to 90 per cent recovery with 1.2 lb. Al per lb. V recovered. The resulting alloy will contain what we call a trace of aluminium, under 1 per cent carbon and less than 2 per cent silicon.

Using silicon as a reducing agent, the efficiency will be about 85 per cent recovery, with 1.25 lb. Si per lb. V recovered. The resulting alloy will contain less than 0.30 C., trace of aluminium, and 4-5 per cent Si. This silicon may be brought under 1 per cent by a second operation.

The reduction cost per pound V recovered we are at present not at liberty to divulge, but with furnace upkeep, electrode consumption, energy, fluxes, labor, overhead, etc., while very heavy, it still allows a very great saving over processes of reduction in which electric energy is not used.

The recovery of vanadium from ferrovanadium to finished steel castings probably averages 70 or 75 per cent.

If we assume all of the above data to be correct we may arrive at the average recovery from the raw oxide to the steel and knowing the market price of vanadium we may determine the cost per pound V in steel.

Taking the average efficiency of silicon reduction by multiplying by 0.75, we arrive at the value 63.75, which means that the higest recovery we may expect is in the low sixties.

This value further means that a pound of vanadium in steel requires one and two-thirds pounds of vanadium as oxide, and at a value of $2 per pound as alloy, costs $2.66.

Vanadium pentoxide contains 56 per cent metallic vanadium. One pound of vanadium in steel, therefore, required 2.96 lb. of oxide, which 15 per cent was lost in reduction, and over 20 per cent lost in the addition to steel.

It is evident, therefore, that if vanadium oxide could be added directly to steel, with a high efficiency, the cost of reduction and the loss in efficiency might be greatly reduced with a benefit to both the alloy manufacturer and the steel maker.

Vanadium may be introduced directly into steel, cast iron or any ferrous alloy from the pentoxide. The method of doing this is very simple and economical, and as will be seen by referring to the analytical data the recovery is excellent.

If a quantity of a vanadium compound, such as calcium vanadate, be thoroughly mixed with a small quantity of iron scale and sufficient silicon to allow an excess of 10 per cent above the theoretical quantity, there will result a mixture, which when added to molten steel, will introduce vanadium into steel efficiently and without appreciable segregation.

Any vanadium compound may be used instead of calcium vanadate and aluminium may be used instead of silicon.

Upon further consideration of this reaction several very desirable advantages will be apparent.

Although, as stated above, the reaction between vanadium pentoxide and silicon is not self-propagating, it is exothermic. The only heat necessary, therefore, is that required to fuse the lime which is added to insure a complete separation of the reduced vanadium from the resulting slag. The addition of vanadium in this manner, so far as chilling the metal is concerned, is equivalent to adding alloy in the molten state.

It is possible in this manner to provide an additional agent of absolute uniformity, not only in grade, but in composition as well.

This exothermic mixture may be added to all classes of ferrous metals at any stage, with the assurance that the vanadium will be effective and will be uniformly distributed throughout the metal.

The electric furnace is particularly useful in carrying on this reaction, the recovery being as nearly perfect as it is possible to hope for.

It is not necessary to carry on any subsequent slagging operations and the vanadium mixture may be added without removing or otherwise disturbing the slag or any other normal working condition.

In certain alloys, as with many crystalline substances, the solution takes more readily at the time of the formation of the compound than after the compound has cooled and assumed a solid state. This condition apparently exists upon addition of the exothermic vanadium mixture to steel, with the result that a high vanadium recovery and a uniform distribution of vanadium takes place.

The melting point of vanadium alloys varies with several things outside of the vanadium content. The presence of carbon raises the melting point rapidly, while alminium and silicon tend to lower it.

In adding this exothermic vanadium mixture to the open hearth, the amount of silicon can be increased to take care of the iron oxide. In this case the iron oxide may be wholly or in part omitted from the mixture, since the function of this material is to afford a medium in which the vanadium is instantly soluble—otherwise the reduction would be very incomplete and the recovery low. The oxide of iron is simultaneously reduced and a very rich vanadium alloy is formed, which is further dissolved throughout the molten steel.

On the other hand, in crucible melting the quantity of silicon may be decreased on account of the highly reducing conditions which exist at the time of the addition.

An examination of the results obtained when treating cast iron will reveal the fact that the reaction begins at a relatively low temperature.

Some interesting results were obtained while experimenting with aluminium as a reducing agent in the exothermic mix.

The reaction proceeded with more violence than when silicon was used, as might have been predicted. The resulting slag, which was high in alumina, was not sufficiently fluid at the temperature of the molten iron and consequently did not allow the vanadium to act as efficiently as it would otherwise have done.

The metal was poured from the cupola into a 600-lb. ladle, the alloy added and the iron poured. The metal to which the aluminium was added purged badly from every flask, large and small. The plain metal did not purge, nor did that to which the silicon mixture was added.

The addition of vanadium to cast iron in the ladle did not seem to give the castings any additional strength or other desirable properties, although no physical tests were made upon the bars.

Vanadium added to cast iron melted in the electric furnace, the silicon mixture being used, gave the bars a very dense structure, while the strength and hardness were apparently unaffected. No tests were made beyond breaking the bars.

MATERIALS

The following materials were used in making the exothermic mixes:

Calcium vanadate,	24.3	per cent	V_2O_5
Vanadium oxide,	83	per cent	V_2O_5
Iron scale,	70	per cent	Fe.
Aluminium,	99	per cent	No 30 shot.
Silicon,	85	per cent	Si.
Lime,	85	per cent	CaO.

Mix A.

10 lb. calcium vanadate.
4.7 " aluminium.
10 " vanadium oxide.
1 oz. mix = 0.243 oz. V, or 0.0152 lb. V.
1 lb. mix = 0.243 lb. V.

Mix B.

10 lb. calcium vanadate.
9.2 " silicon.
10 " vanadium oxide.
1 oz. mix = 0.206 oz. V, or 0.0128 lb. V.
1 lb. mix = 0.206 lb. V.

Mix C.

100 lbs. iron scale.
21.4 " silicon.
1 lb. mix = 0.573 lb. Fe, or 9.2 oz. Fe.

The following steels were made in a small arch furnace lined with magnesite. In each case the boiler punchings were used, these being melted under a neutral slag.

The chromium was added as 60 per cent ferrochromium, the silicon as 85 per cent ferrosilicon and the manganese as 50 per cent ferromanganese.

With but one or two exceptions the steels poured quietly, without purging and the castings were apparently solid.

The vanadium mixture should be added to the electric furnace just before pouring into the ladle in order to get the best efficiency. In pouring larger quantities of steel it is probable that the vanadium could be added in the ladle, although if added in the furnace we are more certain of avoiding segregation.

In case the vanadium silicon mixture does not contain iron oxide, segregation takes place to such an extent that the analyses are not dependable.

100 lb. steel, 5 lb. chromium, 1 lb. 15 oz. silicon, 6 oz, ferromanganese, 4 oz. ferrosilicon, with 19 oz. Mix B and 7 oz. Mix C, yielded steel A 800, containing 0.36 V, 1.19 Si, 1.53 Cr, and 0.70 Mn.

100 lb. steel, 4 oz. ferrosilicon, 6 oz. ferromanganese, 1 lb. 10 oz. ferrochromium with 19 oz. Mix B and 7 oz. Mix C yielded steel A 803, containing 0.08 V, 0.09 Si, 0.92 Cr, and 0.18 C.

100 lb. boiler punchings, 4 oz. ferrosilicon, 6 oz. ferromanganese, with 19 oz. Mix B and 7 oz. Mix C yielded steel A 804, containing 0.20 V, 0.07 Si, 0.10 Cr. and 0.19 C.

100 lb. steel, 1 lb. nickel, 5 oz. ferrosilicon and 4 oz. ferromanganese, with 19 oz. Mix B and 7 oz. Mix C yielded steel A 806, containing 0.08 V, 0.28 Si, and 0.25 C.

50 lb. steel with 11 oz. vanadium-aluminium-thermit (0.3 V) (thermit in cartridge) yielded steel A 1086, containing 0.29 per cent V.

100 lb. steel, 1 lb. silicon (50 per cent), ½ lb. manganese (80 per cent) and 19 oz. Mix B gave A 1193, containing 2.4 per cent Si and 0.29 per cent V.

100 lb. steel turnings, 1 lb. silicon (50 per cent), ½ lb. manganese (80 per cent) with 19 oz. Mix B and 7 oz. Mix C gave A 1195, containing 1.10 per cent Si and 0.28 per cent V.

100 lb. boiler punchings, 3 lb. 12 oz. nickel, 6 oz. ferromanganese, 4 oz. ferrosilicon and 1 lb. 13 oz. ferrochromium, with 19 oz. Mix B and 7 oz. Mix C, gave A 794, containing 1.32 per cent Cr, 0.20 per cent C and 0.33 per cent V.

100 lb. steel, 6 oz. ferromanganese, 4 oz. ferrosilicon, with 19 oz. Mix B gave A 798 containing 0.22 per cent V.

100 lb. boiler punchings, 4 oz. ferrosilicon, 6 oz. ferromanganese, with 10 oz. Mix B, and 7 oz. Mix C and 1 lb. 10 oz. ferrochromium (67 per cent Cr.) gave A 802 containing 1.31 per cent Cr., 0.22 per cent C, 0.19 per cent Si, and 0.23 per cent V.

50 lb. cast-iron scrap, with 8 oz. Mix B and 4 oz. Mix C, gave A 1090, containing 0.09 per cent V.

50 lb. cast-iron scrap, with 8 oz. Mix B and 4 oz. Mix C gave A 1091, containing 0.11 per cent V.

50 lb. cast-iron scrap with 4 oz. Mix B and 2 oz. Mix C gave A 1088, containing 0.23 per cent V.

50 lb. cast-iron scrap with 4 oz. Mix B and 2 oz. Mix C, gave A 1089, containing 0.18 per cent V.

Cast-iron bars made at Washington, Pa.:

A 1092	0.048% V	2.14% Si
A 1093	0.032	2.32
A 1094	0.027	2.26
A 1095	0.03	2.11

Charges A-1088 and A-1089 were made in the eletcric furnace and the vanadium added before pouring the cast iron into the ladle. It will be seen in this case that the efficiency is very high.

The samples A-1092 to A-1095, inclusive, were the result of adding the vanadium mixture to cast iron in a 600-lb. ladle, as the metal came from the cupola. It will be seen that while the efficiency is very low the temperature of the cast iron was sufficient to ignite the vanadium mixture and cause the reaction to proceed.

It must be concluded that vanadium may be added to steel, in the form of oxide, when mixed with a proper reducing agent and slagging elements.

It is further apparent that this process will result in the saving of the cost of reducing the vanadium in the production of the ferro-alloy.

Starting with a given quantity of oxide, we may expect, by this process, to find more vanadium in the steel than in case we introduce the intermediate step of making ferrovanadium.

American Electrochemical Society

The San Francisco meeting of the American Electrochemical Society will be held from Thursday to Saturday, Sept. 16 to 18, 1915. Friday, Sept. 17, will be devoted to joint sessions in the morning with the American Institute of Mining Engineers and in the afternoon with the American Institute of Electrical Engineers.

American Chemical Society

The next meeting of the American Chemical Society will be held at Seattle, Wash., from Monday to Thursday (Aug. 30 to Sept. 2). The schedule of the special train was given on page 419 of our July issue. The headquarters at Seattle will be at Hotel Frye, corner Third avenue and Yesler Way.

On Monday night, August 30, the council dinner will be held.

On Tuesday morning the first session will be opened by an address of welcome by Henry Suzzalo, president of the University of Washington, followed by the response by Charles H. Herty, president of the American Chemical Society. Dr. Leo H. Boekeland will then lecture on Chemical Industry, and Dr. H. K. Benson will speak on Industrial Resources and Opportunities of the Pacific Northwest.

In the afternoon the symposium of the Industrial Division, devoted to the influence of chemistry in various industries (which had been begun at the New Orleans meeting) will be completed. Papers will be presented by G. W. Sargent and A. S. Cushman, on iron and steel; by Alvis von Isakovics and E. T. Beiser, on perfumery; by G. W. Thompson, on lead; by Maximilian Toch, on paints and varnishes; by David T. Day, on petroleum, and by Sidney Mason on illuminating gas. A symposium will also be held on wood distillation.

In the evening a complimentary smoker will be given by the Seattle Commercial Club.

On Wednesday division meetings will be held during the day, and in the evening Dr. Charles H. Herty will present his presidential address.

For Thursday an excursion on Puget Sound is scheduled, and for the evening a subscription dinner.

The **Tyneside Alloys Co., Ltd.**, is a new British company operating at Pelaw, Newcastle-on-Tyne, for the manufacture of tungsten and molybdenum powders. The plant is open to purchase and treat all kinds of stanniferous tungsten ores and leady bismuth-molybdenum ores. The plant is under the management of Mr. William Jones, who formerly represented Mr. John Hays Hammond in Brazil.

Blast-Furnace Plant Auxiliaries and General Arrangement

BY J. E. JOHNSON, JR.

(*Concluded from page* 439)

The General Arrangement of Furnace Plants

In early days blast furnaces were very generally built singly, plants of two were scarce, and a greater number than that in charcoal practice were almost unknown. But as the world's consumption of iron has gone up the number of furnaces per plant has increased almost as rapidly as the tonnage per furnace, there being two in the United States with eleven, many of six and seven, and probably only a small portion of the total furnaces are single furnace plants. This fact has modified the general design of plants fundamentally. It is obvious that when a furnace stands alone the different elements of the plant as a whole may be arranged in almost any relation to one another, but when two or more are grouped together it is plain that their raw materials should come in by a means of transportation common to all, and that their output should be similarly taken away. Also that labor can be saved by grouping certain components of the equipment of each furnace together, notably the blowing engines, boilers and stoves. The first two can be supervised by the same men, and the third sometimes is. In considering the arrangement of furnace plants, therefore, we need scarcely to consider plants of less than two furnaces, because as stated above the equipment of the single furnace can be arranged in almost any reasonable way and meet the conditions fairly well.

On account of the enormous quantities of materials handled it is obvious that the best possible arrangement of the railroad tracks must be at the basis of any proper design, and all multiple furnace plants for many years past have virtually had the stock houses for all the furnaces in common, all being served by the same set of tracks. These for obvious reasons are made straight except in rare circumstances, and should always be so. This virtually forces the furnaces to be built in a straight line parallel to these stock house tracks.

The next points in the design involving the handling of a heavy tonnage of material are the casting arrangements and the cinder pits, and here it took us many years to reach a sensible design. Probably the greatest defect of all our designing is a tendency to put every part of the design either at right angles with or parallel to the next element, and plants have in general been laid out with their parts at right angles with or parallel to the other parts. The fact which seems to have escaped observation is that railroads do not run around right angles, and therefore with one part of the plant at right angles to another if the first were parallel with the tracks, the second must be at right angles to them, and therefore relatively inaccessible. In spite of this the line of the cast house was for many years built at right angles with the line of the stock house tracks, and in order to bring cars alongside the cast house to permit the direct loading of pig iron these tracks all had to make a sharp right angle turn. What is even worse is that, as the curves practically must all be laid down from the same direction they could turn to a tangent along the near side of the cast house wall, but could only approach it with great difficulty on the far side, a very disadvantageous condition.

A little careful consideration will show that there is no fundamental reason why the cast house should be at right angles to the stock house tracks, and when the first pair of Lorain furnaces were built an attempt was made to evade this difficulty by turning the cast houses toward one another, so making them parallel to instead of at right angles to the stock house tracks. This somewhat increased their accessibility, but took up much room, since obviously the two furnaces were more than the length of both cast houses apart.

Various modifications of the right angle plan were used, but without reaching any design which met the conditions satisfactorily. When designing the plant of the Federal Furnace Company of Chicago, Julian Kennedy adopted a plan which will undoubtedly be more and more used, though often in modified form, as time goes on. Fig. 11 shows a ground plan of these works on which the names of the different parts are clearly marked so that the arrangement is easily comprehensible. It is obvious from this plan how easily all parts of the plant are reached by railroad tracks with short and easy curves, and it will be equally obvious on a little reflection that if the cast houses had been placed at right angles to the line of the stock house trestles, in the old-fashioned way, their four sides in particular would have been almost inaccessible to railroad tracks within the yard limits available.

A further development of this idea took place when the Gary plant of the Indiana Steel Company was designed. A small scale plan of this plant reproduced from "The Iron Trade Review" is shown at Fig. 12. The scale is so small that some study is necessary to distinguish the different parts, but this can be done with a little pains.

In this case the cast houses were turned to an angle of about thirty degrees with the center line of the row of furnaces. The angle of the skip was made flatter and the base of the skip bridge further from the base of the furnace than in the Federal design so that tracks could be run along between the under side of the skip bridge and the foundation of the furnace itself, which greatly increases the accessibility of all parts of the plant to railroad tracks. These tracks underneath the skip communicate with the other tracks in front of the furnace by ladder tracks between every second pair of furnaces which run through diagonally on the same angle as that of the cast houses. These tracks serve not only the cast houses, but the dust-discharges of the different dust catchers as well. In this case each pair of furnaces becomes a lozenge shaped island in a wide river of tracks, with practically every part of the plant within easy reach of at least one track. It is seldom wise to prophesy finality in any technical matter, but the general principle of this design is so nearly perfect that it seems likely that it will eventually come to be the only plan considered for multiple furnace plants, but, of course, modifications to suit individual conditions or changes in the component parts of the plant may be made in every case.

The Distance of the Furnaces Apart

This is controlled by various circumstances. When the ore supply for the large part of a year has to be stocked that becomes one of the controlling factors because the cost of ore bridges increases very rapidly with their length, and commercially their practical length is limited on this account, as also by the great time required to traverse the trolley from one end to the other of a long bridge. The height of the ore pile is limited by considerations affecting the cost and strength of retaining walls at the sides of the stock pile, and the slope which the ore takes running back from them. The pile is thus limited in two dimensions, and in order to store a given tonnage of ore the required volume must be obtained by making the length of the

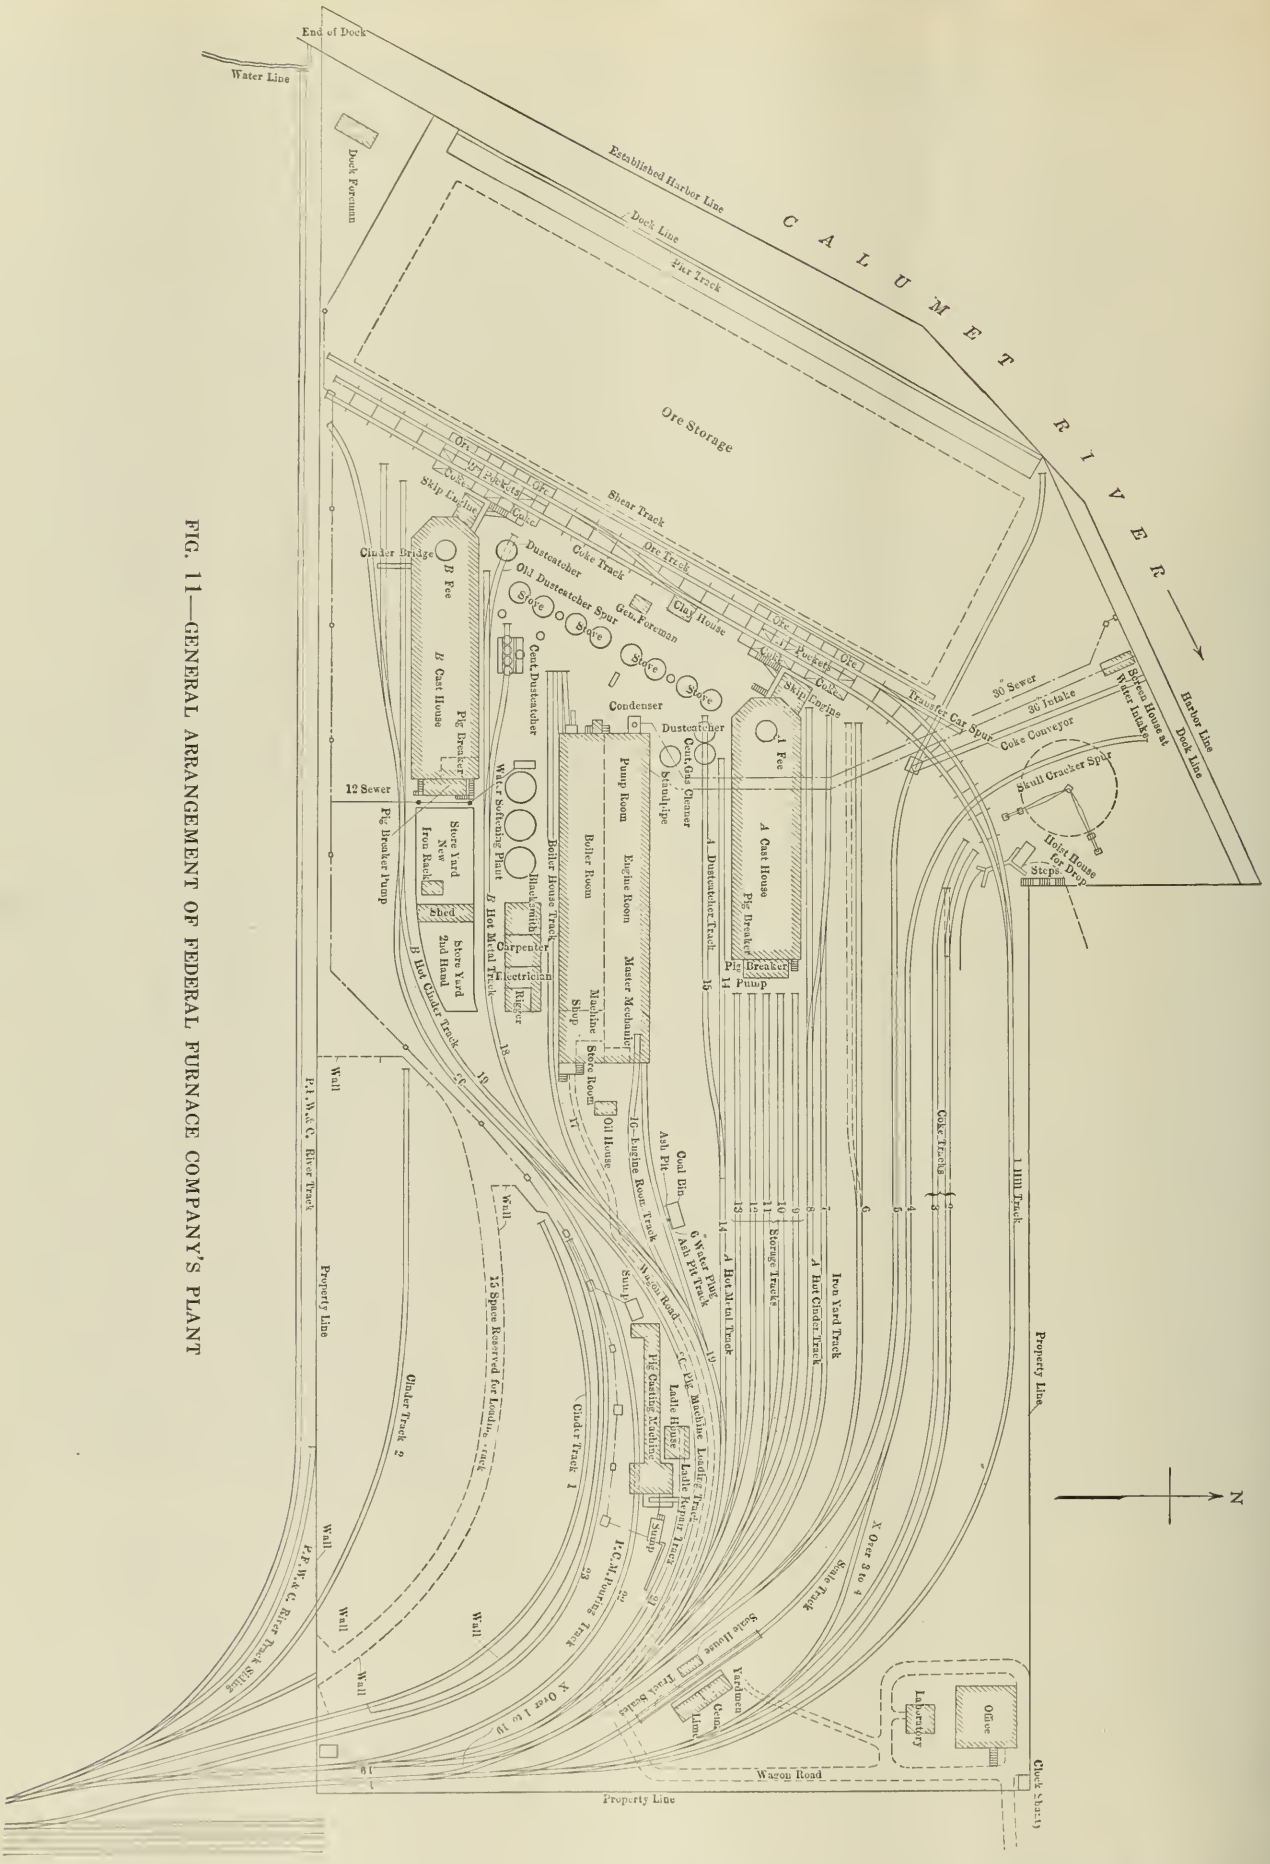

FIG. 11—GENERAL ARRANGEMENT OF FEDERAL FURNACE COMPANY'S PLANT

pile per furnace as great as is necessary, and this length is obviously the minimum distance between furnaces, for those conditions.

There are many other considerations affecting the spacing of the furnaces, however, especially in those cases where considerations of the size of the stock pile

do not control them. It is very undesirable to have the furnaces crowded together as it is more difficult to work around them under those conditions, more danger is likely to be done to one furnace by an accident at another, and questions of accessibility of various kinds arise which it is practically impossible to provide for in detail in advance, and which can only be met satisfactorily by having a certain amount of room around each furnace.

On the other hand, it is undesirable to have them spaced too far apart on account of the initial expense of land, tracks, etc., and such spacing not infrequently defeats its own ends by offering a temptation to put something into the unoccupied space, another furnace or some other part of the plant. This has happened on more than one occasion. The supervision of furnaces is also more difficult when they are scattered over too wide a territory. One blower can frequently blow two furnaces if they are spaced close together, but would not be close enough to the work to manage two located very far apart. When the stoves for each of a pair of furnaces are arranged in a continuous row as shown in Fig. 11 this in itself controls the minimum distance of the furnaces apart, as it virtually does at that plant.

Furnaces are very generally arranged in pairs, rights and lefts, as shown in Fig. 11, and more clearly shown in Fig. 13, which illustrates the arrangement of a pair of furnaces with their stoves, gas mains, etc., in some detail. On the other hand, at one of the best built and most successful plants the plan was adopted of having the furnaces all built the same "hand," that is to say, looking at the plant from the front, the stoves are all on the left hand side of their respective furnaces.

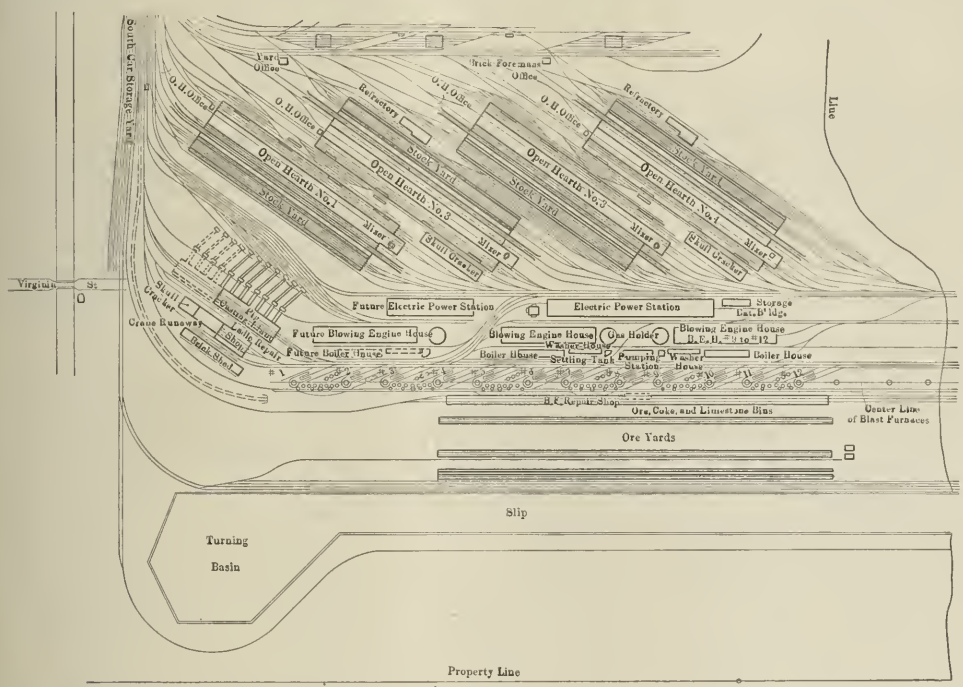

FIG. 12—GENERAL GROUND PLAN AND TRACK LAYOUT FOR THE PLANT OF THE INDIANA STEEL COMPANY AT GARY, IND.

One of the advantages of the pair arrangement is that it makes the distance between furnaces alternately very short and quite long. The close grouping of one pair of furnaces is an advantage since that is about the limit of what a single blower can supervise satisfactorily, and having these two close together makes it possible for him to keep in much closer touch with their operation. The fact that the next pair is several hundred feet away is of no importance to him whatever.

The Arrangement of the Stoves and Hot Blast Main

This is a subject deserving the most careful consideration. Stoves in modern practice are universally arranged in one straight row, where considerations of room permit, but this exposes the maximum amount of surface to radiation, takes up the most room, and requires the longest hot blast main.

About thirty years ago the late Samuel Thomas built the Pioneer Blast Furnaces now owned by the Republic Iron and Steel Company in Birmingham, with the four stoves at the four corners of a square, with the hot blast main running between them. This takes up much less room than the linear arrangement and shortens the length of the hot blast main by the diameter plus clearance of two stoves, and where room is a matter of importance this plan is worthy of serious consideration.

The location of the stoves in relation to the furnace is a matter of much importance from another point of view. The hot blast main becomes heated to quite a high temperature in spite of a heavy lining of fire brick, and as a result expands in ordinary cases from one to three inches. No expansion joint has as yet been designed that is satisfactory for this service on account of the high temperature to which it is necessarily more or less exposed, and in consequence one end or the other of the hot blast main must move. Owing to the construction of the hot blast valve seats shown in an earlier article these act as expansion joints to the extent of about half an inch or an inch. That is, the main can slide on the flat surface of the joint to this extent without breaking anything. The bustle pipe is suspended from the furnace itself on swinging hanger bolts, and these are free to move more or less, but movements of the bustle pipe in relation to the center of the furnace are extremely undesirable because if it was put up truly concentric with the furnace originally every change must move it from the center, which means that the distances from the base of the tuyeres to the bottom of the penstocks is not constant, as it should be, but longer on one side of the furnace than on the other. This necessitates having special blow pipes for some or all of the tuyeres and greatly increases the spares necessary to be kept on hand, and, what is even more important, increases very greatly the difficulty of changing tuyeres or the like on account of the difficulty of securing the right length of blow pipe.

For these reasons the design of the hot blast main, particularly in relation to expansion, should be very carefully considered before a final plan is adopted.

The Elevation of the Furnace

Furnaces in the early days were set practically flat on the ground and their operating level was the general ground level, it being possible to walk about them without the intervention of stairs of any kind. But the tendency has steadily been to raise the furnace proper

higher and higher above the furnace ground, primarily to permit placing ladle cars under the spouts delivering the iron and cinder from the cast house. Many low built furnaces were equipped for handling cinder in hot pots by digging deep pits for the ladle tracks and running down into these on a sharp grade. This is a way out of the difficulties which arise by not having sufficient height but it is an exceedingly poor one because it increases enormously the difficulty of pulling the cars out of the pit and of handling them in it. Moreover if a "mess" occurs, as it occasionally does in spite of the best management, the cinder and often the iron flow into the pit, or fill up the ladles, and then overflow them running down into the pit itself and making in some cases a pool two or three feet deep of molten iron and cinder at the bottom of a deep pit with masonry walls. The task of removing this, which is absolutely necessary before the furnace can be put back into operation, is bad enough to contemplate but much worse to experience, while the expense of the delay and repairs to tracks are very heavy. Even where the pig iron is handled cold, by hand, it is extremely desirable to have the cast house set well above the level of the iron shipping tracks since frequently transfer trucks are used in tak-

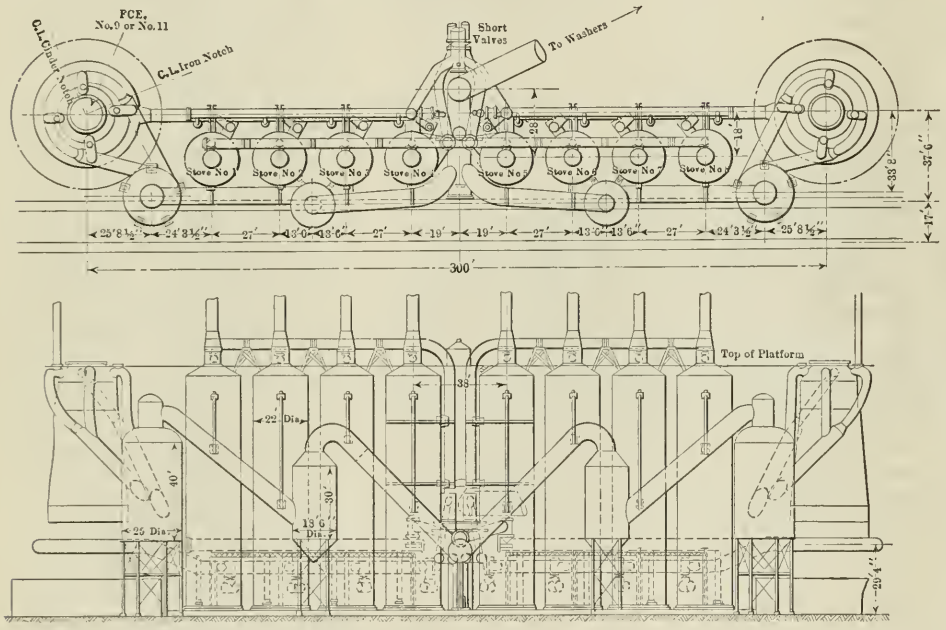

FIG. 13—GENERAL GROUND PLAN AND ELEVATION OF A PAIR OF FURNACES WITH THEIR STOVES AND DUSTCATCHER. INDIANA STEEL COMPANY, GARY, IND.

ing the iron from the cast house to the iron scales or the storage yard, or to the broad gage cars for final shipment. It is of course important to be able to drop the iron down to these transfer cars and also to drop it again to the standard gage cars. All of these considerations have demanded that furnaces be set higher and higher with the result that the hearth level at modern furnace plants is from 15 to 20 feet above the ground level.

The tracks serving the cast house and the cinder runners instead of being of the "dead end" variety as they must be if they are in pits, are, if possible, always made through tracks on the ground level, so that if there be an obstruction in one direction the liquid iron and cinder may be hauled away in the other.

It is probably advisable to go even a step further than this and to have the level of these tracks where the ladles stand on them raised a little above the level of the surrounding territory so that in case of a breakout or other accident the runaway iron and cinder instead of forming a pool on top of the tracks to their complete destruction may run down hill off of them.

The Arrangement of the Boilers and Engines

The blast can be carried for very considerable distances from the blowing engines without much loss of pressure and with but little expense. It is therefore possible to locate the blowing engine house at a considerable distance from the furnaces, but of course it is very undesirable to carry the steam any further than is absolutely required. This means that the boiler house must be located close to the engine house, and as the gas from the furnace must be brought to the boiler house the location of the latter is deserving of considerable study.

At small plants attempts have been made to set boilers and stoves close together so that one man could attend both sets of burners, and this is on many accounts an excellent idea, but cannot generally be followed at larger plants, and therefore a location is chosen for the boiler house which will give the shortest and most convenient gas main to reach it and at the same time give the best steam connections to the engine house. It might almost be said to be standard practice to put the engine house and boiler house parallel and close to one another, although very many plants have departed from this practice for one reason or another.

Where room is an important consideration these two buildings can be placed in spaces relatively difficult of access without much detriment because very little material has to be hauled to or from them on railways, but, of course, provision must always be made to bring in an ample coal supply for the boilers even though it be useless 95 per cent of the time.

It is almost indispensable that the engine house should be served with a track to handle the heavy parts of blowing machinery during erection and subsequently during repairs, but these tracks being very little used need not have the location and alignment required for tracks carrying a continuous and heavy traffic.

The number of furnaces served by a single blowing plant must be decided by the general arrangement of the plant along the lines laid down above. The expense of carrying the blast is, as there stated, not very heavy. At the same time if it were attempted to supply blast for a large plant of eight or ten furnaces from a single blowing engine house the quantity of piping involved would become very large, and the room which these pipes would take up running, in many cases, close to one furnace in order to reach others would be a very serious matter. For this reason it is possible that four furnaces is about the limit of the number that can be advantageously blown from a single engine house. Moreover, it is to be noted that when the number of engines in the plant has reached the limit of what one given crew can supervise adequately another crew then becomes necessary, or a large portion of one, and it makes little difference in the operating cost whether these be in one house or in

two, while it makes an enormous difference both in cost and in room required if blast pipes for more than four furnaces have to be distributed from a single blower house.

The electrical, compressed air and dry blast plants are almost always located, as they should be, in or adjacent to the blowing engine house so as to be under the charge of the blowing engine operators, and served by the cranes installed over the blowing machinery. The feed pumps for the boilers were formerly in the same building but are now very generally placed in the boiler-house proper and put under the charge of the boiler house attendant. The pumping plant must be located primarily with relation to the water supply, and while it is exceedingly desirable that this also should be in the main power house it is not always possible to arrange it in that location without sacrificing even more important considerations. At the same time the cost of attendance of isolated plants of relatively small power is very high as compared to that in a single large power house, and for this reason the pumping plant should be either in the main power house or as close to it as practicable.

Arrangements for the Disposal of the Iron

These necessarily vary according to the purpose of the plant. If it be a component part of a steel works then the prime consideration is safe and convenient methods of hauling the ladle cars to and from the steel works. If on the other hand the furnaces constitute a merchant plant all the iron is required to be cast either in beds or a pig machine. In the latter case the location of the pig machine is a matter of some moment as is also the location of its service tracks. In an earlier article were given a description and illustrations of a pig machine plant with an excellent arrangement of "ladder" tracks. Such an installation can within reason be located wherever consideration of tracks and space require.

The Disposal of the Slag

The prime consideration in this is that the runners shall be short since even the hottest and best-running cinder builds in the bottom of the trough and has to be cleaned out and disposed of before the next flush. The labor required for this increases almost as the square of the length of the trough and it is therefore very important to keep the latter as short as possible whether it is to discharge into a hot pot or into a granulating pit.

The location of the slag dump for the final disposal of the slag may be any distance up to one or two miles or even twice as much, but of course it is desirable to keep this distance as small as possible in order to diminish the time of the ladle cars on the road and so enable the smallest number of them to perform the necessary service.

Panama Canal Commission Award.—The contract for furnishing material under circular No. 891 for complete pumping plant for Dry Dock No. 1, Balboa Terminals, Balboa, Canal Zone, Isthmus of Panama, was awarded by the Panama Commission to Henry R. Worthington, N. Y. The contract involves design, fabrication and delivery on the Isthmus of the structural, mechanical, electrical and hydraulic parts required for this installation. The pumping plant comprises four 1000-hp. main pumps, two 200-hp. drainage pumps and one bilge pump. The contract further includes all of the hand and power operated gate valves as well as the automatic check valves. For operating the gate and sluice valves by power a hydraulic pressure system is provided consisting of a weighted accumulator and the necessary pressure pumps in duplicate. Delivery is guaranteed within 210 days.

Faraday Society Meeting

The seventy-fifth ordinary meeting of the Faraday Society was held on May 11, 1915, at the Institution of Electrical Engineers in London. The president, Sir Robert Hadfield, was in the chair.

Prof. ALFRED W. PORTER read a paper "On Von Babo's Law and Kirchhoff's Equation for the Latent Heat of Dilution."

The following are the chief points in the paper:

1. Accurate formulas are found for the heats of dilution (both reversible and irreversible) for a solution of any concentration at any hydrostatic pressure.

2. A sufficiently accurate formula is obtained connecting the heat of dilution with vapor pressures. Von Babo's law is discussed in this connection.

3. It is shown that, at any rate for sugar solutions

$$\log \frac{\pi}{\pi_o} = \frac{n}{N - an} \text{ approximately,}$$

where a is the hydration factor of the solute.

4. It is emphasized that $N - an$ cannot be interpreted as the number of effective molecules of solvent in the solution on account of the association of the solvent molecules with one another. For example, in the case of water the association is almost certainly between 2 and 3. Hence the actual number of solvent molecules *in the solution* which are unattached to solute is between $\frac{N}{2} - an$ and $\frac{N}{3} - an$; because N is the number of molecules of solvent reckoned as in the vapor state, and steam is not associated.

Mr. D. ORSON WOOD read a paper on "The Vapor Pressure of Concentrated Sugar Solutions."

The vapor pressure of solutions containing approximately 50, 60 and 70 grams of cane sugar per 100 grams of solution have been determined by a static method for the temperature range 60 deg. to 90 deg. C. The results show that the lowering of the vapor pressure of the solution relative to that of water (Babo's constant) decreases slowly with temperature, and the variation indicates that heat should be evolved when the solutions are diluted with water, thus agreeing with the previous work on the latent heat of dilution.

The value of Callendar's hydration factor a is calculated for each solution. It varies continually with temperature from 3.5 to 4.5; but the mean in each case is very nearly 4, not 5, the value given by Callendar for less concentrated sugar solutions.

The osmotic pressure is deduced from the vapor pressures by means of Porter's equation. For the strongest solution it is of the order of 320 atmospheres. It has a tendency to decrease with rise of temperature. The theoretical aspects of all these results are considered at length.

A paper by Mr. F. J. HARLOW and Mr. R. S. WILLOWS on "A Simple Method of Deriving the Gibbs Adsorption Formula" was read by Mr. Harlow.

The usual method of deriving the Gibbs adsorption formula involves the use of chemical potential. As students find a difficulty in understanding this, a simple method of obtaining the formula is given which involves only elementary thermodynamics.

Mr. F. H. CAMPBELL communicated a paper entitled "The Vapor Pressures and Specific Volumes of Binary Mixtures of Volatile with Non-volatile Liquids."

By the use of a new method, the effect of varying quantities of a liquid of negligible volatility upon the vapor pressure of volatile liquids dissolved in them has been determined.

It has been shown that the results receive adequate qualitative explanation, on the assumption that the form of vapor pressure curves is determined by molecular

changes accompanying the process of solution. Thus the solution may consist of a smaller number of particles than did the liquids constituting it before admixture, as the result of solvate formation; the number may be greater, owing to dissociation of an associated liquid. Probably the commonest case is that in which both solvate formation and dissociation occur together.

Attempts to apply Dolazalek's theory quantitatively were not successful, even in the simplest cases. It must be concluded that it requires amplification.

An explanation of the apparently abnormal behavior of certain mixtures is put forward.

The specific volumes of a number of mixtures of pairs of liquid have been determined.

Mr. R. H. Callow communicated a paper on "Reaction Velocity in Viscous Media."

The reaction considered was the hydrolysis of methyl acetate in gelatine-water mixtures by NaOH and HCl. Conductivity experiments on the alkaline hydrolysis failed to give satisfactory results owing to the hydrolysis of the Na salt of gelatine. The acid hydrolysis gave a series of velocity constants which showed a diminution as the gelatine concentration increased. The change in the velocity constant was small compared with the change in the viscosity, *e. g.* the velocity constant for the reaction proceeding in a set jelly was only about 10 per cent less than that in the case where no gelatine was present. The curves showing the relation between the velocity constant and the viscosity and fluidity of the mixtures do not appear to obey any simple relation. The fall in the velocity constant is supposed to be due partly to the neutralization of the HCl by the gelatine, and partly to the viscosity. The author suggests that the effect of the viscosity is given either by a reciprocal relation such as $\eta(K - c) = \text{const.}$, where c is a constant, or by an exponential function.

Mr. K. C. Browning and Mr. C. T. Symons sent in a description of "A Convenient Thermostat for Accurate Specific Gravity Determinations and a Gas Pressure Regulator."

The authors, having had occasion to make a number of accurate specific gravity determinations, devised a thermostat the temperature of which can be kept constant to considerably less than 1/100 deg. C., which has advantages over others they are aware of.

The advantages of this regulator are:

1. It does not leak either at the valve or at the flexible top. If a gas pressure of 30 in. water be applied at the inlet, a water gauge at the exit will not alter its level perceptibly when the pressure at the inlet is maintained for half an hour.

2. It is portable and takes up little room.

3. It can be rapidly set for any desired reduction of pressure.

4. It does not require careful leveling and is very strong.

Mr. E. J. Hartung communicated a paper on "A New Method for Determining the Specific Heats of Liquids."

In the course of a research on certain thermal properties of binary liquid mixtures it was found necessary to measure the specific heats of a large number of liquids. It was therefore very desirable to have a simple, rapid and reasonably accurate method of measurement. The paper contains an account of a method which has been found very suitable for the purpose named. It has the added advantage of requiring a relatively small quantity (60 c.c.) of the particular liquid for a determination. The method retains the simplicity of the old mixture method for measuring specific heats while greatly diminishing its serious errors.

The initial idea, from which the method was worked out, was supplied by Prof. Orme Masson, who suggested that the liquid in question be cooled by the application of a known weight of dry ice sealed up with a roll of silver gauze in a thin glass bulb. This suggestion was acted upon, and, after suitable apparatus had been constructed, good and consistent results were obtained. The method in brief consists in freezing the bulb containing the water in a suitable apparatus and then introducing the bulb into the liquid in the calorimeter and noting the fall in temperature.

Mr. J. S. Anderson contributed a paper on "An Electromagnetic Vacuum Balance."

The balance was designed to allow weighings being carried out *in vacuo*. The principle involved is that of the well-known Kelvin balance for "weighing" electrical currents. One of the scale-pans of an ordinary balance is replaced by a circular coil of wire which is movable between two larger fixed coils of wire, the three coils having a common vertical axis. The coils are so connected that, when a current of electricity is passed through them in series, the movable coil is attracted by the lower, and repelled by the upper, fixed coil. These attractive and repulsive forces, which may be increased or decreased by varying the electrical current, are made use of to counterbalance the action of gravity on the substance to be weighed in the scale-pan hanging from the other end of the balance-beam. Should the weight of the substance vary from time to time, the variations in weight can be determined by altering the current through the coils until equality of the forces acting on the two ends of the balance-beam is obtained. The balance must first, of course, be calibrated.

The base of the balance is fixed to a glass plate, over which a bell-jar is placed, thus allowing of the apparatus being evacuated. Two terminals, which serve for leading in the current for the coils, pass through the glass plate. The arrestment is controlled by an electromagnetic device operated from outside the balance. Attached to a lever at the back of the balance are two iron rods which can move freely in a vertical direction inside two solenoids. When an electrical current is passed through one solenoid the balance beam is released; when passed through the other solenoid, the beam is fixed. As soon as the beam is either released or fixed, the current may be switched off without altering the position of the beam.

A difference in weight of .35 to .7 milligram could easily be detected when use was made of an amperemeter which was not very sensitive. The balance is specially suited for measuring changes in the weights of substances *in vacuo*. Measurements were made of the velocity of absorption of water vapor by silicic acid gels.

Mr. E. B. R. Prideaux sent in a "Note on the Neutralization Curve of Boric Acid."

The hydrion concentrations of boric acid at various degrees of neutralization may be calculated with one dissociation constant. If that of Walker $K = 1.7 \times 10^{-9}$ is used, the calculated acidities over the greater part of the curve are too high as compared with the experimental values of Sorensen. A modified dissociation constant $K = 4.5 \times 10^{-10}$ derived from these values gives a good agreement, except that the acidity is too low at the acid end.

These differences are accounted for by the formation of complexes in solution.

Mr. Norman Murray Bell contributed a paper "On the Anodic Solution of Lead."

This paper is due to an attempt made to collect further evidence bearing on the production of monovalent lead ions (Pb.), the existence of which in aqueous solution has been inferred by Denham (*F.C.S.*, 93, 424, 833).

The results of the preliminary investigation of the

electric solution of an anode of pure lead in six different electrolytes, viz. lead acetate, potassium hydrogen tartrate, hydrofluorsilicic acid, sodium acetate, potassium bromide, and sodium thiosulphate, are here recorded. Of these the sodium acetate and the sodium thiosulphate yield apparently positive evidence. The author hopes to be able soon to supply a more detailed study of these two solutions.

Mr. F. C. THOMPSON communicated a paper on "The Elastic Strength of Metals."

In a normal pure metal the inter-crystalline boundaries are by far the strongest part of the whole. This rather unexpected fact has recently been explained by assuming that a hard vitreous modification of the metal exists between the crystal grains, the strength of which "cement" is sufficiently great to stiffen up the whole mass. This explanation, however, necessitates the assumption of a tensile strength for the cement of an almost impossible order.

On the assumption that surface tension effects are to be expected in the "glassy" films, an expression for the elastic limit of a pure metal is derived.

If E is the E.L. in dynes per sq. cm.,
n is the number of crystals per cm.,
T is the surface tension of the films, and
d is their thickness,

$$E = 1.5n\frac{T}{d} \qquad (1)$$

The equation agrees well with recent work on the yield-point in metals and on their mechanical properties at high temperatures.

Bars of pure lead, tin, zinc, antimony, silver, copper, iron and nickel were used to test the relationship, the iron being used in five different conditions.

Although this equation governs the elastic limits of metals, the maximum stress and Brinell hardness are dependent on other terms, chiefly the "intrinsic pressure," with the result that alterations may be made in the elastic limit of a material without appreciable effect on its hardness.

The electrical resistance of a normal metal ρ is shown by measurement of the samples of treated iron to be the sum of the resistance of the crystalline material ρ_1 and an added resistance due to the crystalline junctions, so that if n is the number of the latter per centimeter and R their resistance,

$$\rho = \rho_1 + nR \qquad (2)$$

Thus from (1) and (2)

$$d = \frac{1.5T}{E} \cdot \frac{\rho - \rho_1}{R} \qquad (3)$$

which allows d, the thickness of the film of undercooled metal between the crystals, to be calculated.

Results are obtained for a pure iron, and discussed in their bearing on the theories of the origin of the films.

Mr. LESLIE AITCHISON sent in a paper entitled "Experiments on the Influence of Composition upon the Corrosion of Steel."

The work embodied in this paper has been performed upon a series of some sixty steels, comprising (1) plain carbon steels, (2) steels containing a constant proportion of carbon and varying proportions of tungsten, chromium, cobalt or vanadium, (3) steels with constant proportions of tungsten, chromium, vanadium, manganese or nickel, and (4) some steels containing copper. The attacks recorded are those of (1) 3 per cent sodium chloride, (2) 10 per cent sulphuric acid, and (3) 1 per cent sulphuric acid. The work shows that in the case of the pure carbon steels an increase of the carbon produced at first a fall of the corrosion and then a rise to a well-marked maximum of 0.9 per cent of carbon. The addition of varying proportions of tungsten to a series of steels containing about 0.7 per cent of carbon has produced a definite increase of the corrosion throughout. Varying percentages of cobalt added to a similar series have produced an increase of the corrosion with the presence of smaller quantities of cobalt, and in all cases a gradual fall of corrosion with a rise of cobalt. In the two acid solutions the higher proportions have produced a corrodibility less than that for the corresponding pure carbon steel. The presence of vanadium in varying proportions has resulted in a definite increase of the corrodibility. The addition of chromium produces an increase of the corrosion up to 5 per cent, then a remarkable fall to a material containing 19 per cent of chromium, which is quite non-corrodible in brine, and almost so in 1 per cent sulphuric acid, but which is highly corrodible in 10 per cent acid.

In the third series the percentages of the third elements present are fairly low, and the addition in all five cases has produced an increased corrosion in brine. In the 1 per cent acid, tungsten and nickel have (in general) produced a decrease, while vanadium and manganese show a tendency to produce an increase of the corrosion. In the 10 per cent acid, tungsten and nickel generally produce a decrease, while chromium, manganese and vanadium show a distinct increase. The steels containing copper show an increased corrosion in brine and 1 per cent acid, but a decreased corrosion in 10 per cent acid, after the copper has risen above 1 per cent.

In general it is suggested fairly strongly that anything tending to the production of finer pearlite in steels, but which does not produce a mixture of carbide and solid solution (as distinct from a eutectic), causes an increase in the corrosion of the material. The relation of the presence of carbides to the corrosion is also discussed. Further conclusions to be drawn from the work are postponed until other experiments on the question have been published, these being promised for the near future.

The discussion on this paper was postponed until the autumn, when a general discussion will be held on "The Corrosion of Metals—Ferrous and Non-ferrous."

Oxy-Hydrogen Electrolytic Cells for Japan.—The Tokio-Electric Co. has ordered a large installation of I. O. C. cells for the electrolytic production of oxygen and hydrogen gas from the International Oxygen Co., of New York.

Electric Steel Furnaces.—The Halcomb Steel Co., of Syracuse, N. Y., who installed the first electric steel furnace in America seven years ago, have contracted for a three-ton Snyder electric furnace, which will run basic, melting and refining cold material. It will have a 24-hour output of 24 tons of refined steel and will melt cold scraps and refine it on a basic bottom. Messrs. S. Fair & Son, Inc., of Saginaw, Mich., have contracted with the Snyder Electric Furnace Co. of Chicago, for the installation of a furnace with a 24-hour output of 8 tons of refined steel. It will receive cold charges and will be used for making high-grade vanadium steel castings.

Antimony.—Construction on the first antimony smelting plant on the Pacific Coast was begun at Harbor Industrial City, Cal., on April 8. It is reported that the capacity of the plant now under construction and which is to cost $75,000 will be 1000 tons per month. It is to be built with a view to future extension to much larger capacity. The smelter is being erected by the Merchants' Finance Company represented by M. Elasasser and Henry E. Simpson on part of a 6-acre tract purchased for the purpose.

Metallurgical and Chemical Engineering in Great Britain

(From Our London Correspondent)

Technical and Scientific Attaches

In Elizabethan days a cynical diplomat described an ambassador as a good man sent to lie abroad for the sake of his country. I cannot remember a good epigram concerning naval and military attaches, nor can I perpetrate an indifferent one as to the new class of diplomatic officials suggested in a short paper appearing in the Journal of the Institution of Electrical Engineers. This short monograph pays a high tribute to many German qualities unrecognized in the days before the war: "Much, very much more than is supposed, of German success in the past has been due to the possession of scientific and commercial imagination. Others, time and again, have done the pioneer work, have opened new fields of discovery, but it has been left to the imaginative Teuton to carry the discovery to its logical conclusion, to foresee its fields of application, and to build thereon great and remunerative industries. We shall be indeed a short-sighted race if, when military warfare gives place to the commercial warfare waged by manufacturing countries for foodstuffs and luxuries, we do not strain every nerve to apply systems to our methods. We must remember that the added burdens not only of direct taxation but of reduced numbers of foodgetters will render commercial success more vital to our welfare than in the past. Europe has had one example of an economic rehabilitation and industrial renaissance of a conquered nation following upon defeat and the payment of a big war indemnity. It is well within the bounds of feasibility that German industrialism may make a recovery not quite so rapid, but sufficiently rapid to justify forethought at this stage. At the time of writing, her factories and equipment are uninjured. Only raw materials and markets are needed for industrial production to be resumed. The raw material can be produced or obtained; there will be every incentive to regain the latter. Just as the important and in some respects almost dominating position which Germany held in the neutral markets of the world before the war was in part due to the thorough and systematic methods of her commercial engineering departments, so her innate gains of organization and co-ordination, her capability of concentration of purpose, and her logical industrial imagination, will guide and steady her progress toward a recovery of her previous position. To this she will be relentlessly spurred by the grimmest of necessities, that of food earning."

The remedy or weapon advocated by the author of the monograph is that of a new type of attaché at our legations and embassies. "Unless written by specialists, neither the reports of commercial attachés and trade commissioners nor the consular reports can be reasonably expected to give details, say, of the successful types of competing foreign manufactures, the reason of lower price, the reasons apart from price why British types are not successful, and the local conditions which may render British articles unsuitable.

"The professional status of a technical commissioner, say, in engineering, should be at least the equivalent of full membership of one or more of the institutions most closely concerned in his work, viz., the respective institutions of mechanical engineers and of electrical engineers. Those concerned with mining machinery or metallurgical matters should belong among other bodies to the Institution of Mining and Metallurgy. The chemist, too, should possess equivalent qualifications. Were it once decided to appoint technical commissioners, the councils of the various institutions could submit names to the Secretary of State, who would make a selection therefrom in the usual manner. Before proceeding to take up his post, the newly appointed technical commissioner should have ample opportunity of conference with representatives of the industries concerned with his sphere of work, both as regards their selling and their technical departments, and methods of manufacture. At stated intervals he should return to England to confer with those concerned in his work."

The author has, however, omitted to say that certain reports issued by your Bureau of Standards in Washington would prove useful models, and are convincing examples of what can be done. Also, too, but not so well known, are the published Japanese reports. The unpublished Japanese reports, moreover, would probably surprise many people, not only in Europe but on your side also.

Government Aid for Scientific Research

The Rt. Hon. J. A. Pease, who until the reconstruction of the Cabinet was President of the Board of Education, has made a very important announcement in the House of Commons. In the course of his annual statement he observed that the war had shown up the fact that Great Britain was far too much dependent on the foreigner for many processes and for much material. It had made us realize that if we were to maintain our manufacturing position in the world we must endeavor to promote a better system for the encouragement of scientific research, especially in the universities. He stated that he could give case after case where, by research and by a little expenditure in connection with the training of scientific and able men, we would be able as a country to succeed just as Germany had succeeded. His fear was that after the war we should have to contend with a fiercer competition than that which we had had to contend with in recent years. The government agreed with him that something ought to be done at once, that we must make more use of the workers who exist in our country and prepare for an increased supply of them, that we must bring our universities and technical schools into closer association with industries and bring our leaders of industry into closer association with skilled workers. He proposed to proceed at once to the appointment of an advisory council in industrial research. He wanted a committee of experts who themselves would be able to consult with other expert committees working in different directions. They in turn must be associated with leaders of industry. The department would work in close co-operation with the Board of Trade. He hoped the Advisory Council would be at work within the next few weeks. He hoped to place on the supplementary estimates a vote of between £25,000 and £30,000 as a beginning. The schemes must be dependent on state help for years to come, and this state help must steadily progress.

The Iron and Steel Institute

THE SECOND DAY'S MEETING

The second day's meeting was much quieter than the first. A resolution drafted by the Council removing the names of all alien enemies from the list of members was considered and adopted. After this the Carnegie Medal, which had been awarded to Mr. E. Nusbaumer of Paris for his researches on "Rotary Bend Tests," was handed to Mr. H. Le Chatelier, as Mr. Nusbaumer was serving with an artillery regiment.

The first paper discussed was that by Dr. A. McWilliam and Mr. E. J. Barnes on the "Brinell Hardness and Tenacity Factors of a Series of Heat-Treated Special Steels."

Dr. C. A. Edwards, who opened the discussion, said that in certain experiments which he had carried out with chrome steels he had found that when heat-treating them in various ways he obtained different variations in the Brinell hardness; this he illustrated by a number of curves on the blackboard. He had concluded from the tests he illustrated that chrome steel was a self-hardening steel. When tungsten was also present the effect was not due to the tungsten, but was due to the chromium. He (the speaker) had taken curves of a 6 per cent chrome steel, and had found that in cooling down great variation occurred in the occurrence of the critical points, and his experiments pointed out that by carrying out cooling at different rates in a laboratory it was possible to control any property of the steel.

Mr. H. Le Chatelier, who followed, said the experiments carried out by Messrs McWilliam and Barnes confirmed the absence of proportionality between the Brinell hardness number and the yield point. For the passing of certain material in the case of which the yield point was of the greatest importance, the use alone of the Brinell test would not afford a sufficiently accurate guide. On the other hand, the Brinell test could be resorted to, and serve as a guide when other conditions are extant for determining the metal; when, for example, the chemical composition or thermal treatment was known. The constancy in these conditions, coupled with the fixity in the hardness number, sufficed to show that the characteristics of metals which were being compared together remain constant, the yield point, therefore, remaining also constant.

Dr. Stead found the paper most interesting, in that it pointed out the value of the Brinell testing machine. This machine was now in almost constant use, and it should be met with in every works, since in one minute it was able to give a good indication of the properties of the steel.

Dr. Rosenhain said it would be wrong for the Brinell test to be resorted to for investigating new material, but it was a useful method for a number of purposes, such as routine tests carried out when comparing series of similar pieces similarly treated. He indorsed Mr. Le Chatelier's remarks.

Dr. J. E. Stead then read an abstract of his paper on "Iron, Carbon and Phosphorus." Much of the discussion was devoted to methods of detecting phosphorus —the beautiful photo-micrographs in color which accompanied the paper were greatly admired, and favorite etching media warmly praised or sharply criticized according to the predilections of the speakers. For instance, Dr. W. H. Hatfield was not really satisfied with either Dr. Stead's or Dr. Rosenhain's reagents. Mr. H. Le Chatelier said that a very simple means for characterizing phosphide of iron was to have recourse to caustic soda and electric current. The phosphide of iron was attacked and the cementite remained intact. He added that electrolytic methods could, he thought, be used more frequently than they were at the present time; they made it easily possible to regulate the action of the reagent.

Dr. Rosenhain said that the reagents were new in the sense that they had been worked out a little more fully than formerly. Osmond used copper solutions for etchings, but he (the speaker) believed Osmond removed the copper from the surface. There were two kinds of actions, a dissolving one and a pure etching one, with at the same time a deposition of copper. One or the other might preponderate. If the etching action preponderated the effect would be similar to that with picric acid. Ghost lines were so common in all commercial steel that it was ridiculous to say that the mere existence of bands containing more or less phosphorus necessarily rendered the steel bad. But when the bands were excessive in number or in width and intensity, it was necessary to beware of them. There was a concentration of phosphorus in the bands. There occurred also alternate layers of two materials which differed in their critical temperatures and in their mechanical properties, both hot and cold. They were being rolled or forged together, and they were unequally expanded in the process. Their internal behavior was different, with the result that internal stress was produced when the metal cooled. Where large plates had cracked spontaneously, the cracking was associated with a large amount of banding and with a large difference in the phosphorus content between successive layers. There was also the effect of the bands upon the critical points of the steel. He (the speaker) thought Dr. Stead had got over the difficulty with his reagent. To judge properly of the new copper solutions extremely low magnifications had to be used, 2, 3 or 4 diameters at most. He (the speaker) thought Dr. Stead was right when he said that the whole question of the rate of deposition of copper was the ease of sollubility of the ferrite, and consequently the question of the purity of the ferrite. Carbon dendrons were not obtained when the metal was etched with picric acid, because the carbon diffused so rapidly. Silicon diffused more rapidly than phosphorus. Phosphorus, in fact, was one of the most slow diffusing components, if not the slowest.

Other speakers included Mr. E. H. Saniter, Mr. R. G. Scott, Dr. McWilliam and Dr. Edwards. Dr. Stead in his reply agreed with what Dr. Hatfield had said, as his own experience was practically identical. But the reagents were not intended to apply to pig iron, to which Dr. Hatfield had applied them. With pig iron Dr. Stead had also found they not only showed the phosphorus areas, but also silicon concentrations, which had never been shown in pig iron by any other reagent. Up to 5 per cent silicon there occurred a large area which remained white. The graphite had decomposed into pure iron and graphite, while the silicon in the primary crystalite form had not had time to diffuse out. Dr. Hatfield's magnification was too great. Mr. Le Chatelier's method was a good one for detecting free phosphorus, but it did not apply to phosphide in solid solution. He agreed with Dr. Rosenhain on all points. Other things besides phosphorus interfered, and it was necessary to be careful in the use of reagents.

The last paper read and discussed was that by Mr. Kotaro Honda of Tohoku University, Japan, and dealt with "The Nature of the A_2 Transformation in Iron." The speakers were Dr. Stead, Mr. H. Le Chatelier and Dr. Rosenhain.

Market Prices

JUNE, 1915

Tin opened at £162, fell to £160 (3d), and then rose steadily to £167 (9th). After a slight drop to £166.10 (10th) it rose sharply to £175 (14th), then fell to £168.10 (17th), recovered to £171 (19th), again dropped to £168.10 (25th), after which it improved considerably, closing at £172.10.

Haematite has remained steady at 95/- throughout the month.

Scotch Pig opened at 71/6, and remained steady till the 8th, it then rose slowly to 74/- (15th), declined to 72/- (20th), recovered to 72/6 (22d), and after slowly falling to 72/- (29th) it rose slightly, closing at 72/6.

Cleveland opened at 65/6 and remained steady till the 8th, it then improved to 67/6 (15th), declined to 66/- (20th), recovered to 67/- (22d), and after slowly falling to 66/- (29th) it rose slightly and closed at 67/-.

English Lead opened at £21.10 and rose steadily to £28.10 (15th), it then dropped rapidly to £26.10 (16th), and after a slight improvement to £27 (18th) declined to £24.10 (24th). It then rose decidedly, closing at £27.

Copper opened at £79.10, improving to £83.5 (6th), and after a slight fall to £83.15 (8th) continued to rise to £86.10 (14th). It then fell sharply to £82 (18th), recovered to £83 (20th), but went lower to £81 (24th), and after improving to £82.10 (25th) it declined slightly, closing at £82.

Recent Chemical and Metallurgical Patents

Iron and Steel

Combustion Apparatus for Carbon Analysis.—A form of apparatus for making carbon determinations has been patented by Mr. John S. Cox of Buffalo, N. Y. It is an improvement on the type in which a water-cooled stopper fits a crucible in which the combustion takes place. The idea is illustrated in Fig. 1, in which *A* represents the crucible and *B* the cover, the latter having the usual tubes *bb'* for ingress and egress of oxygen and other gases. The crucible has a flange *c* which fits into an annular depression *e'* in the annular cooling chamber *E*. The crucible cover *B* also has a flange *c'* corresponding with the flange on the crucible and between these two is placed a gasket of rubber, *D*. The cooling chamber has suitable inlet and outlet tubes *f* and *f'*, the latter not shown, for the circulation of cooling water. A screw *G* is provided to secure the cover firmly in place on the crucible and form a tight joint. Advantage is claimed over similar apparatus in which a cooling chamber is formed integrally with the crucible, because the cooling water forms incrustations in the chamber. An improvement is claimed also over apparatus with a water-cooled stopper, because the latter tends to condense atmospheric moisture on its surface that is likely to run into the crucible when the stopper is removed. (1,140,802, May 25, 1915.)

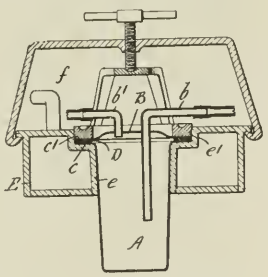

FIG. 1—COMBUSTION APPARATUS

Aluminium

Aluminium Nitride.—Some interesting developments in connection with aluminium nitride manufacture in the electric furnace, are brought out in patents recently issued to Mr. Paul Bunet of Whitney, N. C., and assigned by him to the Société Generale des Nitrures, of Paris, France, which company owns the Serpek patent. Special interest attaches to these developments in view of the fact that a large plant has been in course of construction at Whitney, N. C., for the manufacture of aluminium. Detailed information on the Serpek process may be found in Metallurgical and Chemical Engineering, Vol. XI, pages 137 and 139.

The raw materials are essentially the same in this new process as in the Serpek process, but the new process embodies a departure in the fact that the mixture of alumina or aluminous material and carbon is used itself as the heating resistor. The mixture advances in the furnaces in the same general way as in the Serpek process, but owing to the fact that carbon is used up in the reaction it is necessary to adopt some means of keeping the current normal. This is effected in two ways: either by increasing the thickness of the layer of mixture as it advances and becomes poorer in carbon; or by interposing electrodes into the mixture at intervals which can be adjusted according to the conductivity of the mixture between them.

Two types of electric furnace in which the above process may be carried out are also patented by Mr.

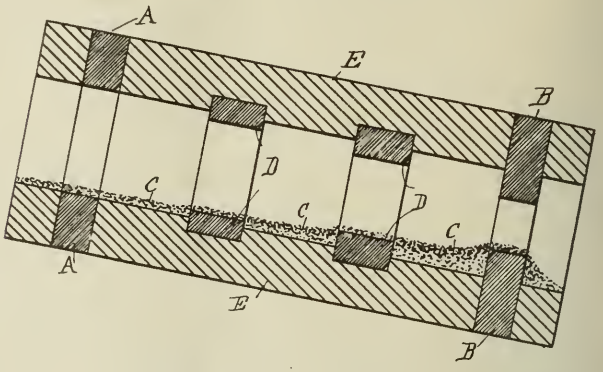

FIG. 2—ELECTRIC FURNACE FOR ALUMINIUM NITRIDE

Bunet. The first is a furnace in which the thickness of the layer of mixture increases with the advance, and the second effects the uniform passage of the current by having electrodes interposed in such a way that the distance between them can be regulated according to the conductivity of that part of the mixture. These two types may be combined. A drawing of an inclined revolving furnace of the first type is given in Fig. 2, in which *A* and *B* are annular conductors, the lower electrode *B* projecting into the furnace so as to form a diaphragm to retain the mixture *C* traveling through the furnace. *DD* are conductive rings which may be placed in the refractory lining *E*, thus allowing of a better passage of the current. These rings may be projecting on not. (1,145,747 and 1,145,748, July 6, 1915).

Aluminum Alloy.—An alloy consisting of aluminum, silver, copper, and cadmium, which is very useful for casting purposes, is patented by Mr. William A. McAdams of Bay Shore, New York. This alloy is not corroded by the action of the ordinary city water and has withstood pressures up to two hundred pounds per square inch without sweating. (1,146,185, July 13, 1915).

Zinc

Treating Zinc-Bearing Materials.—Improvements in electrical zinc smelting are the basis of a patent of Mr. Woolsey McA. Johnson of Hartford, Conn., and assigned to the Continuous Zinc Furnace Company of Hartford, Conn. A process is described for treating zinc-bearing slags, by reducing the zinc from the slags with iron, the zinc being subsequently volatilized and condensed. The slags treated are such as come from the lead blast furnace or from the reducton of ores containing zinc and copper. "Such slags are essentially silicate compositions in which iron and calcium predominate, carrying minor proportions of aluminium, manganese and magnesium, and containing some 8 per cent, more or less, of zinc oxide."

A cross section of the author's furnace is given in

Fig. 3, in which 1 represents the refractory structure, in a metal sheath 2. Interior chambers 3 and 4 are separated by partition 5, which is cooled by water pipes 6. A layer of molten iron on the hearth is indicated by 7 and 8,8 are the lower electrodes. Above the molten iron is a layer 9 of molten zinc-bearing slag, 10 being a runway for introducing same. The upper electrodes 11,11 depend into the slag. 12 is a flue for the volatilized zinc, 13 represents a tapping hole for slag, 14 a tap for matte, and 15 a lead tap communicating with a sump 16; 18,18 are hoppers for introducing coal or coke; 19 and 21,21 are tuyeres.

In operation of this particular type of furnace, the iron is run into the furnace in the molten state and in quantity sufficient to cover the hearth to a depth of a few inches. Fluid zinc-bearing slag is run in above the iron, and the temperature maintained at a point sufficient to effect the reduction of the zinc by the electric current.

This reduction occurs in accordance with the following reaction:

$$Zn\ O\ SiO_2 + Fe = Zn + FeO\ SiO_2.$$

The zinc vapor passes from the furnace by flue 12. The slag, denuded of most or all of its zinc, and proportionately enriched in iron, flows beneath the depending wall 5, into the furnace chamber 4, in which it is smelted in the presence of carbon. In this operation a certain portion of the iron is reduced to metal, and collects in the layer 7, serving to replenish same. The slag level may be maintained by tap 13 and lead carrying any gold and silver drawn out through tap 15. Instead of slag derived from lead blast furnaces or the like, the process may, of course, be operated with a properly compounded ore-charge from any source. In conjunction with a lead blast furnace the slag would be run into the electric furnace, thus conserving the heat, and "the lead blast furnace may be operated at high capacity and without strict regard for exact metallurgical conditions, the rich slags thereby formed being readily worked in accordance with the present process." (1,146,075, July 13, 1915.)

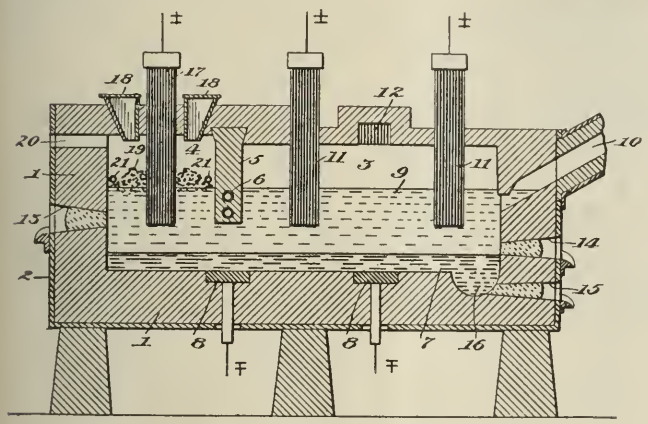

FIG. 3—ELECTRIC ZINC FURNACE

Roasting of Zinc Ores.—An improvement in roasting furnaces for zinc ores is patented by Mr. JOHN J. SIMMONDS of Iola, Kan., relating to that type of roaster in which two tiers of hearths are disposed side by side, and through which rabbles are drawn and transferred from the hearths in one tier to those in the other. The mechanism operating the rabbles is in connection with an engine or motor running continuously in one direction, and which does not have to be reversed in order to reciprocate the rabbles. The means for controlling the reversing mechanism, and for throwing the rabble-operating mechanism into and out of connection with the driving engine, are controlled from an operator's platform adjacent to the furnace. (1,133,068, March 23, 1915.)

Gold and Silver

Chlorination of Ores.—The production of electrolytic chlorine from salt for use in chlorinating the metals in gold, silver and copper ores, is the basis of a patent granted to Mr. JASPER A. MCCASKELL of Salt Lake City, Utah. An aqueous solution of the chlorides of the metals is subsequently electrolyzed in the cathode side of a diaphragmed cell, resulting in the regeneration of the original chloride solution and the deposition of the metals. The process and apparatus are illustrated in Fig. 4, in which *A* represents an agitating tank in which the ground ore pulp is treated with chlorine delivered from the tank *F* in which the gas has been stored under pressure. The chlorine gas itself is thus used as the agitating medium. If the ore contains silver, sodium chloride is added to the water used in crushing, being delivered from the tank *B*. After the first cycle the tank *B* will contain spent liquor from the anode compartment of the electrolytic cells. After the ore is chlorinated in tank *A* it is filter-pressed, and the liquor is delivered to the cathode compartment of the cells. The diaphragm is impervious and serves as a bi-polar electrode. It is formed of two sheets of asbestos or two pieces of porous earthenware between which is a thin film of mercury. The solution of metallic chlorides being under electrolysis, the metals collect at the cathode and the chlorine tends to accumulate at the diaphragm. In the anode compartment the sodium chloride is dissociated, the chlorine collecting at the anode and being used as already described, while the sodium collects at the diaphragm and amalgamates with the mercury. Ultimately reaction will occur between the sodium and chlorine at the diaphragm, and sodium chloride will be regenerated in the cathode compartment. The mechanical loss of chlorine would be made up by the addition of salt in the anode compartment. (1,137,874, May 4, 1915.)

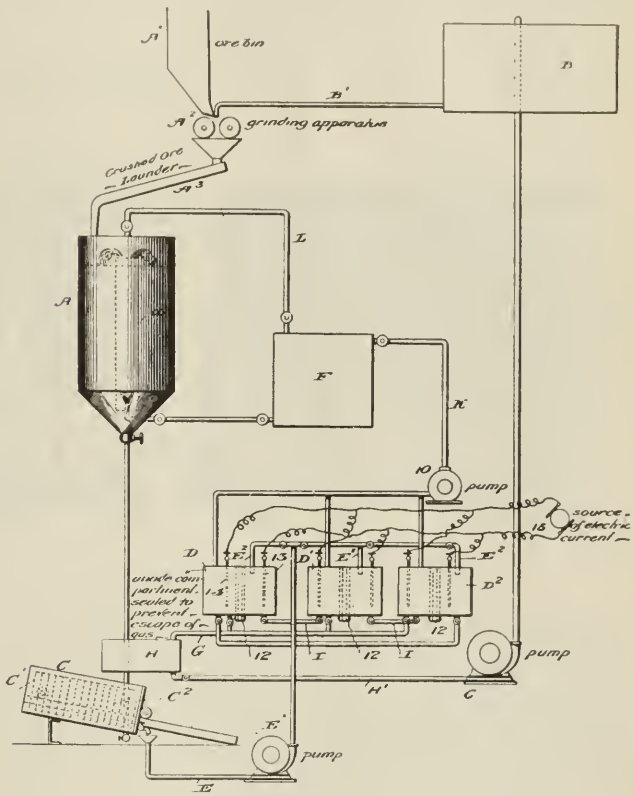

FIG. 4—PROCESS OF CHLORINATING ORES

Electrolytic Processes

Electrolytic Production of Caustic and Chlorine.—A patent issued to Mr. William M. Jewell and assigned to the Chloride Process Company of Chicago, Ill., describes a combination of gravity and diaphragm cells. In this cell for producing chlorine and caustic solution from brine, the anode liquor is heavier than the cathode liquor, and is drawn off gradually from beneath the cathode liquor which remains practically undisturbed. This is done for the purpose of keeping the solution around the anodes in motion in order to prevent formation of hypochlorite and chlorate. A longitudinal section and cross-section on end of this cell is given in Fig. 5. The cathodes are the same as the anodes with the exception of being shorter. The cathodes are represented by 23, the anodes by 19; 18 is a partition separating the anode chamber from the cathode chamber and 17,17 are other partitions dividing the whole cell into single sets. A is the chamber for caustic solution, B contains the fresh electrolyte, a saturated solution

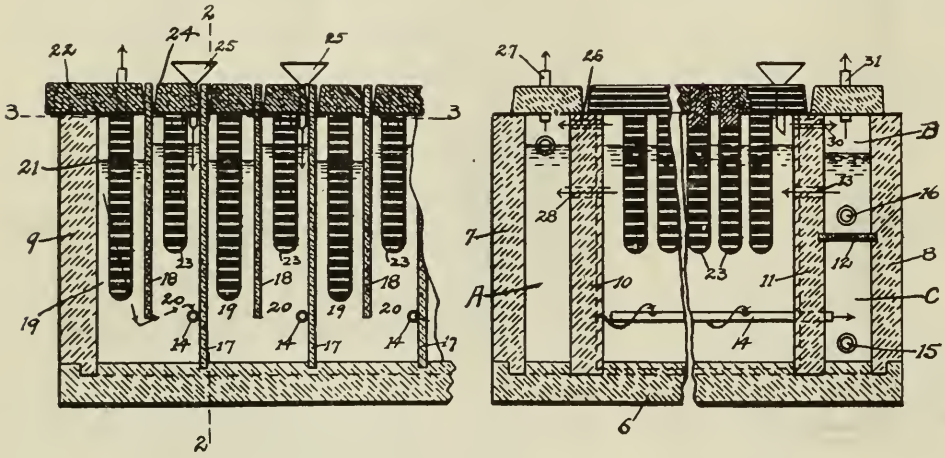

FIG. 5—ELECTROLYTIC CELL FOR CAUSTIC SODA AND CHLORINE

of brine, and C contains the spent brine, which is conducted away and replenished; 14 is a pipe through which the anode liquor flows from the cathode compartment into C, the cathode liquor not reaching down as far as this pipe, 28 is a passage for caustic solution into chamber A; 13 is a passage for conducting new electrolyte into the anode chamber, 12 is a partition separating chambers B and C. "By circulating the anode liquor, a very rapid rate of flow can be maintained without adding any appreciable amount of salt or chlorine to the cathode products, and I am able to obtain very high efficiencies both in chlorine and caustic soda production. By using anode and cathode elements arranged vertically, I also obtain much better results than when horizontal electrodes are used, as the electrode area being substantially vertical the gaseous products of the electrolysis are very readily eliminated." (1,145,593, July 6, 1915.)

Electrolytic Purification of Liquids.—An apparatus for the electrical purification of milk is described in a patent issued to Mr. James L. Goucher of New York, N. Y., and assigned by him to The New York Conveyancers Company. The feature of the apparatus is the use of vessel-shaped electrodes. The milk flows through the apparatus at a rate which is mechanically controlled. The electrical treatment is claimed to render the milk pure and sterile, and to generally improve its qualities. (1,145,862, July 6, 1915.)

An **electrical method of treating lumber,** which is claimed to greatly shorten the time of seasoning and protect the lumber from bugs and insects, is described in a patent of Mr. John P. Sullivan of Memphis, Tennessee. Electrodes are connected to the timber in such a way that the current flows along the grain. A compound consisting of salt, bluestone, alum, indigo-blue and water, applied to the surface of the wood, before applying the electrodes, is claimed to aid in the conduction of the current. The dynamo should have a capacity of 110 volts and 30 to 40 amperes. (1,146,212, July 13, 1915.)

An **electrical controlling device** which utilizes the variable conductivity of solutions is patented by Messrs. Walter J. Pike and Roy J. Sutton of Grand Rapids, Mich. In this device, which depends for its action upon the principle of the Wheatstone bridge, a solution of low conductivity may be passing through the apparatus and it may be desired to have a solution of a higher conductivity emerge. By so setting the apparatus that it is balanced when the desired solution emerges, any solution of lower conductivity sets up a current in the bridge, which closes a switch and operates a valve which supplies the necessary ingredients to bring the solution up to the required conductivity. The solutions themselves are, of course, parts of the bridge connections. (1,145,509, July 6, 1915.)

Chemical Engineering

Water Treatment.—An invention relating to the prevention of corrosion and pitting in steam boilers is patented by Mr. Charles Haythorpe of Kennington, London, England. Zinc plates as heretofore used for this purpose have proved inefficient in that they do not prevent grease deposits or incrustations, and their effect is only local. The present invention contemplates the use of plates of zinc and carbon which are maintained in close and intimate contact, forming an efficient galvanic couple, and are also arranged in good metallic contact with the boiler. It is claimed that apparatus constructed in accordance with the invention has been found sufficiently intense in its action to remove old scale and incrustation in boilers already used. Economy in cost of 30 per cent to 40 per cent is effected since fewer plates are required than with other types. (1,127,360, Feb. 2, 1915.)

Synopsis of Recent Chemical and Metallurgical Literature

Chemical Engineering

Sugar-House Evaporating Apparatus.—Bulletin 149 of the Agricultural Experiment Station of the Louisiana State University and A. & M. College (Baton Rouge, La.) relates to "performance tests of sugar-house heating and evaporating apparatus." The author is Prof. E. W. Kerr, who was assisted by Messrs. J. F. Gunther and W. A. Tolsten. The first part of the Bulletin contains an account of laboratory experiments made in continuation of the author's former researches of which a very full account was given in our Vol. XI, pages 333 and 611 (June and November, 1913). The final results of the laboratory work are summed up as follows:

The temperature conditions in the steam compartment

are very erratic and changeable, especially with very low steam pressure.

Air or other incondensable gases in the heating steam greatly reduce the heat transmission even with relatively low vacua. The coefficient of heat transmission* varies according to the equation $U = C(P_s/P_t)^n$, in which C is a constant, P_s the partial pressure of the steam and P_t the total pressure. The value of n seems to lie somewhere between 3 and 4. The presence of air pockets may be conveniently determined by means of thermometers in the steam compartment; good circulation and distribution of steam are important in preventing them.

The loss in heat transmission due to hydrostatic head is considerably in excess of the theoretical, and this excess is greater for short tubes than for long tubes. The loss with varying heads, other conditions being equal, varies according to a straight line formula.

Other conditions being equal, the lower the "temperature level" the smaller the coefficient of heat transmission; in other words, the lower the temperature and density of the heating steam the smaller the coefficient. The coefficient of heat transmission varies according to the equation $U = 2.25 + 17{,}500D$, where D = density of heating steam in pounds per cubic foot.

Increasing the density of the boiling liquid causes a loss in heat transmission due to the decrease in temperature fall according to the equation $y = CD^{3.1}$, in which C = a constant and D = density in degrees Brix. The total loss due to the density of the boiling liquid seems to be in excess of that due to loss of temperature fall. This may be due to lower velocity of circulation.

The vapors evolved from liquor of high density or from liquor under hydrostatic head are superheated.

The entrainment was less in a double-tube calandria than in the standard calandria, probably for the reason that the spouting action was lacking.

The coefficient of heat transmission seems to be independent of the quality of the steam. Superheated steam gives coefficients as high as those obtained with saturated and moist steam.

Within reasonable limits the coefficient of heat transmission seems to be independent of the temperature fall.

The coefficient of heat transmission is independent of the temperature of juice feed.

The coefficients of heat transmission obtained in the small laboratory apparatus were much higher than are obtained in full-size evaporators. This is probably due to better circulation, cleaner heating surface, better steam distribution and the relatively large condensation pump used with the laboratory apparatus.

The great temperature fall required in the last body of a multiple-effect evaporator is due to the combined influence of greater amounts of air, steam of lower density, liquid of higher density, also, in many cases, more foul heating surfaces than in preceding bodies.

The downtake or circulation tube was shown to increase heat transmission materially. Long tubes give better results as to heat transmission than short tubes, due to better circulation.

*For definition see our Vol. XI, p. 334.

The tests show that the double-tube and the baffle-plate calandria gave greatly increased heat transmission as compared with the standard types tested, and indicate that attention to steam distribution and the removal of incondensable gases is very important.

The second part of the Bulletin gives an account of large-scale tests of the capacity and economy of evaporating and heating apparatus in sugar factories in four chapters, relating to multiple-effect evaporators, vacuum pans, juice heater, and condensers. Rather full extracts from the chapter on vacuum pans are given elsewhere in this issue.

Air-Lift Pumping.—A resumé of air-lift pumping is given in an article by Mr. PAUL H. BERGGREEN in the *Sibley Journal of Engineering* of Cornell University for May, 1915. For this important mechanism of the hydraulic engineer, which is becoming of such importance in chemical and metallurgical practice, no accurate formulæ are available because of the numerous variables encountered. A great deal more experimental work is needed in order to establish accurate details. "It was at first supposed that in all air lifts the water was discharged because of aeration in the eduction pipe, due to the intimate commingling of air and water, as the rising air bubbles gave a constant discharge of air and water. This may be true in the case of very moderate lifts, while with a sufficient head and a large volume of water, piston-like layers of air and water are formed." The many different services to which this pump may be applied are its chief cause of success. In places where ordinary pumps cannot be used, such as pumping from great depths where fine sand is encountered, and also in such cases as conducting water a great distance and subsequently elevating it, the air-lift pump has shown itself to be very useful and its future seems to lie in the direction of high lifts, in which it shows a remarkable ease of operation wherever there is a sufficient amount of submergence available.

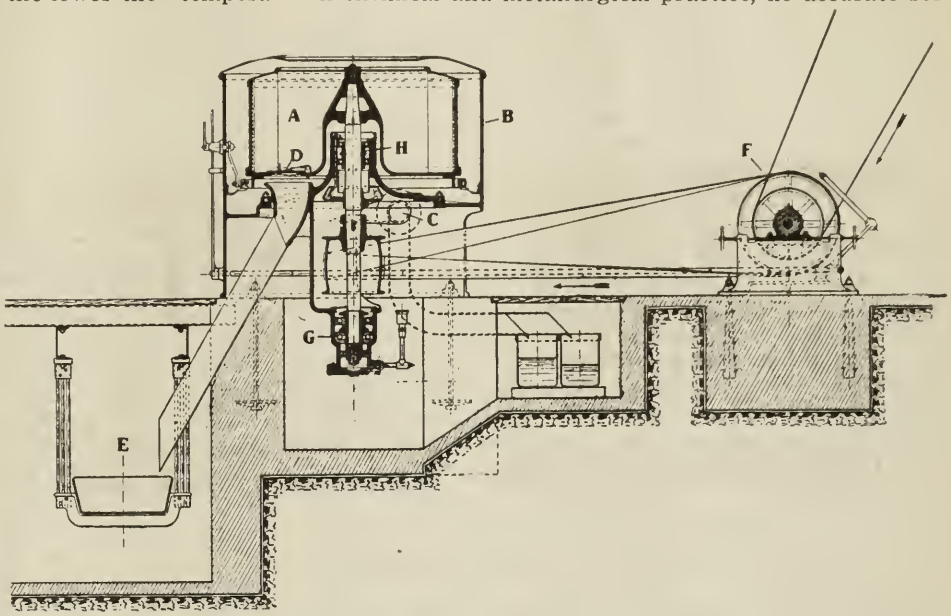

FIG. 1—UNDER-DRIVEN CENTRIFUGAL

Centrifugals.—G. BARNICK describes in *Chemische Apparatur*, June 25, improvements to centrifugal machines which are of special interest in view of the important part these machines now play in industrial chemistry. Ball-bearing machines, driven from beneath are described, together with some of the uses of centrifugals, main features of construction, and the exacting requirements which they have to meet. The advantages of the under drive, over the over-head drive, are

claimed to be: freedom of operation in charging, ease of access to driving mechanism, and the impossibility of contaminating the product with oil. On account of the high velocity (1000-2000 r.p.m.) at which a centrifugal runs, the construction must be very excellent and only the best materials must be used. The maximum load must not exceed the strain which the metal can stand. Lately, spindles have been equipped with ball bearings and this method is finding increasing application. A novel application of the centrifugal is its use in dewatering tar, the tar being freed of its water down to 1 per cent, so that it is directly applicable to felt roofing manufacture. In centrifugals for treating vaccinating serum a speed of 2000 r.p.m. is used, and the machine for this purpose must be constructed to stand a speed of 3000 r.p.m. For materials containing acid, the inside construction is made of lead, tin, copper or sometimes covered over with rubber. A machine of the under-driven type is shown in Fig. 1, in which *A* is the inside rotating cylinder, *B* the outside stationary frame, *C* the discharge pipe for liquid, *D* the discharge for solid into the receptacle *E*. *F* is the driving pulley, *G* shows the ball bearings, and *H* is an ordinary collar bearing.

Alum for Water Purification.—In an American Chemical Society paper read at the New Orleans meeting (abstracted in *Science*, July 16), C. P. Hoover described the manufacture of alum at the Columbus water softening and purification works. The process most generally employed to-day for coagulating and purifying water contemplates applying to the water under treatment a solution of aluminum sulphate. The cost of this chemical varies from $17 to $20 per ton. A plant for making alum has recently been built and put in service at the Columbus water purification plant. This is the first plant of its kind ever built at a water purification works for making alum to coagulate water, and, although it has only been in operation a short time, it has been a success both technically and economically. The process is short, simple, and inexpensive, because it consists simply in boiling bauxite with sulphate acid and applying the resultant solution to the water under treatment, thus eliminating five distinct steps in alum-making, namely, filtering, concentrating, crystallizing, grinding and redissolving. An investment of $12,000 was required for its construction, and it has been conservatively estimated that $6,000 per year will be saved the city in the cost of alum. Between 800 and 1000 tons of alum will be manufactured during the coming year at a cost of about $10.50 per ton.

Temperature of Hydrochloric Acid Formation in Evaporation of Magnesium Chloride Solutions.—Dr. H. Hof in *Chemiker Zeitung*, June 23, 1915, gives the results of a research which confirms the assertion of Casaseca, that when a pure magnesium chloride solution is evaporated the separation of hydrochloric acid takes place at 157 deg., the boiling point of $MgCl_2.6H_2O$. A paraffin bath was used for the evaporation, and it was noticed that if the surface of the solution was below the surface of the paraffin, an over-heating occurred, which caused the formation of acid at 107 deg. When the surface of the magnesium chloride was kept above the surface of the paraffin, in most cases the water could be almost completely evaporated without any formation of acid. It was also noticed that in distilling the magnesium chloride by-product from potassium chloride manufacture, the separation of acid took place at a lower temperature. This was attributed to the presence of magnesium sulphate.

Gold and Silver

Refining Gold by Miller's Chlorine Process.—In the July *Bulletin* of the Canadian Mining Institute, Mr. Ralph Pearson describes the process of refining gold at the Royal Mint, Ottawa, by the use of chlorine. The process is best adapted to the removal of silver and base metals from gold, even if present in large quantities. The requirements for the Miller process are: a constant supply of chlorine gas at a pressure of not less than 5 to 6 lb. per sq. in.; melting furnaces using either coke or oil for fuel; condensing chambers; and suitable pots, tongs, molds, etc. At the Ottawa mint the chlorine is delivered from steel cylinders holding 100 lb. liquid chlorine at a pressure of 97 lb. per sq. in. at 20 deg. C. The cylinders are housed in a cupboard that is ventilated by connection with the furnace flue leading to the condensing chamber and a pipe communicating with the outside air. The connections between cylinders and crucibles are lead pipes, rubber tubing and glass stopcocks. The desired pressure is obtained by connection with a lead receptacle like a Wolff's bottle, the third neck holding a lead pipe connected with a glass tube which is in turn connected with an enlarged lead bulb, similar to a large pipette. The lead receptacle holds sufficient water to give a column 11 ft. in height, corresponding to a pressure of about 5 lb. per sq. in. Should the pressure exceed this amount, the water is forced up into the lead bulb and the gas escapes outside the building.

From 500 to 700 oz. of the metal to be refined is charged into a clay pot and placed in the plumbago crucible in the furnace. Borax is added to form a cover about ¾-in. deep. The clay crucible has a clay cover with a slot to permit the passage of a clay pipe stem through which the chlorine is delivered to the bottom of the molten mass in the crucible. The chlorine is admitted cautiously until it passes with a steady pulsation. Dense fumes of copper and lead chlorides appear and practically all of the chlorine is absorbed. Later silver chloride is formed and floats above the gold and beneath the borax. The finishing point of the process is judged by the brown stain formed on a cold piece of clay pipe held in the fumes issuing from the pot. The fumes resulting from the chlorination and from the products of combustion are all carried through condensing chambers to a washing tower.

When the chlorination is complete the pot is withdrawn from the furnace and allowed to cool until the gold sets. Then the borax and silver chloride are poured off and separated when cold. The silver chloride is freed from some contained gold by remelting and treating with sodium carbonate, sprinkling the latter on the surface of the molten chloride. Globules of silver are reduced and sink to the bottom, carrying gold with them. The gold-free silver chloride is then treated with hot water to remove copper, which is separated from solution by precipitation on iron. The silver chloride is then reduced to metallic silver by contact with iron plates in a hydrochloric acid solution, and finally washed and melted. The fineness of the gold produced by the process will average 995, the silver fineness varies from 995 to 998. The time required varies with the amount of silver and base metals present in the gold. Thus an ingot weighing 500 oz. and containing 140 oz. base and 80 oz. silver, required 7 hours.

Treatment of Arsenical-Antimonial Sulphide Ore.—A record of experimental and practical work on the cyanide treatment of a gold ore containing arsenic and antimony sulphides is reported by Messrs. K. B. Moore and H. R. Edmands in the February *Journal* of the Chamber of Mines of Western Australia. A representative analysis of the ore follows: Insoluble, 70.04 per cent; iron, 8.3; antimony, 0.21; arsenic, 0.96; sulphur, 5.62; carbon dioxide, trace; magnesia, 2.74; alumina, 2.02; lime, 3.36; alkalies, water, etc., 6.75; total, 100.00 per cent.

A vast amount of research work was done in an effort to find a suitable method of treatment. Amalgamation and cyanidation yielded only about 50 per cent. of the gold. Concentration gave still poorer results, and the tailing yielded less than half its gold to cyanidation. Flotation gave disappointng results. Bromo-cyanide was tried without success, and preliminary treatment with NaOH did not improve matters much, as some of the gold was associated with arsenic and was not liberated. Experiments with roasting and cyaniding indicated that roasting was an essential, and a plant has been constructed in which the ore is dried, ground in a Krupp ball mill and roasted in an Edwards duplex furnace.

After this treatment the ore is mixed with oxidized ore and given the usual cyanide treatment.

It has been found unnecessary to give a perfectly sweet roast in order to get maximum extraction. Roasting must be carried far enough to liberate all gold from the sulphide, and no unaltered pyrite or arsenopyrite must be left. Ore carrying 3½ per cent to 4½ per cent sulphur retains from ½ per cent to 1 per cent after roasting, about two-thirds of which is soluble in Na_2CO_3. Samples taken half way down the roaster have given as good extraction as those taken from the discharge. The addition of lead acetate is a necessity to remove soluble sulphides.

The roast cannot be tested satisfactorily by the ordinary iodine absorption method. Owing to the frequent presence of antimony in the roasted product, which separates out on acidifying the soda extract, iodine does not give a sharp end point. The method used is to boil 20 g. of ore in 100 cc. of 5 per cent soda for one minute, decant 50 cc., acidifying with H_2SO_4 and titrate with N/30 $KMnO_4$. While this is not altogether satisfactory it gives a more definite end point and concordant results. If less than 10 cc. permanganate is required the roast is considered fair, but often a roast with far more reducing power gives quite as good extraction.

The loss of gold by volatilization has not been great, amounting to from 1s. to 2s. per ton on ore containing 53s.

In fact, the loss rarely exceeds 1s. 6d. or under 3 per cent.

Plant solution is tested for reducing power by taking 50 cc., acidifying and titrating with N/30 permanganate. Usually from 25 cc. to 50 cc. of permangante is decolorized.

Fine grinding is essential to a good extraction. The average screen test shows only about 15 per cent plus 150-mesh. A thin pulp of about 35 per cent solids gives better results than one of 45 per cent solids.

Zinc shavings were first used for precipitation, but with poor results. The authors devised a system of zinc-dust precipitation which they installed and operated with great satisfaction. The extraction has averaged over 84 per cent, with a residue of 7s. per ton. Cyanide consumption does not exceed 1 lb. NaCN per ton. The total cost is 9s. per ton, distributed as follows: Breaking and transportation, 8d.; drying, 8.5d.; ball milling, 1s. 8d.: roasting, 2s. 6d.; fine grinding sand, 6d.; agitation and vacuum filtration, 2s. 4d.; precipitation and smelting, 6d.; tailing disposal, 1.5d.

Copper

British Columbia Copper Company's Smelting Plant.—In a paper presented to the American Institute of Mining Engineers, Mr. FREDERIC K. BRUNTON describes the plant and smelting practice of this company, which operates at Greenwood, B. C. We abstract the following condensed data.

RÉSUMÉ OF FURNACE OPERATING DATA

Tons smelted per day	2,250.0
Tons smelted per square foot of hearth area, average	6.62
Tons smelted per square foot of hearth area, maximum	8.70
Tons smelted per man per day	35.70
Cu on charge, per cent	0.8 to 1.2
Cu in matte, per cent	30.0 to 45.0
Cu in slag, per cent	0.22 to 0.27
S on charge, per cent	2.00
S burnt off, per cent	85.00 to 90.00
Coke used on charge, per cent	12.00 to 14.00
Coke ash, per cent	20.00 to 28.00
Blast per cubic feet per minute	25,000
Blast, temperature	Atmospheric
Cooling water for jackets, gallons per minute	2,500
Men per 8-hr. shift	21.0
Matte, per cent of total charge	1.65
Matte, specific gravity	5 to 0
Slag, per cent, SiO_2	38 to 45
Slag, per cent Fe	13 to 20
Slag, per cent, CaO	20 to 26
Slag, per cent, Al_2O_3	6 to 9
Slag, specific gravity	3 to 2

TOTAL COSTS

The Following Costs Do Not Include Overhead Expenses, Depreciation, or Insurance

Cost per ton of smelting ore to matte	$1.18
Cost per pound of copper of converting matte to blister	0.0048
Cost per ton of copper of converting matte to blister	9.60
Cost per ton of smelting ore to blister copper	1.23
Cost per ton of copper to produce blister copper	0.105
Cost of coke per ton of ore smelted to matte	$0.851
Cost of flux per ton of ore smelted to matte	0.114
Cost of labor per ton of ore smelted to matte	0.15
Cost of power per ton of ore smelted to matte	0.033
Cost of supplies per ton of ore smelted to matte	0.03
	$1.178
Cost of coke per ton f.o.b. smelter bins	$6.00
Cost of flux per ton f.o.b. smelter bins	2.75
Cost of power per kilowatt-hour	0.0065

Concentration

Flotation Tests on Bisbee and Cobalt Ores.—An investigation of some of the variable factors in flotation undertaken by Mr. HERBERT J. FRENCH is published in the Columbia School of Mines *Quarterly*. The factors considered were (1) oil, variety and amount; (2) amount of sulphuric acid; (3) agitation, length of time and speed; (4) temperature of solution, and (5) size to which ore is crushed.

The oils tested were fish, sperm, whale, corn, cylinder, pine, pine-tar, lard and cottonseed.

The ore from Bisbee, Ariz., contained copper as chalcopyrite, chalcocite and malachite. It analyzed as follows: Insoluble, 65.1 per cent; iron, 10.9; lime, 0.9; alumina, 0.28; sulphur, 12.7; total copper, 6.04, of which 1.7 per cent was soluble in dil. hydrochloric acid. The conclusions reached as a result of the tests were: Pine-tar oil of 0.98 sp. gr. was the best frothing agent, collecting more sulphides per unit of volume than the other oils tested. Sulphuric acid in quantity approximating 0.3 per cent by weight of the water in the pulp seemed to be necessary to increase the selective action of the oil and the total extraction. Extraction improved with increase in temperature, the best condition being at 65 deg. C. Nothing shorter than 10-min. periods of agitation gave efficient flotation. Sizing the ore was necessary to secure the best results, which were obtained from material ground to from 100 to 150-mesh. The greater losses occurred in particles larger than 65-mesh.

The Cobalt ore was from the Coniagas mine, containing about 13 oz. silver per ton, mainly in the form of antimony, arsenic and sulphur compounds, with some native silver. With this ore pine-tar oil proved the most efficient flotation agent. Adding the oil in successive portions and giving longer periods of agitation gave as good an extraction with less consumption of oil.

The Silver King Coalition Mines Company is to add flotation to its standard concentrating practice at Park City, Utah. The new plant will have a capacity of 600 tons per day, and is expected to be in operation within sixty days. The Callow pneumatic process will be used.

Low-Pressure Oil-Burning Metallurgical Furnaces

Economy and efficiency in modern metallurgical work have been greatly promoted in recent years by improvements in accessory apparatus for the laboratory and mill. As an example of such apparatus may be mentioned the improved line of Case metallurgical furnaces, manufactured by the Denver Fire Clay Company, Denver. Col. These furnaces have been used with marked success in the heat treatment of metals, for assaying ores and refining cyanide precipitates, for annealing and enameling, and for melting brass and other foundry metals.

An important feature of the Case furnaces is the low-pressure oil burner, illustrated in Fig. 2. Oil is introduced usually by gravity (although high pressures can be used), and issues from the central part of the burner in a cone spray diverging at an angle of 45 deg. All air for combustion also goes through the burner, issuing from two annular rows of holes and forming a cone of jets converging at an angle of 60 deg. This produces an excellent mixture of oil and air which enters the combustion chamber of the furnace through a small opening of the same size as the face of the

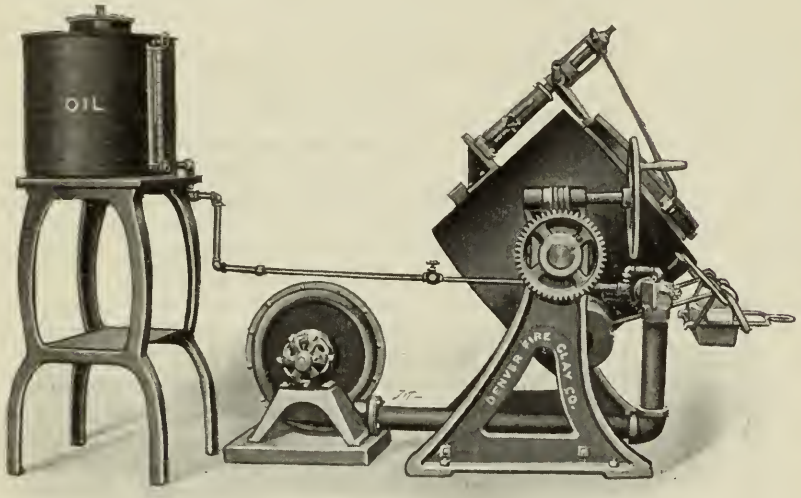

FIG. 1—OIL-FIRED TILTING CRUCIBLE FURNACE

burner, thus excluding auxiliary air. Both oil and air are under valve control, so that a mixture of proper proportion for complete combustion is easily maintained under all conditions. Air is supplied to the burner by a direct-connected motor-driven blower which runs at 3600 r.p.m. and delivers 3000 cu. ft. of air per minute at a pressure of about 6 oz. The fan has 20 blades of aluminium mounted in a cast-iron casing.

The advantages claimed for the low-pressure burner over those operating under high pressure are the freedom from noise, economy of fuel, control of air supply, perfect combustion without formation of carbon, and reduced wear and tear on the crucible and other parts of the furnace. The poor features involved in needle valves are entirely eliminated.

The burner is applied to a variety of furnaces constructed for special purposes. The one shown in Fig. 1 is a crucible furnace of the tilting type, with swinging frame to carry the mold while pouring and a cover that can be moved either vertically or laterally. This type of furnace is used for melting brass and other foundry metals, refining cyanide precipitates, and melting gold and silver bullion. Other types of furnaces are built for the heat treatment of steel, for annealing and enameling, and for assaying.

The tilting furnace illustrated, embodies many conveniences which relieve the operator of a vast amount of hard labor and protect him from the heat while pouring the charge. Between the steel shell and fire-clay lining is a layer of refractory insulating material which acts as a cushion during the expansion and contraction of the furnace, and conserves heat. The interior lining is of fire-clay tile, molded with numerous projections in the form of checker work, which support the crucible laterally. The crucible is molded with a lip that forms a pouring spout. A fire-clay stool in the combustion chamber supports the crucible from the bottom, the upper surface of the stool being channeled to permit circulation of heat around the bottom of the crucible.

The combustion chamber is below the crucible. The flame enters tangentially and complete combustion occurs almost instantaneously. The crucible and fire-clay

FIG. 2—FACE OF LOW-PRESSURE OIL BURNER

lining become highly heated as the gases of combustion rise through the checker work, and the lining radiates heat uniformly to all parts of the crucible.

The motor for the blower consumes 1½ kw. per hour. Oil consumption varies from ¾ gal. to 2 gal. per hour, depending on the nature of the work and the temperature required.

Numerous records for economy and efficiency have been established by Case furnaces. An assay furnace running 129.9 burner-hours consumed 179.8 gal. of 26 deg. Baumé fuel oil, or only 1.39 gal. per burner-hour. In another case the cost of fuel for assaying was reduced 60 per cent by the adoption of a Case furnace. An interesting comparison of fuel consumption under high-pressure and low-pressure air gave the following results: With high-pressure air 3200 gal. of oil was consumed in a month, firing three muffles; with low-pressure air the consumption was but 800 gal. for a month, and four muffles were fired.

Equally good records have been made for the tilting crucible furnace. In melting cyanide precipitate one of these furnaces used only 20 gal. of oil at 17.5 per gallon to accomplish the same results formerly attained by the combustion of 1000 lb. of coke at $16 per ton. The value of the slag was reduced from about $200 to $12 per ton. For remelting 1500 oz. of gold bullion the oil consumption at one mill was 1¾ gal. oil at 6 cents per gallon, as against the former use of 140 lb. coke at 1.12 cents per pound. In addition the time of operation was greatly reduced and the life of crucibles doubled. Another record made was the melting of 800 lb. cyanide precipitate in one hour with a fuel consumption of 1⅞ gal. of oil. In this case a saving of 66 per cent was made in fuel cost as compared with former practice.

Calibration Curve for Horizontal Cylindrical Tanks

Wherever horizontal cylindrical tanks are used for storage of fuel oil or other liquids, a simple method of calibrating becomes desirable. In Fig. 1 we show a

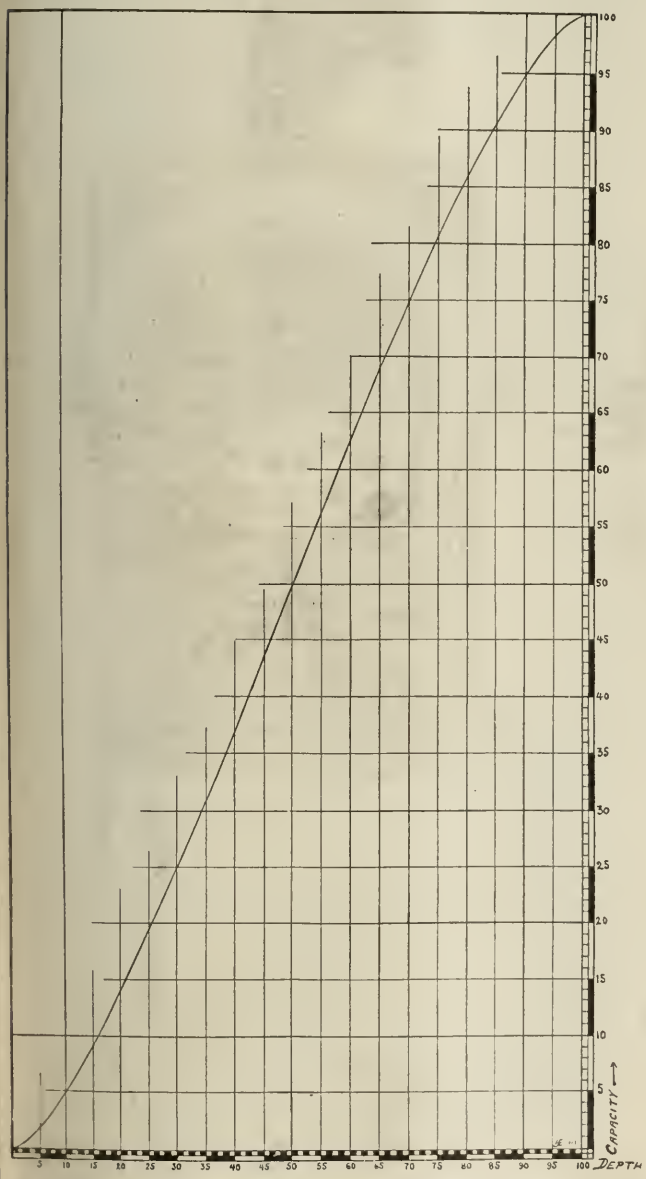

FIG. 1—CALIBRATION CURVE FOR HORIZONTAL CYLINDRICAL TANKS

calibration curve for such tanks of any dimensions, devised by Mr. H. J. Elson, Universal Iron & Supply Company, 325 Locust Street, St. Louis, Mo. The curve as here presented is somewhat reduced in size, but a full size curve can be secured on application at the address given.

The horizontal scale in Fig. 1 indicates percentage of total depth, and the vertical scale percentage of capacity. By entering the horizontal scale at the bottom with percentage of total depth, and rising to the curve, the percentage of total capacity corresponding to depth can be read at the right.

The total capacity of the tank in gallons equals the square of the diameter in feet multiplied by the length in feet, multiplied by 47, divided by 8; or, equals the square of the diameter in inches multiplied by the length in inches, multiplied by 17, divided by 5000.

To adapt the curve to a particular tank, a scale of gallons may be written in the column at the left by entering at the top, corresponding to 100 per cent, the capacity of the tank found by the above rule, and dividing it proportionately down to 0. The depth of the liquid in the tank may be taken in percentage of total depth by dividing into 100 parts a line or rod of length equal to the diameter of the tank, and then the scale can be read directly by way of the curve to gallons on the left. Or, a scale in feet and inches corresponding to the tank diameter may be put on the 0 to 100 depth scale, and the depth of liquid in the tank read from a line or rod divided in feet and inches.

Titanium-Aluminium Bronze Castings

BY W. M. CORSE

Practically every mechanical engineering handbook contains references to aluminium bronze, describing it as having the properties of good steel and in addition great resistance to corrosion. When the engineer is interested, however, in this metal and searches for a source of supply, he finds that rolled aluminium bronze can be bought from several reputable manufacturers, but he immediately encounters difficulty in securing it in the form of castings. Further inquiry develops the fact that while some foundries have made castings of this metal in the past the difficulties involved are so great that its manufacture has been practically discontinued.

The Institution of Mechanical Engineers of Great Britain, realizing the valuable properties of the copper aluminium alloys for engineering purposes, presented its eighth report to the Alloys Research Committee on this subject in 1907. This report contains a very exhaustive study of the metal commonly known as aluminium bronze and calls particular attention to the facts that it resembles a Swedish bessemer steel of 0.35 carbon to a remarkable degree and that the castings have practically the same physical properties as rolled material; this is a unique exception to the general rule.

That castings of copper and aluminium have the strength of steel and show up equally well under alternating stresses and impact tests is a fact worthy of more than passing notice.

The 10 per cent aluminum bronze has the following properties:

Ultimate tensile strength (standard test bar), 70,000 per square inch.
Elongation in 2 in., 20 per cent.
Hardness Brinell scale (500 kg.), 100.
Specific gravity, 7.5.
Weight per cubic inch, 0.27 lb.
Permanent compression under 100,000 lb. load per square inch, 12 per cent.
Coefficient of friction (Cornell University bearing testing machine), 0.0018.

It is practically non-corrodible in sea water and has a high resistance to corrosion in such chemical liquors

as the sulphite liquors in the paper industry and the tanning liquors in the leather industry.

On account of its high aluminium content the metal is approximately 16 per cent lighter than phosphor bronze and 10 per cent lighter than manganese bronze. When it is remembered that the strength of this metal is practically the same as manganese bronze and its wearing properties at least equal to phosphor bronze, the possibility of reducing weight through its use is certainly interesting from an engineering standpoint.

This metal is also analogous to steel in that it can be hardened by heat treatment. This is a very useful and unusual property for a bronze alloy to possess.

Recent letters from several prominent British manufacturers indicate that very little has been done in casting this material commercially in Great Britain. Similar inquiries in the United States reveal the fact that while aluminium-bronze castings are offered in some instances, either the quality or the price is not all that may be desired, thus practically barring this valuable metal from engineering specifications.

It is well known that small accounts of certain elements exert a profound influence on the properties of iron and steel, and it is, therefore, reasonable to expect that similar influences might be exerted upon certain copper alloys.

On this theory the Titanium Alloy Manufacturing Company of Niagara Falls, N. Y., put one of its research men on this problem with the result that it has found that small additions of titanium or its compounds exert a like profound influence on the properties of certain copper alloys, among which are the aluminium bronzes. After three years of careful research it was decided to build a foundry to manufacture bronze castings and to specialize on the aluminium bronzes. This is an important industrial achievement, and one which will enable the engineer to avail himself of these metals which have proven to be so important for many industrial uses.

That such an alloy can now be made commercially at a reasonable price is also notable.

Numerous uses immediately suggest themselves for castings having the properties enumerated above. Among these may be mentioned gears and gear wheels for high speeds and heavy loads, bearings for high-speed machinery, marine fittings exposed to sea water and parts exposed to the action of chemical liquors, parts requiring great strength and resistance to shock, and castings to withstand high pressures.

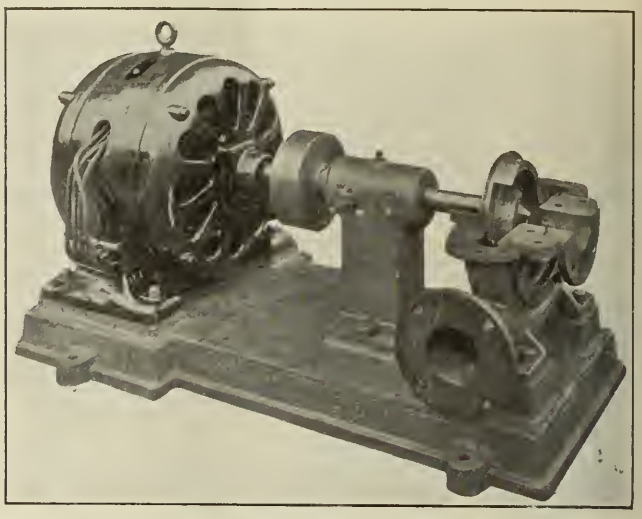
Centrifugal Pump for Thick Liquors

The cut shown herewith shows a high-efficiency type of centrifugal pump suitable for handling liquors containing large amounts of solids, chemicals, wood pulp, or gun cotton pulp solution. The impeller has very wide passages in proportion to its capacity, but its design is such that in spite of these wide passages a high efficiency is obtained, while the pump characteristic is such that no heavy overload is produced on the driving motor when the pump operates at pressures below the rated pressure, which is a condition occurring in most pumps made to handle thick liquors.

The pump has a horizontally parted case which facilitates access to the interior for convenience of inspection, cleaning and repairs. The pedestal bearing is equipped with two ball bearings operating in a housing packed with a non-fluid oil or light ball-bearing grease. They are so arranged as to carry not only the radial load but any thrust that may come on the pump in either direction. The impeller, however, is provided with a balancing ring so as to secure hydraulic balance.

On account of the large passes through the impeller, the pump is also very suitable for pumping sewage, as solids which would ordinarily choke up a small capacity impeller pass freely through the pump.

The particular pump shown in the adjoining illustrations is driven by a single-phase motor and for the purpose of keeping down the starting current a special centrifugal clutch coupling is provided, which allows the motor to come up to speed before the load comes on the



CENTRIFUGAL PUMP FOR THICK LIQUORS

motor. Either this type of coupling or the standard type of flexible coupling with steel pins and rubber bushings is furnished.

This type of pump is particularly suited for handling the nitrated cotton liquors in connection with the manufacture of gun cotton.

The pump is manufactured by the D'Olier Centrifugal Pump & Machine Company, Philadelphia, who make a full line of centrifugal pumps as well as centrifugal machines used for nitrating cotton and for general chemical purposes.

A New Assay Balance

An assay balance operated like a typewriter is a novel development in scientific instruments that is being

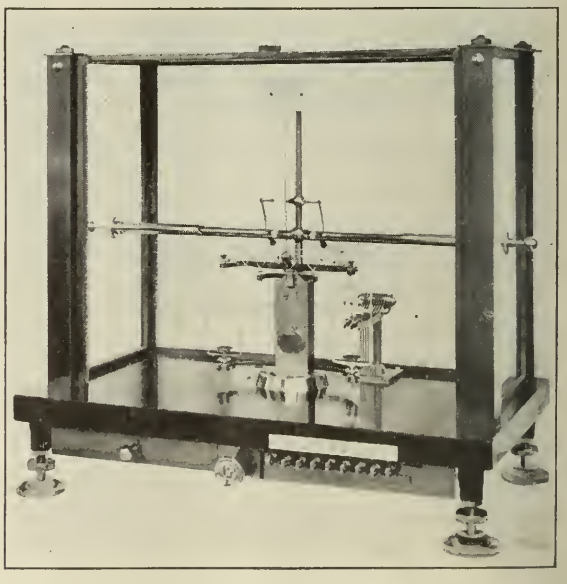


FIG. 1—A NEW ASSAY BALANCE

brought out by the Mine & Smelter Supply Company, Denver. Col. This balance is the invention of Mr.

Wilfrid Heusser, of Salt Lake City, Utah, who has for some time past been manufacturing a line of metal-case balances.

The feature of the instrument that marks a distinct advance in balance construction is the method of handling the weights, placing them on or removing them from the pan hanger. By merely pressing one or more keys which are in front of and outside the balance case, any weight or combination of weights can be deposited on the pan hanger. The balance is shown in Fig. 1, and a detail of the apparatus in Fig. 2.

The weights themselves consist of perforated discs, made of aluminium for the lighter and of platinum for

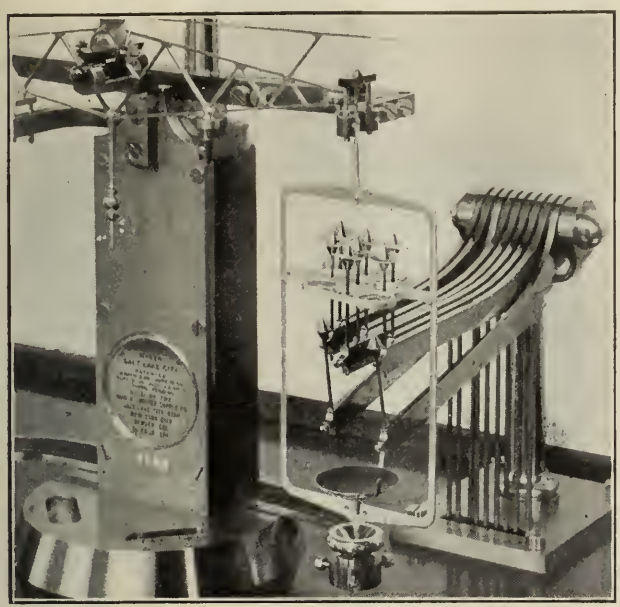

FIG. 2—MULTIPLE-WEIGHT DEVICE FOR ASSAY BALANCE

the heavier weights as is usually the case. Normally each disc is carried by one of a series of upright posts with conical tops, passing through a perforated horizontal frame which forms a part of the pan hanger. Each of these upright posts is operated by an individual key on a keyboard in front of the balance. On depressing a key, the corresponding upright post is lowered, and the weight, which is too large to pass through the perforation, rests on the pan hanger frame and registers its weight as though placed in the scale pan. In like manner, raising the key raises the upright post which, with its conical top, lifts the weight and removes it from the pan hanger frame. By this means any weight or combination of weights can be placed upon or removed from the pan hanger without opening the balance case. The device marks a distinct improvement over all previous forms of multiple-rider attachments, the object of which has been to avoid handling the weights with pincers as well as the opening and closing of the balance.

An analytical balance embodying the Heusser construction as to truss beam and metallic case has also been developed, and can be equipped with the same multiple-rider attachment just described.

Pan-Americanism

The Second Pan American Scientific Congress

BY GLEN LEVIN SWIGGETT

During the present year two great Pan American gatherings convene in Washington under the auspices of the Government of the United States. The first of these, the Pan American Financial Conference, occurred the week of May the 24th, 1915. In this conference delegates from the Latin American countries conferred with representative bankers and business men from our nation at the Pan American Union, on invitation of the Secretary of the Treasury, on financial questions of pertinent interest that must have far-reaching beneficial results to Pan American banking and commerce.

Of greater interest to the professional world, however, is the Scientific Congress that will convene in Washington beginning December 27, 1915, and concluding its sessions on January 8, 1916. Through the splendid cooperation of the Latin American countries, the second Pan American Scientific Congress, likewise held under the auspices of the United States Government through the Department of State, bids fair to be not only thus far the greatest Pan American Congress, but the most important international scientific congress ever held in the United States. The first congress of this name was held in Santiago, Chile, in 1908. It had its origin in earlier Latin American Scientific Congresses; and at the time of the Santiago congress was enlarged through the generous initiative of the Latin American countries to include the United States. This congress was well attended by visiting delegates from the United States. On its adjournment, entirely unsolicited on the part of the latter, Washington was designated as the place of meeting of the Second Congress.

This honor has a singular appeal to our nation at this time. The present European war has brought the Western Hemisphere suddenly face to face with grave economic problems that invite the serious attention of scientists and experts in the various fields of applied science. The Scientific Congress will concern itself with the constructive discussion of these as well as with the contributions in the domain of pure science wherein great advance has been made since the last congress in Santiago, Chile. Science is comprehensively defined by the congress and includes, under nine heads, such main subjects as: Anthropology, Astronomy, Meteorology and Seismology, Conservation of Natural Resources, Agriculture, Irrigation and Forestry, Education, Engineering, International Law, Public Law and Jurisprudence, Mining and Metallurgy, Economic Geology and Applied Chemistry,* Public Health and Medical Science, Transportation, Commerce, Finance and Taxation.

Washington offers unusual advantages for a congress of this nature. It enjoys an enviable distinction among the world capitals for the keen scientific interest and investigation in its various Federal Bureaus, the varied and extensive nature of its libraries and museums, the beauty of its buildings and the growing importance of detached but semi-official institutions and bureaus engaged in work of international scope. Among these none occupy a position of greater importance than the Pan American Union, the governing board of which, composed of the diplomatic representatives of the participating Latin American countries with the Secretary of State of the United States as ex-officio chairman, has signally honored the Second Pan American Scientific Congress by authorizing the use of its beautiful building for the office and sessions of the congress. The board also, in response to the request of the President and Secretary of State of the United States, authorized to act as secretary-general of the Scientific Congress the Director-General of the Pan American Union, the Honorable John Barrett, who has doubtless done more than any one American in the establishment of commerce and comity among

*The chairman of this section is Mr. Hennen Jennings.

the republics of the western world; whose good fortune it has also been to see, through the seeming accident of war, the potential promise of his great work becoming realized so soon.

The Feasibility of Continuous Causticizing

This article will be devoted to a discussion of the feasibility of adapting continuous agitation and continuous counter-current washing to causticizing soda ash by means of lime, according to the equation

$$Na_2CO_3 + CaO + H_2O = 2NaOH + CaCO_3$$

The application of these two features to metallurgical problems, especially in the cyanide treatment of gold and silver ores, has met with great success and it is believed that in other fields where the agitation of solids in liquids and the subsequent washing of the solids free from liquid containing dissolved substances is practised, the possibility of their use will be of economic interest.

Continuous operation invariably means lower labor costs and a high load factor, thus assisting in lower power costs and interest charges. Where the change from intermittent to continuous work does not sacrifice control of the operation, it results usually in allowing a large output of uniform nature.

From a mechanical standpoint the problems of a scheme for continuous causticizing are readily solved by the use of Dorr continuous thickeners and Dorr agitators.

The Dorr continuous thickener, Fig. 1, consists of a slow-moving mechanism placed in a suitable tank, by means of which the operation of settling may be made continuous through the removal of the settled material to a point of discharge and the prevention of the accumulation of solids in the tank.

It consists of a central shaft with radial arms equipped with scrapers to bring the thickened material to the discharge opening at the center of the tank by the slow rotation of the mechanism. The thick material may be

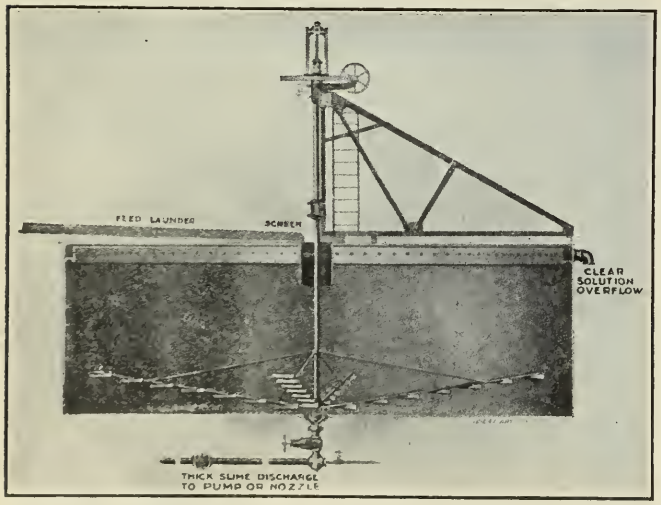

FIG. 1—CONTINUOUS THICKENER

discharged at this point into a launder, or piped to the side of the tank and raised by pump or other suitable means to the level of the overflow or higher.

The machine is arranged for raising the shaft so that the arms will not become imbedded in the thick material if the power should be shut off for any length of time. The shaft can be lowered again gradually while running.

The thickener has been operated at speeds ranging from one revolution in two minutes to one revolution in forty minutes, depending upon the nature of the solids to be settled out. The power required varies with the size of tank, but for mechanisms to be operated in tanks up to 40 ft. in diameter ½ hp. can be allowed for each machine when driving several from one line shaft.

Normal operation of the thickener causes no wear except on the worm, and many machines are operating to-day that have not cost a cent for repairs in several years. The attendance required varies with the regularity of the conditions maintained and is usually confined to lubrication two or three times per twenty-four hours.

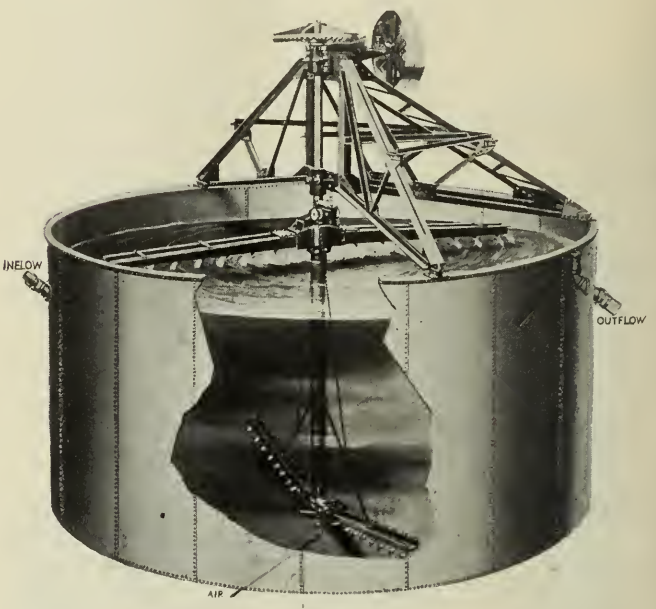

FIG. 2—AGITATOR

The illustration of the agitator (Fig. 2) will give a good idea of the machine, which is very much like the thickener, the central shaft being replaced by a pipe at the top of which distributing launders are arranged so as to distribute the material as it is raised through the pipe by means of air, the solids as they reach the bottom being raked to the center by the arms as in the thickener. The arms are arranged so that they can be raised, in which position the machine is easily started after a shutdown.

From a theoretical viewpoint the use of air in agitating caustic soda solution would be detrimental because of the possibility of reverting the caustic to carbonate, due to the CO_2 content. No data is at hand on this point, but men, both technical and practical, who are actually engaged in making large amounts of caustic soda solution, have been consulted and the consensus of opinion is that the small amount of air required, 6 to 10 cu. ft. per minute at 15 lb. pressure, would not produce a noticeable effect in practice.

The installation for a scheme such as proposed here would consist of a series of possibly two or three agitators and three or four thickeners for washing the lime mud. Referring to the flow sheet shown in Fig. 3, lime and soda ash sufficient for twenty-four hours' operation are to be reduced to ¼ in. and smaller and stored in the hoppers. Crushing becomes necessary in order to insure against the presence of unslackable lime in large lumps to cause trouble in the agitating and washing system. However, the operation could be cheaply effected while filling the hoppers each day by means of suitable crushers.

From the hoppers the lime and soda ash would be fed continuously and in the desired proportion to the first agitator of the series, either with an endless belt with

hopper-gate control or by other suitable devices, many of which are on the market. Weak solution from the washing system would be transferred directly to this agitator as indicated.

A series of agitators are advisable because it reduces the possibility of "short-circuiting," that is, the escape of lime or soda ash from the agitating system before they have had time to react. The size of the agitators in such a system is a function of the time required for the reaction to come to an end or, in other words, reach chemical equilibrium. Sufficient capacity would be necessary to allow the required time.

The heat necessary to maintain the desired temperature would be best supplied by steam coils in each agitator.

The mixture would gravitate between the agitators and finally to the first of the series of thickeners "*X*."

Overflowing from thickener *X* would be the clear caustic solution for storage and use. The lime mud as it settles out would be discharged and transferred to the succeeding thickener *Y* by means of a pump, being thoroughly mixed with the wash liquor flowing from thickener *Z* in the feed launder before entering the tank. The overflow from thickener *Y*, as previously mentioned, would be transferred directly to the first agitator and the lime mud discharged and transferred to thickener *Z*. Wash water would be introduced into the feed launder of this last thickener and mixed thoroughly with the lime mud which would be discharged from this last machine with a very low caustic soda content.

It would be feasible to feed the "mud" from this last thickener to a continuous dewatering filter and thence to calciners, so that the carbonate of lime will be reduced to calcium oxide and may be returned to the causticizing system for reuse.

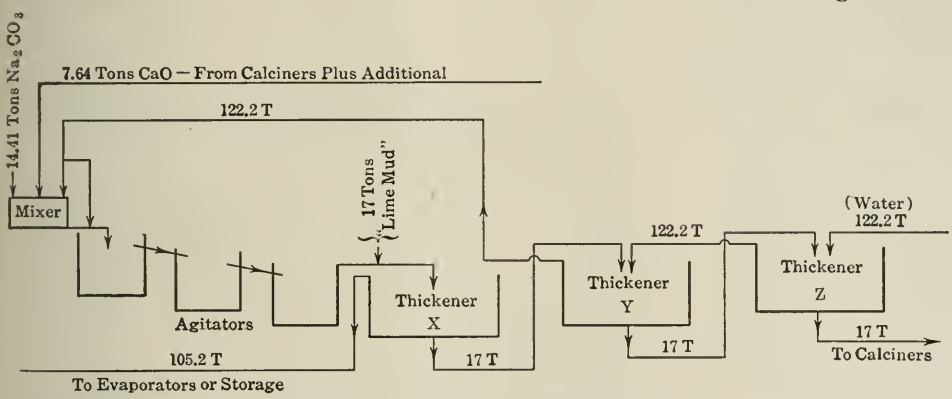

FIG. 3—FLOWSHEET OF PROPOSED PROCESS OF MANUFACTURE OF CAUSTIC SODA FROM SODA ASH AND LIME, USING CONTINUOUS AGITATION AND CONTINUOUS COUNTER CURRENT WASHING

The objects to be attained by continuous counter current washing are the dissolution under most favorable conditions of a portion of the solids treated, the separation of a solution from a finely divided solid with minimum dilution or both. It would appear that both would be expected in connection with causticizing.

Worthy of notice in such a system is the possibility of the reversible reaction involved coming to equilibrium under the most favorable conditions. It would reach this point in exactly the amount of water that goes to storage from the system as strong liquor. The washing, as will be noticed from the flowsheet in Fig. 3, yields absolutely no weak liquor, with accompanying dilution, to be added to the storage solution.

The following calculations show the results that may be expected by washing the lime mud in such a system as the one proposed. They are made along lines which have found wide favor in metallurgical work because they have given results which compare very closely with those obtained in actual practice.

T = Tons of water.

Conditions Assumed:

1. Ten tons NaOH produced in twenty-four hours.
2. Overflow from thickener "*X*" to have approximate Sp. Gr. 1.1 (190 lb. per ton).
3. Yield of NaOH, 92 per cent of theoretical.
4. Sufficient time of agitation to complete reaction.
5. Lime mud discharged from all thickeners with approximately 1 part water to 1 part lime mud.

Let *X*, *Y* and *Z* equal tons dissolved NaOH per ton water in respective thickeners.

Equating values *out* and *in* of each thickener:

1. $105.2\,X + 17\,X = 122.2\,Y + 10$ tons.
2. $122.2\,Y + 17\,Y = 17\,X + 122.2\,Z$.
3. $122.2\,Z + 17\,Z = 17\,Y$.

Then $X = 7.32\,Y = 0.0948$ ton = 189.6 lb. per ton.

$Y = 8.2\,Z = 0.0129$ ton = 25.8 lb. per ton.

$Z = 0.00158$ ton = 3.16 lb. per ton.

From the above the following results are deduced:

Liquor going to evaporators or storage contains 9.974 tons NaOH.

= 189.6 lb. NaOH per ton water.

= 8.68 per cent.

= 94.8 grams per liter.

= 13.2 deg. Baumé.

Washing efficiency = 99.7 per cent. No data are available now to bear out these figures.

A careful study of continuous counter-current decantation as practised in gold and silver metallurgy, with some knowledge of the operation of the standard type of causticizing plant as used in the soda, pulp and soap industries, leads the author to summarize in favor of an installation described as follows:

1. The personal element, so prevalent in intermittent work with the possibility of attendant losses in charging, agitating, decanting and washing, would be reduced to a minimum.

2. The reaction would proceed under the most favorable conditions for the production of a solution of a given strength, thus insuring the highest possible yield of caustic soda at all times, and the washing would be accomplished with the least possible water.

3. A relatively large amount of caustic solution of uniform strength would be made in a very compact plant. The installation meeting the requirements set forth in Fig. 3 and the accompanying assumed conditions would require a space of 40 ft. square.

4. The power consumption would be very small. Referring again to Fig. 3, 10 hp. delivered to a line shaft would be more than sufficient to run the six machines and the pumps.

5. The labor required would consist of filling the feeding hoppers. The actual attention to the plant beyond this point would consist of oiling the driving mechanisms, and this could be intrusted to a man whose principal duties were elsewhere.

It is interesting to note that the principles set forth here are the same that have largely taken the place of intermittent decantation and filtration methods in the treatment of metalliferous ores during the past few years, and are now finding their way slowly into numerous other fields of industrial work. R. W. S.

Gas Blowing Engines at the Steelton Plant of the Pennsylvania Steel Company

The advance in the design of blast-furnace blowing equipment during the last five years has been very marked. The directions of progress stand out prominently. First, rotative speeds and piston speeds have been doubled; second, complications in valve gearing have been eliminated, and, third, automatic lubrication has been perfected to such an extent that the cost of attendance and repairs has been materially reduced. All three lines of progress are represented in the two new gas blowing engines which the Mesta Machine Company recently installed at the plant of the Pennsylvania Steel Company in Steelton, Pa. These engines are the largest gas blowing engines ever built in the United States; the gas cylinders are 46 in. in diameter, the

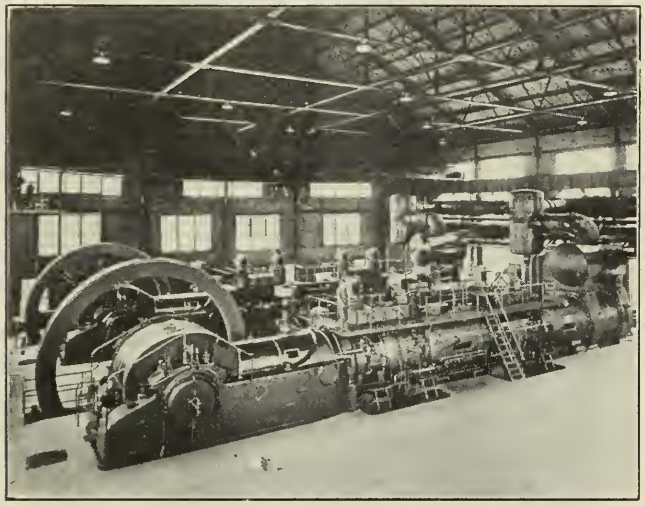

FIG. 1—GENERAL VIEW OF GAS BLOWING ENGINE

air cylinders are 84 in. in diameter and the stroke is 60 in.

As will be seen from the general view, Fig. 1, each of the engines consists of two gas cylinders and one blowing cylinder in tandem. The blowing cylinder is entirely free from valve gearing. The elimination of valve gearing has been made possible by the use of the Mesta automatic plate valves (Iverson patent) which has been so often described and is so well known that no further description is needed here.

The absence of mechanical valve gearing made possible another important step forward; namely, the placing of the blowing cylinder back of the gas cylinder, in contradistinction to previous American practice in which the blowing cylinder was placed on the opposite end of the bed plate and was connected to the main engine crosshead by rods which were arranged to clear the crank and crank pin.

Considered from an engineering standpoint the old American design is wrong. The rods connecting the main crosshead to the blowing piston necessitate a weak crank as well as openings in the bed plate which weaken the latter. Several broken bed plates of gas blowing engines can be traced directly to this design of crosshead, crank and blowing cylinder rods. In the Mesta engines this difficulty does not exist. The position of the blowing cylinder back of the gas cylinder eliminates the rods passing from the crosshead around the crank and leaves the designer free to arrange the bed plate and crank for maximum strength, rigidity and wearing qualities. Furthermore, it made possible the use of a rigid and symmetrical bed-plate construction which is identically the same no matter whether the engine be used for blowing purposes or for the generation of electric power.

The arrangement of cylinders selected by the Mesta Machine Company is the one which is used on practically all gas blowing engines in Europe. American engineers not familiar with European practice have criticised this design stating that trouble might be experienced on account of unequal expansion of the stationary cylinders and the moving rods, and, that such a long train of cylinders would cause an excessive elastic stretch at the end of the blowing cylinder. Results with the Mesta engines just installed prove that any such fears are groundless. The location of the moving parts compared to the stationary parts was carefully measured

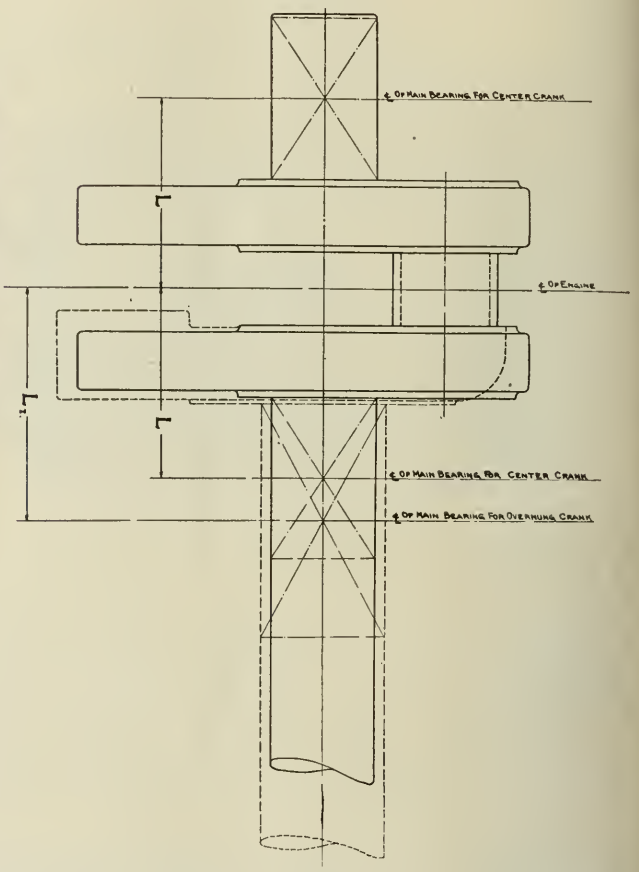

FIG. 2—COMPARISON OF CENTER-CRANK AND SIDE-CRANK CONSTRUCTION

before starting and was again measured immediately after a shutdown following several days operation. The difference in measurement was negligible. Furthermore, the total elastic stretch of the engine measured at the farthest point of the blowing cylinder is imperceptible. A five-cent piece can be balanced on edge in any direction on any stationary part of the engine. In fact, there is less vibration in these engines than is found in ordinary steam blowing engines.

With the Mesta engine the center crank was adopted because its use reduces the bending moment on the shaft to such an extent (compared to the side-crank construction) that a shaft of smaller diameter can be used and yet an engine with a much greater factor of safety results than would be possible with a side-crank construction. In order to illustrate this fact Fig. 2 was prepared in which is shown in full lines the present crank shaft of the Mesta engine and in dotted lines a side crank shaft designed with the same factor of safety. It is evident that the use of the center crank provides a more rigid and safer bed-plate construction with the same weight. In the center-crank design the

characteristic side strains found in the side-crank design are practically eliminated. While the total weights of the center crank shaft and of the side crank shaft are approximately the same, the center crank shaft is of smaller diameter, thus making a smaller opening in the bed plate and making it stronger.

The center crank eliminates one of the most objectionable features of the present-day American gas engine, namely the one-piece design of crank and crank pin. In the one-piece design of the side crank, the pin is cast integral with the crank and must therefore be of a more open-grained or spongy material than a forged crank pin. The builders of large steam engines fought consistently against steel-casting crank pins and would never have consented to the design which was used for about a decade on the gas engine. It is somewhat surprising that American engineers should have held so long to the side-crank constructions in gas engines, when a very simple calculation shows the advantages of the center crank for heavy stresses. In reversing engines for rolling mills where the stresses due to the inertia of reciprocating parts are very great, the center crank has been used for years, and, as already stated, all European gas engines are built with the center crank.

As one of the foremost builders of mill reversing engines in America, the Mesta Machine Company has had considerable experience with center-crank engines, so that it was natural for their engineers to adopt the center crank on large gas engines.

The Mesta engine follows the recent tendency in gas-blowing practice to make blowing engines of the single tandem design rather than to build twin engines. The single tandem engine is preferable from the standpoint

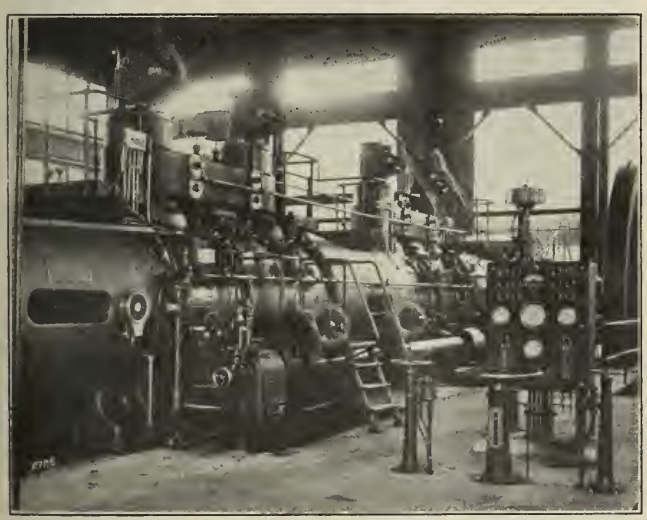

FIG. 3—SWITCHBOARD AND CONTROL HAND-WHEELS FOR GAS BLOWING ENGINES

of first cost and of reducing to a minimum the number of moving parts which require attention. There is only one crank pin and one crosshead and a comparatively small number of valve-gear parts. It is true that each part is larger, but size offers no difficulties in manufacture, so that the single tandem blowing engine will undoubtedly become the standard type.

While heretofore strenuous objection has been made to the gas engine from the standpoint of complication and a multiplicity of moving parts, it can be safely stated that the new gas engine contains a considerably smaller number of moving parts than a cross-compound Corliss engine. Indications are, therefore, that the up-keep and maintenance of this type of engine will be less than that of the cross-compound steam engine.

In the design of the gas cylinders particular attention has been given to the matter of obtaining a sound homogeneous casting absolutely free from strains caused, first, by shrinkage after casting, and, second, by the difference in expansion in service between the outer and inner walls. It was, therefore, decided to make the cylinders in halves of fairly soft close-grained air-furnace cast iron and to securely connect the two halves in the center. By the use of this grade of iron there is less chance for fire cracks to develop than with iron of a harder grade. In order to obtain a good wearing surface, the cylinders were lined with a hard close-grained iron bushing extending over the entire stroke of the piston.

The modern gas blowing engine is just as reliable as the steam engine and, in fact, more reliable. It can be started in less time and does not need to be warmed

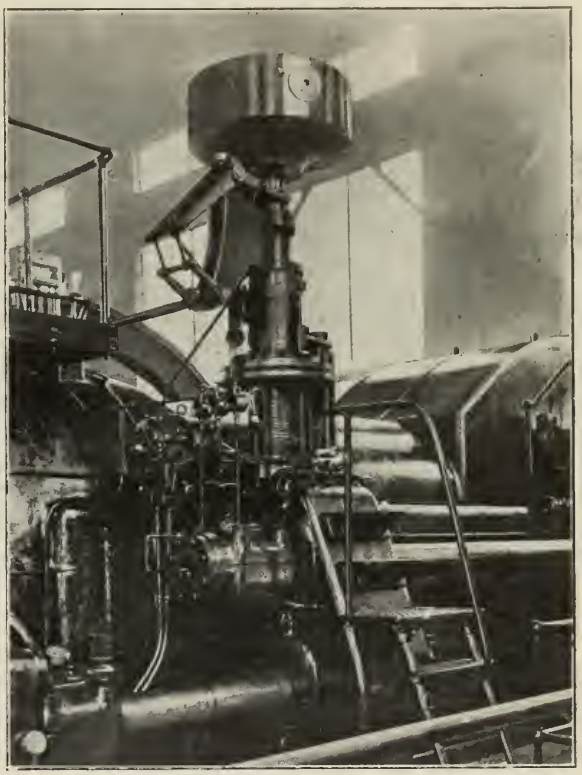

FIG. 4—GOVERNOR AND SPEED-CHANGING DEVICE

up. The Mesta gas blowing engine at the Pennsylvania Steel Company can be started and put on the furnace in less than one minute. This rapidity of handling is made possible by the concentration of all the operating levers and hand wheels on one operating stand.

Fig. 3 shows the switchboard and the control hand wheels. Fig. 4 shows the governor and the speed changing device. When the signal is received from the furnace to slow down the engine, a switch, thrown in at the control stand, changes the tension of the spring in the governor column and thus reduces the speed. As soon as the desired speed is obtained the switch is pulled out. "It beats the throttle all hollow" is the verdict of the operating engineers. The speed-changing device, which is operated by motor drive, is provided with limit switches so that it is impossible for the engineer to exceed the speed-change limit set by the designer of the engine.

Among the minor details contributing toward the success of the engine may be mentioned the exhaust valves which are not water-cooled. The valve seat is cooled and the valve itself can convey enough heat to the valve seat to protect itself. It has been said that a

gas-engine exhaust valve must withstand the action of a red-hot flame passing through it. Theoretical calculations and actual measurements show that the gases passing the exhaust valves are never hotter than 1100 to 1150 deg. Fahr., unless combustion is sluggish during the explosion stroke and continues up to the time when the gases pass through the valve into the exhaust. With a correctly designed engine and ordinary care in operation, combustion is completed before the exhaust valve opens so that water-cooling becomes wholly unnecessary. The operation of the engine at the Pennsylvania Steel Company proves conclusively that water-cooling of the exhaust valve in a properly designed blast-furnace gas engine is a needless complication. It is easily seen that the elimination of water-cooling of the moving valve does away with parts which have previously given trouble in practical operation.

The oiling system for these engines consists of two individual filters, one for each engine, the filters being placed as one unit with one large clean-oil receiver. The

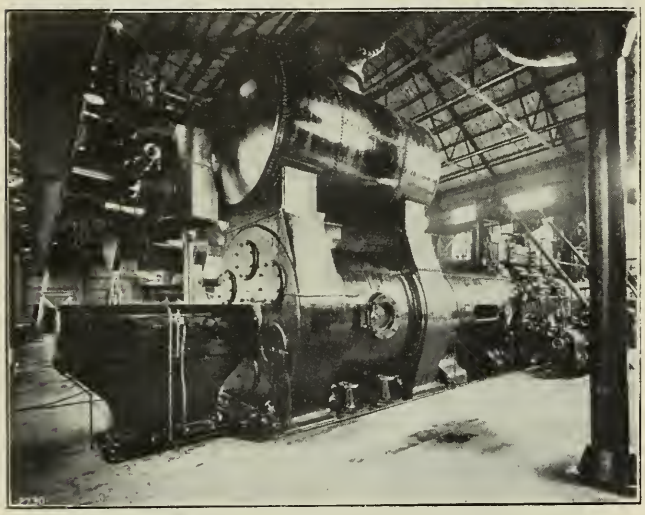

FIG. 5—SNORTING DEVICE AND AUXILIARY CLEARANCE

oil from this receiver is pumped into the system by means of a motor-driven triplex pump running at a very slow speed in order to prevent churning of the oil. This pump delivers the oil to the system at a pressure of 30 lb. per square inch and is equipped with an automatic by-pass which allows the oil to flow back into the clean-oil compartment whenever the pressure exceeds 30 lb. For the purpose of safety there is placed in the system a duplex pump which is connected up to the compressed-air line, also to the steam line, and is controlled by a Foster regulator. If anything should happen to the motor-driven pump and the pressure in the system thereby drop below 30 lb., the duplex pump will automatically start up and thus maintain a constant oil pressure in the system. The filter unit is made by the Richardson Phenix Company of Milwaukee and is capable of handling 800 gal. of oil per hour.

The lubrication of the crank pin is rather unique, in as much as the pin can be supplied with oil from two independent sources. Under ordinary conditions, oil is fed to the pin through the hollow shaft, and the supply coming from the gravity system is controlled by an extra large sight feed. In case of partial clogging of this regular supply, pressure from the oil pump can be turned directly into the pin through a large pipe, thereby flooding, cleaning and cooling it.

Each end of each cylinder is provided with three igniters of the mechanical make-and-break type. A very simple and effective device is arranged on the end of the lay shaft for the purpose of advancing or retarding all igniters. Each cylinder has its separate circuit with coils, switch, fuses and tell-tale lamp. The spark coils, as well as the tell-tale lamps and switches, are arranged on the instrument board immediately in front of the starting stand so that the operator can conveniently check the operation of the ignition system. Arrangement is made on the cylinders so that any igniter can easily be removed while the engine is in operation.

The regulating gear of the Mesta engine is exceedingly simple and efficient. Each cylinder end contains plain butterfly valves, one for gas and one for air. These valves are located immediately in front of the main inlet valve and are free to rotate without coming into contact with any rubbing surface that might cause friction. Since the vanes of these valves are very thin, there is no possibility for any impurities in the gas to collect thereon and make them "sticky."

The governor action upon these valves is such as to obtain a combination of quality and quantity regulation which has proved to be the most correct and efficient method of regulating gas engines.

Since the butterfly valves are practically balanced, it is obvious that the resistance to governor control is very small, and that the governor can act directly on the valve gear, without the interposition of an oil-relay with all its complications.

Turning again to the blowing end of the engine, the photograph shows that there is a large receiver on top of each blowing cylinder. This receiver protects the blast line from vibration. From the action of the ordinary speaking tube, it is well known that vibrations sent into a cylindrical tube are transmitted long distances without diminution of the amplitude. To damp the vibrations it is necessary to interpose receivers in the line. The closer these receivers are to the place where the vibrations are produced, the better it is for the pipe line. On the Mesta engines, there are two receivers in series close to the engine, one receiver directly on the blowing cylinder and the other a short distance away. The last-mentioned receiver acts as a distributor for the two blast lines.

For ease of handling of the engine two additional devices are of importance; namely, that for the variation of clearance space and the snorting device. Blowing engines for blast furnace service, as is well known, are subjected to peculiar conditions, as the blast pressure may at times rise to 50 per cent above its normal value. If the blowing end and gas end are properly proportioned for the average conditions the gas end is too small for the emergency condition. The Mesta Machine Company has overcome this trouble by a combination of a snorting device and auxiliary clearance. In the bed plate under the blowing cylinder are two Mesta automatic plate valves which in ordinary operation of the engine are kept open by hand-wheel operated screws. The hand wheels will be noticed under the blowing cylinder in Fig. 5.

Furthermore some of the inlet valves at each end are connected to a piston which is controlled by compressed air. Ordinarily these valves operate just like the other inlet valves, but if the small hand lever visible at the outer end of the horizontal diameter of the blowing head is turned 90 deg. the above-mentioned inlet valves are kept open. Keeping open the valve in the inlet duct permits the air to be moved in and out by the piston through the open inlet valves so that there is no air delivered. This device is made use of in starting or in changing stoves, etc. If the valves in the bed plate under the blowing cylinder are closed and the inlet valves are kept open, clearance volume is added.

The effect of clearance, as is well known, is to reduce

the delivery of air and to reduce the mean effective pressure. The reduction of mean effective pressure is made use of, if the blast pressure rises beyond 22 lb. per square inch with poor blast-furnace gas or beyond 25 lb. per square inch with good blast-furnace gas. Depending upon the amount of pressure rise above this critical pressure clearance volume is added either to one or both ends of the blowing piston. The volume of air delivered is maintained by speeding up the engine. The engine is designed for a maximum speed of 85-p.m. and has been run successfully at this speed.

Another point of considerable value to the operator of these engines is the ease with which the changing of air delivery from one blast line to another can be accomplished. In each blast-line connection from the second receiver, mentioned above, there is placed a valve operated by compressed air. These valves are controlled from the operating stand and by means of throwing a small hand lever the changing over from one line to another can be accomplished in a few seconds, whereas in older installations of this kind, it took considerable time and manual labor to make the change.

The Pennsylvania Steel Company has installed Venturi meters both in the gas and in the blast mains so that a check can be kept on the performance of the engine. Arrangements are now being made to calibrate these Venturi meters before they are put into actual service. It is expected that a thorough test for volumetric efficiency, gas consumption, regulation, etc., will be made shortly.

Army and Navy Officers Go to Private Plants

A number of army and navy officers have been permitted to resign from the public service to engage in work for private plants turning out arms and ammunition. Among these have been Lieut.-Col. O. C. Horney, U. S. A., formerly in charge of the Picatinny Arsenal; Major William A. Phillips, U. S. A., formerly in charge at the Sandy Hook Proving Grounds; Naval Constructor William E. Ferguson, U. S. N., and Naval Constructor John E. Otterson, U. S. N.

The resignations were held up several weeks, pending a conclusion as to policy by the Government. So far as the army officers are concerned, Secretary Garrison consented to the withdrawal of his officers on the theory that the safety of the United States might eventually rest upon the adequate development of the country's commercial gun and ammunition factories.

So far as the naval officers are concerned, Secretary Daniels took the position, without the announcement of a policy, that the officers in question had fulfilled agreements to serve at least eight years in the service of the United States, entered into when they began their studies at the Naval Academy. Secretary Daniels has always denied that naval officers, after being educated at the government's expense, have the right to resign.

All the officers are to receive salaries far exceeding those paid by the United States Government. In one case this is as great as five times as much as the Government salary, plus a bonus.

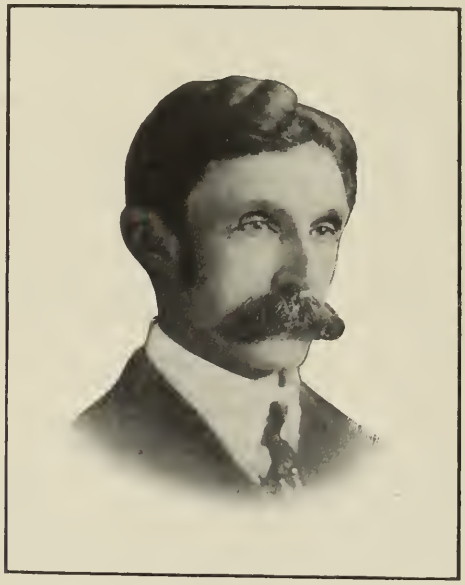
The army officers are to superintend the erection of new plants. Colonel Horney is to be employed by the Aetna Explosives Company. The naval officers are to enter the employ of private shipbuilding plants.

Obituary

Gail Mesereau died on July 14 in Cayuga, N. Y., of cerebral meningitis, superinduced by poisoning by noxious gases. He was a distinguished technologist and a popular chemist. He was born at Cayuga, N. Y., Sept. 9, 1879, was educated at Cayuga, Auburn and Syracuse, and graduated from Columbia University in 1903 with the degree of B.S. For two years he was chemist to the Susquehanna Dye and Silk Works at Williamsport, Pa. He was successively silk chemist, consulting chemist to the Panama Canal Commission, chief chemist Standard Oil Co. of New York, and consulting chemist and chemical engineer. At the time of his death he was engaged in the manufacture of explosives. He was at one time president of the Columbia University Chemical Society. Was a member of the Chemist's Club, the American Chemical Society, the Verein Deutscher Chemiker, and other scientific organizations.

Joseph Austin Holmes

Dr. Joseph A. Holmes, Director of the United States Bureau of Mines since its organization five years ago, died in Denver, Col., July 12, aged fifty-five years. While the news of his death will come as a shock and surprise to those who knew nothing of his condition, it was not unexpected by his co-workers and intimate friends. About a year ago he was persuaded to relinquish the active direction of the Bureau and go to Fort Bayard, N. M., for a prolonged rest. His recuperation was slow, however, and after a severe setback he was brought to Denver last May.



THE LATE JOSEPH A. HOLMES

Joseph A. Holmes was born at Laurens, S. C., in 1859. His early education was received in the South, but later he attended Cornell University, graduating there in 1880. In 1881 he was appointed professor of geology and natural history in the University of North Carolina, remaining there for ten years and continuing for some time thereafter as a special lecturer. For three years following his professorship he was State Geologist of North Carolina. When the St. Louis Exposition was held in 1904 Dr. Holmes was chief of the Department of Mines and Metallurgy. Following this engagement he was placed in charge of the laboratory. of the U. S. Geological Survey for testing fuel and structural material, and was later made chief of the technologic branch of the Survey. When the Bureau of Mines was organized in 1910 Dr. Holmes was appointed Director and continued in that position to the time of his death.

All who knew Dr. Holmes were acquainted with his

habits of industry and incessant activity. Personal sacrifice was not considered or allowed to interfere with the numerous duties which he took upon himself. His official travels took him over the entire United States and to Alaska and Panama, and gave him a wider acquaintance among mining men than falls to the lot of most officials. To the end he maintained an active interest in the conservation of life and resources in the mineral industry, and his work to promote the safety and health of others stands as a monument to his memory. Although frequently cautioned to conserve his own health and energy, his friends found it impossible to prevent him from actually sacrificing himself to the cause to which he was devoted. Suffering exposure and undergoing hardships in Alaska and in mines, he contracted tuberculosis, which caused his death. He is survived by his wife, two sons and two daughters.

Technical Section of the American Paper and Pulp Association

A characteristic sign of the times is the formation of the Technical Section of the American Paper and Pulp Association. It has been organized for the consideration of problems affecting cellulose and paper chemistry, machine design, and the various branches of mechanical and chemical engineering which engage the study of paper mill operators.

The executive committee consists of Mr. Henry E. Fletcher (Fletcher Paper Co., Alpena, Mich.), chairman, and Messrs. W. G. MacNaughton (Nekoosa-Edwards Paper Co., Port Edwards, Wis.), and Ernest Mahler (Kimberly-Clark Co., Neenah, Wis.). Mr. Thomas J. Keenan, editor *Paper*, is secretary-treasurer. The committee on publication consists of Messrs. Charles F. Rhodes (International Paper Co., Glen Falls, N. Y.) and Henry Oberman (Hammermill Paper Co., Erie, Pa.).

Personal

Mr. **J. V. N. Dorr** spent part of the month of July in Colorado and will be in San Francisco in August.

Mr. **Frank R. Farnham** has joined the staff of Walter B. Snow, Publicity Engineer and Advertising Agent, Boston. Mr. Farnham was previously with the McGraw Publishing Co., in charge of the copy service department.

Mr. **N. L Heinz** is engaged in designing and erecting the new zinc and acid plant for the American Steel & Wire Co. at Donora, Pa.

Mr. **Archibald Jones**, who has been general manager for the Bartlesville Zinc Co., Bartlesville, Okla, has been appointed to a similar position with the American Zinc & Chemical Co., at Langeloth, Pa.

Mr. **Milo W. Krecji**, formerly metallurgist at the Boston & Montana Reduction Works of the Anaconda Copper Mining Co., has been promoted to the position of assistant superintendent. He is succeeded in his former position by Mr. E. S. Bardwell, who has been general foreman of the concentrator.

Prof. **Charles E. Locke**, of the Massachusetts Institute of Technology, was a recent guest of "Tech" alumni at Denver. After an informal dinner Professor Locke gave an illustrated lecture on the new home of the Institute, which is expected to be occupied in September, 1916.

Mr. **W. E. Lummus**, of Boston, was in New York and reported great activity in the distillation field.

Mr. **J. B. McKennan** has been made general manager of the Colorado Fuel & Iron Co., and is succeeded as manager of the Minnequa works by Mr. **F. E. Parks.**

Mr. **H. M. Montgomery**, Chairman of the Chicago Section of the American Society of Mechanical Engineers has been elected vice-president and director of the Powdered Coal Engineering & Equipment Co. of Chicago. This company is preparing elaborate plans for the construction and equipment of a large demonstration plant and research laboratory in Chicago where working demonstrations of the adaptation of powdered coal as a fuel to all forms of furnace heat production will be carried on under engineering observation, aided by every influence that scientific research can bring to bear on the production of perfect combustion.

Mr. **Irving A. Palmer** has been appointed superintendent of the Altoona, Kan., zinc smelter of the U. S. Smelting, Refining & Mining Co.

Dr. **William B. Phillips** has been elected president of the Faculty of the Colorado School of Mines and will assume the duties of his office Aug. 1. For some years past Dr. Phillips has been engaged as director of the Bureau of Economic Geology and Technology of the University of Texas.

Mr. **A. M. Plumb** has returned to the Denver office of the American Zinc Ore Separating Co. after a stay of several months at the ore-dressing plant at Plattville, Wis.

Mr. **F. W. Sherman** has resigned his position as superintendent of the Daly-West mill at Park City, Utah.

Book Review

The Cementation of Iron and Steel. By Dr. **Federico Giolitti.** Translated from the Italian by **Joseph W. Richards** and **Charles A. Rouiller.** Price $4.00 net, New York. McGraw-Hill Book Co.

In seeking for words to describe the place which this book occupies in the literature of the industry one may say that what has been done in the past thirty years for our knowledge of the physical properties of steel by Tschernoff, Sorby, H. H. Campbell, and Howe, has been done for the cementation of steel by Giolitti. The empirical rule of thumb which formerly controlled the processes of cementation and case hardening, Giolitti has converted into scientific formulæ; what reliable information existed previous to his work, he has collected and classified; gaps in our knowledge have been filled by his extensive and skillful researches, and the result has been presented in a book which is comprehensive, legible, lucid and intelligible to anyone with even a foreman's knowledge of the trade. It can be conservatively said that the importance of this work is such that the experienced practitioner might now tell by a study of the efficiency in any cementation plant whether those in authority were, or were not, familiar with Giolitti's book.

The work is divided into two parts, of which the first discusses the chemical and theoretical side of the subject upon which the industry itself is based, while the second part describes the industrial application of the process of cementation and gives those rules and hints for the control and guidance of the process which are most useful to those who are practically engaged in carrying on the operations.

The translation of the book by Richards and Rouiller renders it in a form in which the English-speaking public may secure the result of Giolitti's work without the least difficulty in instant comprehension, or fatigue as a result of continued reading. B. S.

Metallurgical and Chemical Engineering

From now on "Metallurgical and Chemical Engineering" will be published semimonthly, on the first and fifteenth of each month. The change from a monthly to a semimonthly has been forced upon this journal by the rapid industrial development of the fundamental idea of which it has been the journalistic exponent—that for the future development of engineering a sufficiently broad and comprehensive basis can only be obtained, if the chemical viewpoint is considered of equal importance for the evolution of our industries as the mechanical and physical viewpoint has been in the past in its application to mechanical, mining and electrical engineering. While the general public has been slow in recognizing the enormous importance of this fundamental idea, the creative power of this idea has been perfectly obvious to those who look below the surface of things. Manifestations of this idea in the economic life of this country are the evolution of the electrochemical industries, the emancipation of the metallurgist from the mining engineer, the dissociation of the chemical engineer from the chemist, and the quiet, steady, healthy, irrepressible growth of industrial undertakings in many phases of metallurgical engineering and chemical engineering—all achievements of hardly more than the last decade. The whole evolution has now accumulated such a momentum that its development is rapid and its influence grows daily broader. That the calamity of the European war has opened the eyes of the American public to the dependence of all our industries on chemistry and metallurgy, is purely incidental. The evolution of metallurgy and of chemical engineering as new engineering professions independent of mining and chemistry has been going on peacefully and logically these last ten years and has left its marks on the whole industrial development. And the American chemical and metallurgical industries are firmly established, rapidly growing realities. To those responsible for the conduct of this journal this evolution has been a subject of intense gratification, but also a source of embarrassment in the endeavor to do justice to the situation, until it has now become evident that the needs of the profession and of the industry which this journal endeavors to serve can no longer be taken care of properly in a monthly publication.

With the change to a semimonthly we wish to attain two objects—first, to cover more intensely and more completely the well defined field of this journal, and second, to do it more promptly, to give "news value" to the technical news we print. The change to a semimonthly means no change in policy, no fundamentally new viewpoint, but it shall mean more intense cultivation and greater promptness such as may be expected

from a live technical newspaper, but is impossible of fulfillment in a monthly. We believe that the service which the metallurgical and chemical engineering field —the profession and the industry—have a right to expect from the representative journal in the field, can be rendered properly in a semimonthly, and in trying to render it we are sure of the support and good-will of our readers which we have so fully enjoyed in the past.

To me personally, the growth of this journal from small beginnings in 1902 has been a constant source of pleasure. It seems eminently fitting that the publishing company which publishes the "Electrical World," the "Engineering Record" and the "Electric Railway Journal" has been instrumental in giving to the glorious new professions of chemical and metallurgical engineers their technical newspaper. I pledge my hearty support to "Metallurgical and Chemical Engineering" in its endeavors to work more strenuously than ever toward the realization of its ideals, and on its entrance into the semimonthly field I bid it God-speed.

James H. McGraw.

The Present Importance of Metallurgy

Not in years has the spirit of optimism been so prevalent in the western mining industry as at the present time. The unprecedented prices for metals and the prospect that those prices will be maintained have operated to loosen the purse strings of that part of the investing public that knows the hazards as well as the profits of mining. But the most significant feature of the revival is the fact that those who are anxious to engage in mining are no longer frightened at the prospect of encountering a difficult metallurgical problem. The rapid progress in metallurgy in the past few years has inspired confidence and has aided wonderfully in the extension of the mining industry. As expressed by one engineer: "If I can only find the mine, I have little doubt of being able to develop a suitable treatment process."

If the past few years have been lean in mining, they most assuredly have been fat in metallurgical research and development. Our time has been spent to good advantage. And now that our opportunity is at hand we are able to make full use of the knowledge that we have been at such pains to gather. In the absence of the discovery of new mining districts operators are looking for neglected opportunities in the dumps and mines of abandoned districts, confident that the metallurgical difficulties and handicaps of the past can be readily overcome.

A good example of this kind of revival, based wholly on the development of modern metallurgy, was chronicled in our last issue. To bring life and activity to a district that has been abandoned for a score of years is an achievement of which the metallurgical industry may well be proud. Doubtless there are other such opportunities. They may lack the spectacular features of those projects that are conducted on a huge scale, but they afford a chance to put into practice the special knowledge that has been developing for several years.

Flexibility in Finished Steel Production

The steel industry has been giving a remarkable exhibition of its flexibility as to the production of different descriptions of finished steel. The engineers have been calling for specialty mills, and it really would seem from a scrutiny of the majority of large steel plants that specialization has been carried very far, yet despite the great change that has occurred in the distribution of demand among the various finished steel products the steel mills appear to be fully equal to the emergency. They appear to be able to operate at capacity and yet to furnish the buying trade with respective proportions of bars, plates, sheets, skelp and what-not that are demanded.

A part of the flexibility that is exhibited is due to the fact that from one product to another one mill begins before another has altogether left off. Thus the regular sheet mill can roll fairly heavy gages, while the jobbing mill can encroach both upon the sheet mill and the light plate mill. Each mill performs best on its specialty, but is not altogether limited to it. In merchant or bar mills the different sizes of mills yield their best service in a relatively narrow range of sizes, but are not confined to those sizes. Almost since there have been rail mills and billet mills there have been built "interchangeable" rail and billet mills, which could change from the one product to another merely by changing rolls. In the past few months still greater flexibility has been secured in certain rail mills, by changing rolls and adapting them to the production of large steel rounds, for which there has been a very heavy demand. The demand for ordinary merchant steel bars has been abnormally large, but thus relieved the bar mills are able to keep up with their orders fairly well.

Apart from the considerations just mentioned, the apparent flexibility of steel-finishing departments is maintained in large part by there being a very considerable excess in steel finishing over steel-making capacity. Probably at no time in the history of the steel industry, as now constituted, has it been possible to find sufficient steel to operate all finishing departments at 90 per cent of their real capacity. As new plants have been erected they have usually started with insufficient finishing capacity, and have appeared in the market as sellers of billets or sheet bars, but it has been almost the invariable history for such plants to add finishing mills one after another, so as to have reserve finisihng capacity and be able to catch the market in its various twists. Local conditions determine largely whether or not this is a wise policy. There is some investment lying idle, or but partly employed, in a plant that is making steel at capacity but has an excess of finishing capacity, but if it were not thus aligned it would at times have idle steel-making capacity instead. In the case of the plant the United States Steel Corporation is completing at Duluth, strictly local conditions obtained, and this plant was laid out to give the finishing mills a wide latitude in the character of the product they could turn out, for the demand in the far Northwest is yet to be gaged, and the plant is built largely against the demand of the

future. Such flexibility, of course, is purchased at the expense of an increased cost per ton, but in a practically isolated plant the first thing to do is to arrange to fill such demand as develops.

Chemical Engineering

The announcement of Columbia University on the establishment of a separate department of chemical engineering, independent of the department of chemistry, is but another characteristic sign of the times. The only other American university where this experiment has been made before, is, we believe, Wisconsin. Yet it is a most natural and logical development when once the conception of chemical engineering, its function and scope, are fully understood. No one would now suggest that for the training of mechanical engineers and electrical engineers the department of physics is sufficient. Yet the analogy with chemical engineering is as perfect as analogies can be, and the really interesting feature of the Columbia announcement is that it is Columbia University which takes this step.

Another characteristic sign of the times is the emphasis laid on chemical engineering in the series of able papers at the recent annual meeting of the British Society of Chemical Industry, reported elsewhere in this issue. Particularly Dr. Beilby's paper will be found most interesting and suggestive in defining the chemical engineering viewpoint.

Steel Capacity and Demand

The prince and pauper industry, otherwise the steel-making industry, has passed through its period of depression and entered upon a period of prosperity. It is either a feast or a famine, a chill or a fever. There are reasons. Two of them are, first, that inasmuch as steel is employed rather than consumed, the quantity that is put into employment in any one year may vary within wide limits, and second, that inasmuch as stocks of steel are carried by buyers rather than by producers the market demand increases or decreases more greatly than the actual employment or consumption, as buyers increase or decrease their stocks.

A little reflection and study of the statistics will indicate that there is in existence in the United States fully 400,000,000 tons of iron and steel, all performing more or less useful service, and naturally the additions to the store from year to year are not uniform. In 1905, 1906 and 1907 there were very large additions, since by far the major portion of the steel made in those years could be traced directly to large employment operations, in bridges, buildings, rails, cars, locomotives, etc. The present demand, however, does not run so largely in that direction. There is, for example, a large demand for steel for war purposes, where the actual employment covers in some instances only a few seconds of time. The second of the two causes noted above for the steel industry being either prince or pauper is the more potent at this time. A large tonnage of steel is distributed by jobbers, while another very large tonnage is purchased from the mills by manufacturers of hardware, machinery, motor vehicles, agricultural implements, etc. These buyers, jobbers and manufacturing consumers carry such stocks of the various sizes and descriptions of steel as they consider adequate to the smooth conduct of their business. When the steel mills are slack of work they can make very prompt shipment against new specifications, not hesitating to change rolls, for instance, from day to day or even more frequently. When they can accumulate a tonnage ahead they arrange their rolling schedules to much better advantage, and thus almost overnight, in a trade revival, the buyer of steel who has hitherto been able to count upon shipment in two or three days may be confronted with a delivery promise of a month or longer. Promptly he increases his specifications, for to conduct his business satisfactorily he must carry much larger stocks than formerly. The steel trade is now in the condition just indicated.

The steel industry may have difficulty in attaining the stage of operating at capacity, and indeed for almost two years there has been more or less idle equipment, but once the capacity stage is reached the full operation lasts for quite a while. In the past seventeen years there have been five such periods of marked improvement, resulting in capacity operations, full employment being reached in 1899, 1902, 1905, 1909 and 1912. The shortest period of full employment was that in 1912-13, approximately a twelvemonth, while the longest was that centering in 1906, about three years. In the shorter periods the chief influence causing the demand upon the mills to exceed the average was the desire of buyers to replenish stocks. In the longest period the chief influence was an actual consumption quite above the normal.

Each time the iron and steel industry reaches a stage of full employment the production is found to be much in excess of the best rate previously attained, and naturally by the amount that capacity has increased the period of full employment is shortened. The condition at the present time is therefore distinctly peculiar in two respects—in that the present capacity is only slightly greater than that of two years ago, when the industry was fully employed, and in that there is not likely to be much disposition to increase capacity in the next year or two. There has been little increase in blast furnace capacity in the past two years, and while there has been considerable increase in open-hearth steel making capacity, it is very doubtful whether the real steel making capacity of the country has been increased by anything like a corresponding amount, when there is question as to there being adequate supplies of pig iron and scrap, and there is less call for Bessemer steel than formerly. As to new construction at this time, a labor shortage is in prospect, and from this and other causes construction is likely to be expensive, while on account of financial conditions during the war, and the prospective release of much steel-making capacity at the close of the war, steel manufacturers are likely to hesitate in the matter of making very large increases in their productive facilities. Thus the period of full employment of steel-making capacity may this time prove to be unusually long.

Readers' Views and Comments

Adjustment of the Direct Electric Lighting Current to Electro-Analysis

To the Editor of Metallurgical & Chemical Engineering:

Sir:—The broadening of the field of usefulness for electro-analysis in the metallurgical laboratory by the introduction of agitation of the electrolyte, and also by the application of the theory of graded potentials, has been of great worth to the chemist and to the manufacturer. However, the writer believes that sufficient stress has not, as yet, been put upon the substitution of accurate, clean-cut electrolytic determinations for older and considerably cruder methods. This especially applies to the average laboratory engaged in work on the metallurgy and chemistry of iron and steel.

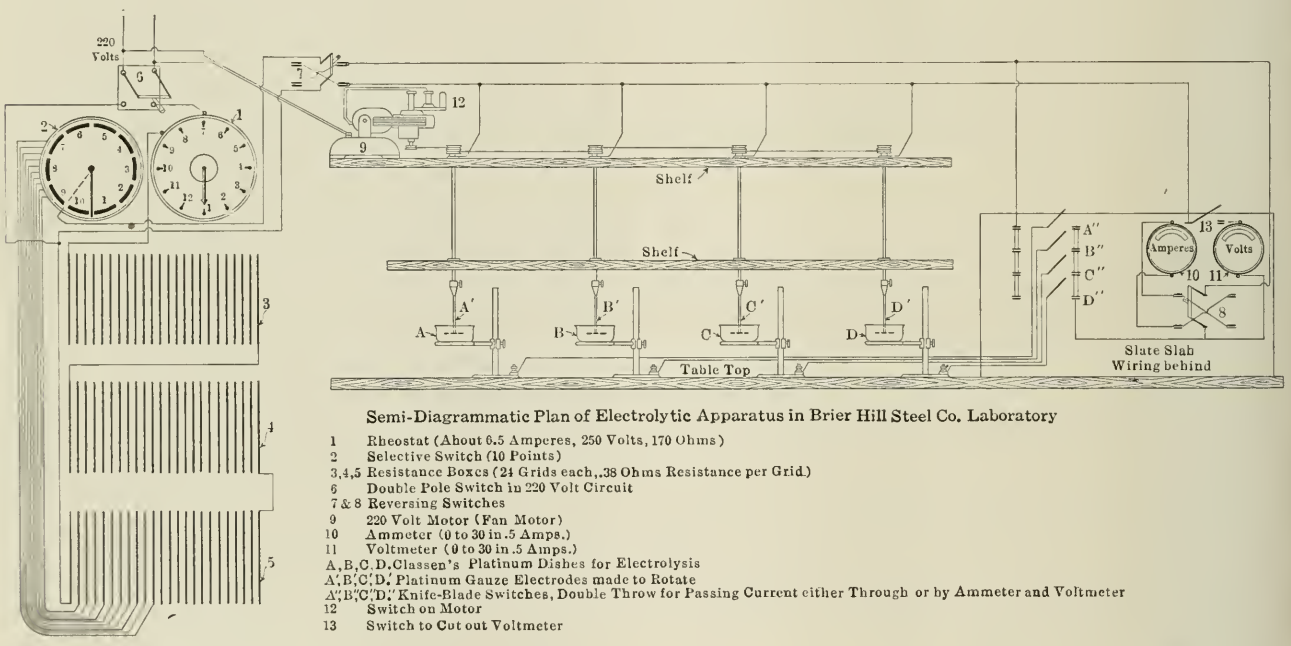
In order to do what he can in furtherance of a broader application of electro-analysis as applied to routine work, the writer wishes to describe an arrangement of apparatus which has saved time, labor and expense, with a large gain in accuracy and satisfaction.

It was decided, when designing the electrolytic apparatus about to be described, to do away with the troublesome and expensive storage battery, utilizing instead the direct electric lighting current. At the same time it was decided to retain the advantage of simple and accurate voltage regulation possessed by the storage battery. It was not desired to use the familiar and inconveniently crude lampboard resistances, so the following was evolved.

The direct current, 220 volts in our case, is led through a suitable rheostat in series with three resistance boxes of the grid type; then by means of a selective switch suitable shunts are established, the voltage of these shunts being that of the drop in potential between the shunt connections. By manipulating the selective switch and rheostat in conjunction with each other, any voltage from 0.1 volt up to that desired may be reached, the current, measured in amperes, obeying Ohm's law according to $C = \frac{E}{R}$.

The accompanying sketch will explain the arrangement so that any electrician can easily install the apparatus. This sketch shows provision for four simultaneous determinations. This obviously may be changed to a lesser or greater number. For the 110-volt circuit, just one-half of the resistance shown in the sketch is necessary. For the 500-volt circuit, just twice this resistance must be used. The resistance boxes and rheostat, if not at hand, may be made if it is not desirable to purchase them. "Nichrome" wire for the resistance; fiber board for the rheostat and selective switch; the contact pieces may be made of large, heavy, copper rivets; the contact arms of spring bronze. The rivets should be spaced so that the contact arms in their travel always touch one or two contact points. This obviates arcing. There should be, for the 220-volt circuit, about 400 ft. of No. 18 "Nichrome" wire for the rheostat, and 70 ft. of the same kind of wire for forming the coil from which the potential drops are taken by means of the selective switch.

There should be twenty-four contact pieces on the rheostat and ten contact pieces on the selective switch,



Semi-Diagrammatic Plan of Electrolytic Apparatus in Brier Hill Steel Co. Laboratory

1 Rheostat (About 6.5 Amperes, 250 Volts, 170 Ohms)
2 Selective Switch (10 Points)
3,4,5 Resistance Boxes (24 Grids each, .38 Ohms Resistance per Grid.)
6 Double Pole Switch in 220 Volt Circuit
7 & 8 Reversing Switches
9 220 Volt Motor (Fan Motor)
10 Ammeter (0 to 30 in .5 Amps.)
11 Voltmeter (0 to 30 in .5 Amps.)
A, B, C, D, Classen's Platinum Dishes for Electrolysis
A', B', C', D', Platinum Gauze Electrodes made to Rotate
A'', B'', C'', D'', Knife-Blade Switches, Double Throw for Passing Current either Through or by Ammeter and Voltmeter
12 Switch on Motor
13 Switch to Cut out Voltmeter

the leads from the rheostat being equally spaced along the 400 ft. of wire and in series with it. The leads from the 70-ft. coil to the selective switch are best adjusted by having the voltmeter and ammeter in circuit along with a pair of electrodes immersed in acidulated water. The current adjustment demanded by the class of work most handled may be easily and quickly obtained by increasing or decreasing the amount of resistance between successive shunts. The frames or boxes upon which the coils are to be wound are best made of "Transite" board. This may be worked with wood-cutting tools, and is resistant to heat as well as being a good non-conductor. The leads from the resistance coils to the rheostat and selective switch are of No. 12 well insulated copper wire.

The writer has used the outfit as sketched for the following determinations: Copper, tin, antimony (separation of tin and antimony), bismuth, nickel, manganese, iron, zinc and lead. The determination of lead in spelter was especially helpful, inasmuch as a great many determinations were required which, by the familiar

lead sulphate method, were very tedious and not nearly so accurate as the electrolytic method. To make a lead determination on spelter requires 30 min., the lead peroxide resulting from the electrolysis being ignited gently and weighed as the red oxide.

With some additional wiring and a small change in the selective switch, the apparatus may be arranged so that two or more unlike determinations may be handled at the same time; that is, a determination requiring say 5 amp. at 5 volts may be carried out with a simultaneous determination requiring 2 amp at 3 volts, etc. This is accomplished by using one pair of switch arms at the selective switch for each electrolytic place required. Each pair of electrodes must have, of course, its own pair of wires corresponding to their respective switch arms. It will be readily understood that by simply setting these switch arms so as to "bite" off the requisite resistances the voltages and amperages desired may be secured. However, this is a modification that is only desirable for quite variable work.

To conclude, the writer wishes to strongly emphasize the value and importance of a broader application of electrolytic work in the iron and steel laboratory, and hopes that the foregoing description will be of help to others desiring to test out such methods.

Acknowledgment of helpful suggestions and criticisms is tendered Mr. H. E. Moyer, chief chemist for the Brier Hill Steel Company, and to Mr. Samuel Farrell of the same corporation.

EDMUND J. KAUFFMAN.

Brier Hill Steel Co., Youngstown, Ohio.

Platinum Boats for Carbon Determination by the Direct Combustion Method

To the Editor of Metallurgical & Chemical Engineering:

SIR:—There has been a great deal written in the past few years in regard to the direct determination of carbon in iron and steel. Many methods have been described for its estimation, and while they are all practically the same in principle, many different suggestions are made as to the best materials to be used for constructing a furnace and for boats in which the small drillings are carried. Various materials have been mentioned for this purpose such as porcelain, fused silica, alundum, vitrified clay and nickel, but rarely, if ever, is platinum mentioned, perhaps on account of it being so expensive.

There appeared in this magazine for June (page 347) an article describing a method for preparing boats made of 22-gage sheet nickel; each boat to cost a trifle less than 5 cents, and good for at least forty combustions. On this basis let us make a comparison between nickel and platinum.

The writer has used the same platinum boat for five years and five months, doing an average of fifteen combustions each day, twenty-six days each month, or in other words the boat has been used for 25,350 combustions to date. The boat weighed 19.6 grams when purchased and it weighs at the present time 19.1 grams, so that there was a loss of 0.53 gram. It was purchased when new for $1.13 per gram, therefore the loss in platinum has cost $0.60. The boat is in fairly good condition at the present time, and is good for many more determinations. At the present price of platinum it could be sold for more money than it cost.

At forty combustions for each boat it would have required 634 nickel boats to complete the same amount of work done by this one platinum boat, and at 5 cents each the nickel boats would have cost $31.70, besides the trouble and expense necessary in preparing them from the sheet metal.

Nickel boats are more expensive than platinum, and they are also objectional from the fact that they readily take up oxygen at high temperatures, causing a continual formation of the black oxide which peels off in the form of small scales. This, of course, is an annoyance to the operator. A platinum boat is always ready for use and it is not necessary to scour it with cleaning compounds or treat it with strong acids to keep it clean. The only attention necessary is to keep it in shape as a boat, and this will not be found difficult if a suitable form is kept on hand for this purpose.

Great care should be exercised in regard to the flow of oxygen passing through the combustion tube, as this is an essential factor in prolonging the life of a platinum boat. With a furnace temperature of 1900 deg. Fahr., and a rapid flow of oxygen the temperature at which the reaction actually takes place will probably reach 2500 deg. Fahr., and at this temperature the drillings will run together like so much mercury and fuse with the boat, indeed sometimes they will bubble high above the boat and fuse with the combustion tube. Many times this has occurred to the above-mentioned boat and it has been found best to cool the furnace. When the slag becomes brittle it can be easily broken from the tube and the boat removed. When a platinum boat is removed from the furnace under these conditions it will not resemble its original shape by any means. In fact, it is a fused mass of platinum and slag. However, with an instrument for crushing the slag, such as a pair of pliers and a steel form, the slag can be removed and the boat hammered into shape in a few minutes. The best results are obtained when the oxygen is so regulated that the drillings just fuse together, but not to the extent that they cannot be recognized as drillings. When the reaction takes place too rapidly, the iron is partly volatilized and if barium hydroxide is used the precipitate will be found contaminated with the reddish brown oxide of iron. The results will invariably be low. Probably some of the carbon escapes through the absorption apparatus as carbon monoxide.

White silica sand is used freely in the boat, since it costs practically nothing. The sand is heated to 2300 deg. Fahr., for some time before using, to free it of any small amount of carbon. This sand being white offers a good background for the drillings and is very desirable for this work.

What has been said in regard to the use of platinum boats is equally true in regard to the use of platinum as a heating element for the combustion tube. The writer has used the same furnace every day for eighteen months, while on the other hand a furnace constructed in the same manner, but using nichrome for the heating element, will not average three months' use, and at the end of this time it is necessary to renew the nichrome, while with platinum the same piece can be used several times.

NEW BEDFORD, MASS.

Newspaper Chemistry of Platinum

To the Editor of Metallurgical & Chemical Engineering:

Sir:—The startling information contained in the following story, taken from the *Dowajiac Daily News*, is a beautiful example of "journalistic chemistry" and should be the means of furnishing some amusement to your readers:

"There is some valuable land down in Jefferson township. Recently a property owner on the line of the Mud Lake Extension drain sent to the State department at Lansing a sample of the excavation made when the drain was dug, and among other things the chemist found was platinum at the rate of 6 lb. per cubic foot of the formation.

"His primary object was to see how much lime the marl contained, and he was informed that the marl was over 90 per cent pure lime.

"Years ago, when platinum was worth $12 per lb., his land was a gold mine, although in those days cost of extracting this metal was correspondingly great, perhaps. With the facilities now in use for extracting, platinum has grown to be valued less than $1 per lb. Even at that price the land is pretty valuable."

Dowagiac, Mich. J. C. A.

The Western Metallurgical Field

Parcel Post Ruling to Affect Shipment of Concentrates

Since the parcel post was established, one of the most difficult problems confronting the Post Office Department has been the handling of tons of concentrates that have been shipped from isolated districts to smelting centers. Concentrates properly come within the classification of parcel post matter, and when put up in 50-lb. sacks have been entitled to the established rates. This method of shipment has been a convenience to producers operating at a distance from reduction works, and many of them have taken advantage of this method of transportation.

The Post Office Department has discovered, however, that the business is not profitable because the length of rural mail routes is frequently much greater than the parcel post zone radius as the crow flies. This often necessitates carrying concentrates a distance equivalent to two or three zone radii, and as a consequence the business is conducted at a loss. Hence a ruling has been made that where the mail route is 300 miles or more between points of shipment and delivery the regular first and second zone rates shall not apply, even though the route lies within those zones on the map, but that third zone rates shall be charged. This means, for example, that where the second-zone rate of 5 cents for the first pound and 1 cent for each additional pound has previously been in effect on some 300-mile routes, the third-zone rate of 6 cents for the first pound and 2 cents for each additional pound shall apply. This will increase the ordinary second-zone rate from $1.08 to $2.08 per 100 lb., or at the rate of $20 per ton. This is an increase that will force many operators to discontinue shipping by parcel post; the rural mail carrier may again use a two-wheel cart instead of a motor truck, and the government will be relieved from an unprofitable business.

Anaconda to Enter Zinc Field

Certain activities on the part of the Anaconda Copper Mining Company point to the possibility of that company becoming a factor in the zinc industry. Anaconda engineers have recently been examining property in the Neihart district, one of the zinc-mining districts of Montana, where silver-zinc ore has been produced, though with unsatisfactory results. In the Butte district also the Anaconda is reported to be investigating zinc properties, such as the Emma and Lexington, and it is reported that when the sale of the Alice is finally consummated the purchaser will be the Anaconda company.

With the acquisition of zinc properties, it is likely that Anaconda has also developed metallurgical methods to treat the ore, and some credence may be placed in the report that the company's metallurgists have been experimenting along the line of electrolysis. Electrolytic zinc has been in the public eye for some time, and has received quite as much attention as did electrolytic copper. The development of an economic hydrometallurgical method for zinc, with electrolysis as the final step, would be a tremendous advance in zinc metallurgy; in fact, it would prove revolutionary in an industry in which the basic methods have never undergone any material change. Were the report credited to any less energetic and capable an organization than Anaconda, it might not be worth a passing consideration, but the progressive character of Anaconda's program in copper metallurgy leads one to feel that new developments in zinc-ore treatment might easily emanate from that source.

American Graphite Manufactures

In view of an interest recently manifested in the domestic production of graphite and its manufactured articles, we give the following information: The production of natural graphite in the United States in 1913 was 4775 short tons. Imports amounted to 28,879 short tons. The principal reasons for the disparity in domestic production and imports are to be found in the superiority of the Ceylon product and its cheap production, and the difficulty in milling the domestic ores. Deposits in the United States are mainly flake graphite in schist. The separation is difficult, especially when the rock contains mica, which is frequently a constituent. Failure has attended so many undertakings in the production of graphite from domestic deposits that the work is in the hands of a few concerns which also manufacture the output into marketable forms.

Domestic graphite is not suitable for the manufacture of pencils, as it lacks that unctuous quality so necessary in producing an even grade of "lead." Crucibles, paints, lubricants and stove polishes are the manufactured forms to which the American graphite is most suited. The Santa Maria graphite mines in Sonora, Mexico, produce amorphous graphite containing 86 per cent graphitic carbon, which is shipped to Saginaw, Mich., and there prepared for use by the Raymond system of pulverizing and air-separation. American-made pencils, of quality said to be equal to that of German and Austrian manufacture, are now produced almost wholly from this Mexican graphite.

Silver and Base-Metal Prices

The steady decline in the price of silver is a matter of grave concern to producers of the white metal, particularly in view of the enhanced value of zinc, aluminium and potassium cyanide which are used in its production. Quicksilver also is used in large quantity at Cobalt, but as it is subject to but little loss in the process of amalgamation, its high price is not a matter of so much importance. In fact, the Buffalo company probably discovered a neat asset in the 41,850 lb. of mercury recovered from residues during the year ended April 30, 1915.

Tonopah and Cobalt are the great silver producing districts on the North American continent, and companies operating there have been forced to witness a steady decline in the value of their product while the cost of supplies has risen. The effect has been to cause operators to store silver bullion in New York and San Francisco until a more favorable market appears. But even this expedient has its unfavorable aspect, for by the time the market recovers to a normal condition the large stores of silver available will tend to hold prices down. Most of the companies concerned are well financed and can await a favorable time to dispose of their product, but smaller companies that have to realize promptly on their output are operating under most unfavorable conditions.

Potash in Utah

The Mineral Products Company, which is developing deposits of alunite at Marysvale, Utah, expects to have its milling plant in operation in September. Accord-

ing to General Manager James A. Lane, no attempt will be made at present to recover aluminium, which is a constituent of alunite, and potash only will be produced. The company has been constructing a tramway and mill, and will begin operations under favorable market conditions.

Flotation at Park City

We have recently commented on the fact that the older mining districts offer fertile fields for the application of the flotation process, particularly where concentrating mills of the customary type have been the only treatment plants in operation. A case in point is the Park City district, Utah, where gravity concentration of lead-zinc ores has long been practised. The Daly-Julge mill is to add the Callow pneumatic flotation process to its present equipment, and thereby effect a saving of fine mineral that has hitherto gone to waste. Another project in the same district is the construction of a mill to re-treat the old tailings of the Grasselli company's dry concentrating mill. The flotation process will be used here also, in addition to the usual methods of wet concentration. At Atkinson, near Park City, a new 250-ton mill has been erected for the treatment of old tailings, flotation playing a prominent part of the process.

Company Reports

Utah Copper Company's report for the second quarter of 1915 shows a production of 40,799,825 lb. of copper from 2,215,159 tons of ore containing 1.42 per cent copper. The extraction was 64.85 per cent, being below normal due to the presence of considerable carbonate mineral in the ore, and to the extra large tonnage handled. The tonnage treated was the largest for any quarter in the history of the company. The cost of copper, without crediting miscellaneous earnings, was 7.49 cents per pound. With other earnings credited, the cost is 6.57 cents. Total net profit from all operations was $4,412,299, from which a dividend was paid amounting to $1,624,490. Of the total quantity of ore milled, the Magna plant handled 59 per cent and the Arthur plant 41 per cent.

Ray Consolidated Copper Co. treated 679,004 tons of ore during the second quarter of 1915, producing 14,524,380 lb. copper. The average grade of the ore was 1.677 per cent copper. Milling costs totaled 44.53 cents per ton, as compared with 48.95 cents for the previous quarter. Coarse crushing cost 3.256 cents per ton. The average cost of copper, after allowing for smaller losses and applying dividends from the Ray & Gila Valley Railroad, was 9.122 cents per pound. Crediting miscellaneous income, the average cost would be 9.057 cents. The net operating profit was $1,367,736; dividend amounted to $547,035. Production for the quarter averaged nearly 1000 tons below what it should have been under normal conditions. Delay in resuming operations on a full tonnage basis, coupled with labor difficulties in June combined to cause a deficiency in production.

Chino Copper Company produced 18,455,502 pounds of copper during the second quarter of 1915. The mill treated 592,200 tons of ore containing an average of 2.38 per cent copper. The average daily tonnage was the highest in the history of the mill, reaching up to 7317 tons per day in June. Extraction was 65.34 per cent, as compared with 66.12 per cent in the previous quarter. The concentrates contained 22.11 per cent copper, as against 27.41 per cent for the first quarter. The ratio of concentration was 14.19:1. Cost of copper, allowing for smelter deductions and crediting miscellaneous income, was 6.10 cents per pound. Net profit from milling operations, $1,937,951; dividends paid, $652,455.

Nevada Consolidated Copper Company produced during the second quarter of the calendar year 15,106,920 lb. of copper, the June production being 5,124,480 lb. Ore milled amounted to 849,155 of Nevada Consolidated ore averaging 1.40 per cent copper. In addition to this there was also milled 17,541 tons of Giroux Consolidated ore. The cost of copper, after crediting miscellaneous income, was 8.93 cents per pound. Earnings for the quarter amounted to $1,364,094, from which dividends were paid amounting to $749,796.

The Non-Ferrous Metal Market

Since our last report the non-ferrous metal market has been comparatively quiet and without particular feature. Prices have steadily declined and business has been only moderate. While sales have been mainly for the domestic market, there is evidence that export business will again increase and it is not felt that the reaction will be marked or of long duration.

Copper.—Export business has suffered somewhat from the sale of Australian and Japanese copper in the European market, but resumption of foreign sales has already begun. Domestic business has been small and at reduced prices. The latest available quotations for electrolytic are 17.60@17.80 cents, New York.

Lead.—Due to a sharp reduction in price by the American Smelting & Refining Company this market has lost its optimistic tone that it showed in July. Competitors have still further reduced the price, so that lead is now quoted at about 5 cents, New York, and 4.90@5 cents, St. Louis.

Tin.—This market has been without special feature. Prices have shown a declining tendency, and the metal is quoted at 35½ cents, New York.

Spelter.—The metal has been consistently weaker for several weeks and the volume of business is small. There seems to be an ample supply for both immediate and future demands. Some metal has been offered for resale by buyers who overbought their requirements. The St. Louis quotation is about 14.50@15 cents.

Other Metals.—Aluminum continues at a fairly high level with fair demand. No. 1 ingots at New York are quoted at 31@33 cents per pound. Prices for antimony are largely nominal, ordinary brands bringing from 35 to 37½ cents, and special brands 48 to 50 cents. Business in quicksilver is only fair, with prices at $92@94, New York, for flasks of 75 lb. The San Francisco market is quiet with prices about the same as at New York.

The Iron and Steel Market

August has shown a further improvement in the steel situation. Although practically 100 per cent of the open-hearth capacity and about 90 per cent of the Bessemer steel-making capacity has been engaged, steel has been described as scarce and prices demanded for billets and sheet bars support such a view. Mill deliveries have lengthened out so that against new specifications filed for plates and shapes the large mills do not promise shipment in less than four to six weeks, while in the case of bars deliveries are still slower. Steel prices have been advancing.

On the surface at least the steel market presents an appearance of great strength, and in most quarters the prediction is made that the trade is definitely promised a long period of full prosperity. When the market situation is analyzed, however, it becomes clear that its strength is due chiefly to export demand, and that mainly for war purposes. This demand has had both a direct and an indirect effect in filling the steel mills

with business. Indirectly it has affected domestic buying by stimulating the price advancing tendency and by causing buyers to fear they may not be able to secure desired deliveries. In the last report it was noted that when mill deliveries begin to fall behind buyers are moved to increase their stocks, and while it was then noted that such an extra demand was being experienced it may be stated that the buying during August was still more of that character.

The government figures for June show exports of iron and steel totalling 355,829 gross tons, against 263,649 tons in May, and an average of 137,000 tons a month during the first seven months of 1914 preceding the outbreak of the war. Excluding pig iron, scrap, castings, etc., the June exports represented about 320,000 gross tons of rolled steel. Indirect exports, including machinery, arms, ammunition, motor cars, etc., may have involved 80,000 tons in addition, making 400,000 tons for the month. The country's capacity, measured as rolled steel is probably about 2,400,000 gross tons monthly, with average weather conditions and after all departments have been in operation long enough to have reached normal efficiency. The June production was probably in the neighborhood of 1,800,000 tons, so that steel export, direct and indirect, appears to have represented about 22 per cent of the output. Exports have been steadily increasing since June in various directions. Large shipments of rails are to be made to Russia, purchases to date having amounted to 250,000 or 300,000 tons, while a large number of cars and locomotives has been bought by France and Russia, and there have been increases in many items that figured in the June exports. It is quite possible that in September direct and indirect exports may represent as much as 600,000 tons of rolled steel, but as moderate weather arrives and the mills through continued operation reach their proper gait it will be possible to produce more steel, probably the 2,400,000 tons per month already estimated, so that allowing for a gain of one-half in exports over what is suggested by the latest government statistics, the exports would represent only 25 per cent of capacity, indicating that in some quarters the importance of the present export trade, from a tonnage standpoint, is being over-estimated. There is little danger, however, of the influence upon the market being overrated, however, because, as indicated, the export business has had an important sentimental influence in helping the advance in prices and encouraging buyers to specify freely on their contracts.

Without admitting these influences it would be impossible to find in industrial conditions in the United States occasion for the steel industry to operate at its capacity. There is no important branch of domestic consumption in which business is active or in which the tonnage actually consumed is at previous record rates, whereas the steel industry has a larger capacity than ever. A few illustrations may be cited. The railroads have bought rails scarcely more freely this year than in 1914, but the production of rails last year was less than 2,000,000 tons, or only one-half the record production, made so long ago as in 1906. The last time the steel industry reached a rate of full employment was at the middle of 1912, and in the eight months preceding there has been 135,000 freight cars ordered. Freight car buying this time has been active only in the three months, May, June and July, orders in those months aggregating about 55,000 cars. Prior to May there was no buying to speak of, and there has been none of any consequence in August. The reports of the Bridge Builders' and Structural Society, covering fabricated steel contracts let throughout the country, show an average in lettings during the first six months of this year representing only 54 per cent of the capacity, while in the single month of July the contracts amounted to 86 per cent. Oil development is practically at a standstill, and has been for a year, while in a good year the "oil country goods" branch of the pipe industry involves nearly a million tons. In the sheet branch there is nearly normal demand for blue annealed and black sheets, but not one-third the normal demand for galvanized sheets.

Admittedly the steel trade finds itself in a prosperous condition, but obviously the condition is not referable to anything like normal full domestic consumptive demand, while even the export demand does not appear to fill the gap. As the country grows more prosperous the domestic consumption may, and probably will, increase. Perhaps the final test will come with October, normally a month of very large outputs, as the plant facilities work well. If the market finds itself strong at the end of October, with firm prices and no surplus of steel, the industry may be regarded as assured a period of prosperity of considerable length.

Pig Iron

The advance in pig iron prices, which became perceptible in the fore part of July and reached more important proportions in the second half, became very marked in August. Averaging all important descriptions of pig iron, the July advance amounted to about 35 cents a ton and the August advance to about 90 cents, a total of $1.25 for the two months. Prior to July the pig iron market had merely shown minor fluctuations.

The advance in pig iron has not rested upon as large a volume of sales as has usually occurred in the case of price advances of similar extent. The conditions were exceptional. There is a much wider range in pig iron costs at the merchant furnaces than there is at the furnaces of the steel works, one important factor being that some of the merchant furnaces have ore mines of their own while others must pay the market price, and an interest having ore mines and blast furnaces may be content to show an apparent loss to the blast furnace operation if the ore is charged to it at the market price. Last winter the furnaces in operation were confined almost entirely to those with ore supplies of their own, and even they were operating at no considerable profit. Pig iron prices remained low for so long that the furnaces were tempted to sell pig iron far ahead. At the beginning of July the furnaces found themselves almost entirely sold up for the second half of the year, while consumers were equally well covered, on the basis of the rate at which they had been consuming iron. A slight increase in their requirements caused additional buying, while the furnace position was that the operating furnaces were already well sold up and the idle furnaces were unable to sell and enter the producing ranks, their costs being well above the market. Accordingly, prices rose rather sharply on relatively light buying. To justify blowing in, a furnace must be able first to sell a considerable tonnage of pig iron, assuming prices to be satisfactory, and the market has hardly been broad enough to permit this. The market stands quotable as follows: No. 2 foundry, delivered Philadelphia, $15 to $15.25; f.o.b. furnace, Buffalo, $14 to $14.50; delivered Cleveland, $14.50; f.o.b. furnace, Chicago, $13.50 to $14; f.o.b. Birmingham, $11 to $11.50; at valley furnaces, 95 cents higher delivered Pittsburgh: No. 2 foundry, $14.25 to $14.50; gray forge, $14 to $14.25; malleable, $14.25 to $14.50; basic, $14.25 to $14.50; Bessemer, $15.50. These quotations are for relatively early delivery, and quotations for the first quarter or half of next year are usually on a higher basis.

Steel

The large consumers of billets and sheet bars are well covered by long term contracts. On some of these prices are adjusted monthly or quarterly, and have been increasing slightly. On a few contracts, particularly for sheet bars with tin plate mills, there is usually one price for the entire calendar year. The demand that passes through the open market is thus very small compared with the tonnage that changes hands, and in periods of relative scarcity the market is sensitive and not very clearly defined. Some of the producers are refusing to quote, having but small tonnages to spare, after filling contracts, and feeling safe in holding the steel for still higher prices. The middle interests have some steel but are naturally reserved in selling. As nearly as can be quoted the market stands at about $23.50 to $24 for billets and $24 to $24.50 for sheet bars at maker's mill. Bessemer steel might possibly be had for less while it might be difficult to buy open-hearth at these figures. Rods are $26 to $27, Pittsburgh.

Finished Steel

Finished steel products have, generally speaking, shown an advancing tendency. In bars, plates and shapes the new buying has been light, but specifications against contracts have been so heavy that the mills have felt strong enough to advance asking prices. On Aug. 16 the steel corporation subsidiaries announced an advance of $1 a ton in bars, plates and shapes, to 1.35c.; Pittsburgh and the other large interests are working up to this basis. There remain small plate mills willing to sell plates at 1.25c.

Current quotations, f.o.b. Pittsburgh, unless otherwise noted:

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.25c. to 1.35c.

Shapes, 1.30c. to 1.35c.

Steel bars and bands, 1.30c. to 1.35c., base; hoops, 1.35c. to 1.40c.

Iron bars, 1.25c., Pittsburgh; 1.40c. to 1.45c., Philadelphia; 1.25c. Chicago.

Sheets, blue annealed, 10-gage, 1.40c.; black, 28-gage, 1.85c. to 1.90c.; galvanized, 28-gage, 3.60c. to 3.75c.; painted corrugated, 2.00c. to 2.05c.; galvanized corrugated, 3.65c. to 3.80c.

Tin plate, $3.10 to $3.20 for 100-lb. coke.

Steel pipe, ¾ to 3-in., black, 79 per cent off list; galvanized, 63½ per cent off list.

Steel boiler tubes (less than carloads), 72 per cent off list.

Structural rivets, 1.50c.; boiler rivets, 1.60c.

Railroad spikes, 1.45c., Pittsburgh; 1.60c., Chicago.

Imports of Potash Salts.—The following table from **Commerce Reports** shows the quantity and value of imports of potash salts into the United States during the month of May and for the five months ending May, 1914, and 1915. The items are grouped to show the salts used chiefly as fertilizers and other potash salts. The unit of weight is the long ton.

Articles	May				Five Months Ending May			
	1914		1915		1914		1915	
	Tons	Value	Tons	Value	Tons	Value	Tons	Value
Fertilizer salts:								
Kainit	11,960	$59,641	.....	.....	239,362	$1,115,151	3,786	$31,553
Manure salts	19,047	203,632	197	$7,639	81,669	895,739	12,456	179,328
Sulphate of potash	2,162	94,788	33	2,204	21,313	907,635	8,806	405,631
Muriate of potash	17,952	619,397	28	3,845	105,759	3,606,445	56,135	2,336,098
Other potash salts:	Pounds		Pounds		Pounds		Pounds	
Carbonate of potash	1,621,787	48,548	769,047	24,947	9,867,075	282,758	8,396,034	261,234
Hydrate of potash	811,313	28,442	141,500	6,389	3,462,638	128,613	2,016,942	97,956
Nitrate of potash	475,724	15,170	.....	.....	1,079,045	35,599	6,855	400
Cyanide of potash	1,236	16	.....	.....	275,977	37,362	828,527	124,934
Other potash salts	512,383	44,519	67,203	7,698	2,704,391	241,075	2,064,260	202,570

Transvaal Gold Production.—The number of mines reporting to the Transvaal Chamber of Mines in April, 1915, was sixty-three. The total quantity of ore milled during that period was 2,341,595 tons. There were 9907 stamps in operation, with an average duty of 9.35 tons per 24 hr. Tube-mills in commission numbered 316. The yield for the month was 744,080 fine ounces gold, or 6.22 dwt. per ton.

Repairing Coke-Ovens by the Cement-Gun Process.—The Cement-Gun Company, Inc., 30 Church Street, New York City, describes in its Bulletin 101 the application of the cement-gun process for permanently repairing coke ovens. This method is interesting as it permits the repairs to be made while the oven is in service, thus doing away with the troublesome effects of cooling and reheating. The "gun process" is the same in principle as has proved so successful in other fields of cement repair work in recent years. The material used in the gun is the usual silica cement which is used in joints in the construction of the walls. This consists of siliceous material such as ground silica rock and ground batts in varying proportions from 100 per cent of the one to 100 per cent of the other mixed with 15 per cent to 20 per cent of fireclay. The finished cement generally running from 85 to 80 per cent silica. The material being deposited in the form of a spray and under high pressure penetrates deeply into the cracks, thus insuring a perfect seal.

Oil Pipe Line.—The first four sections, comprising about 47 miles of the oil pipe line for the Valley Pipe Line Company, a subsidiary of the Shell Royal Dutch Company, which was designed and is being built by Sanderson & Porter, was placed in successful operation on May 15th. This line is 170 miles long, extends from the Coalinga oil fields to a tidewater terminal near Martinez in San Francisco Bay, and will have a carrying capacity of 25,000 barrels per day. In order to comply with the wishes of the Shell Company for prompt completion, the constructing engineers, Messrs. Sanderson & Porter, have pushed this work through in what is believed to be record time. The storage capacity of the pumping stations now in operation on this first section of the line amounts to 225,000 barrels, which is thus made immediately available for the storage of surplus production.

New Zinc Smelting Plants.—Within the past few weeks a number of old and abandoned zinc smelting plants have been put into commission, and new furnaces have been added to existing plants. The U. S. Steel Corporation is making good progress on its new zinc and acid plant at Donora, Pa. The U. S. Smelting, Refining & Mining Co. has purchased old plants at Iola, La Harpe and Altoona, Kan., giving the company an aggregate smelting capacity of 8000 retorts. The Grasselli Chemical Co. is adding two blocks of furnaces at Meadowbrook. Two blocks are being built in connection with the east plant at Pittsburgh, Kan., two at the Sand Springs works, one at Chanute and one at Bruce. An old plant at Nevada, Mo., is to be put in operation this month.

Los Angeles Meeting of the American Institute of Chemical Engineers

The meeting held at Los Angeles from Aug. 16 to 18 by the American Institute of Chemical Engineers is the prelude to a long series of meetings to be held this fall on the Pacific Coast by the national chemical societies. It is to be followed shortly by another meeting of the same institute at San Francisco.

The Eastern members and friends of the institute—some thirty in number—had come to Los Angeles in several parties over the Santa Fé road. The main and official party was personally conducted by the secretary of the institute, Dr. J. C. Olsen, since the president of the institute, Dr. Rosengarten, was unfortunately prevented from participating in the trip on account of sickness in his family. Stops were made on the trip at Colorado Springs for excursions to Pike's Peak and Cripple Creek, and at the Grand Canyon in Arizona, while the exposition at San Diego, so delightfully characteristic of Southern Californian life and achievements, was enjoyed for a number of days.

The institute was entertained at Los Angeles with truly unbounded Californian hospitality by a local committee of the institute, consisting of Messrs. Edgar Baruch and D. B. W. Alexander, in conjunction with the Southern California Section of the American Chemical Society, of which Mr. Baruch and Mr. Henry L. Payne—both real live wires—are chairman and secretary respectively. For the many automobile trips which had been arranged for the entertainment of the visitors, cars were provided by Messrs. E. Baruch, N. M. Hill, R. B. Peters, H. J. Reese, M. P. Waite, Mark Walker and F. C. Winter. Among many others who did a great deal for the entertainment of the visitors, Messrs. W. L. Jordan, H. L. Potter, W. Hirschkind, H. L. Keller, C. H. McCharles, M. P. Spencer, and Mr. Thatcher of the Kieselguhr company should be specially mentioned. With so many active hosts it goes without saying that the visitors were almost overwhelmed with entertainment.

On Monday, Aug. 16, a 120-mile automobile trip was made; first to Redondo Beach, where the oil-fired power station of the Pacific Light & Power Company was inspected; it contains reciprocating sets of 15,000 kw. and turbine sets of 24,000 kw.; the cleanliness of an oil-fired boiler house was duly admired. The automobiles then proceeded to Long Beach; on the way the large-scale precipitation of salt from sea water with the aid of the sun's heat was seen. Lunch was taken at the Hotel Virginia in Long Beach.

In the afternoon the party proceeded to Huntington Beach, where the beet sugar factory was visited and the different chemical engineering processes were explained by the superintendent, Mr. Joseph Varra, and the chief chemist, Mr. A. C. Horn. The return trip to Los Angeles was made over Santa Ana and Orange through extensive walnut and fruit orchards.

The same evening a trip was made to Alhambra, where the mission play, concerned with early Southern California history, was seen. The whole of Tuesday was devoted to a trip to Santa Catalina Islands, while on Wednesday afternoon an automobile trip was made to Pasadena, and on Wednesday morning an automobile trip to the Fullerton oil fields, where the process of "squeezing" gasoline out of natural gas was shown. The technical details were fully explained by Mr. A. Yost, superintendent of the Brea Canyon Oil Company, and Mr. W. A. Culp, superintendent of the Pacific Gasoline Company. The informal lunch of watermelons and figs and the spectacle of a burning snowball (of frozen gasoline) will never be forgotten.

On the evening of Wednesday a joint meeting of the American Institute of Chemical Engineers and of the Southern California Section of the American Chemical Society was held at the University Club, and was preceded by an informal dinner. The attendance was about seventy. The occasion was graced by the presence of many ladies. Mr. Baruch presided. Introductory speeches were made by Dr. J. C. Olsen and Prof. J. M. Stillman of Leland Stanford University, vice-president of the American Institute of Chemical Engineers, who had specially come from Palo Alto to Los Angeles to welcome the institute to California.

Two very interesting papers were presented and elicited some extended discussion.

The first paper, by Mr. W. C. Hanna of the California Portland Cement Company at Riverside described the Fleming dust collecting system which is successfully used at that plant for collecting any dust and preventing damage to the surrounding orange groves. Briefly, the installation consists of normal rotary kilns using dry process and oil for fuel. The draft for the kilns and dryers is produced by fans sucking at the ends of separate flues. Instead of discharging the gases into the atmosphere, the same exhauster fan blows the dust and fumes into a large "dry dust settling chamber," where the velocity of the gases is reduced about 90 to 95 per cent, resulting in a large amount of dust being deposited.

The extremely fine dust which does not settle, and the gases, then go to the "wet washing chambers," where the gases are forced up and down several times while following a serpentine course through a system of seven baffle chambers, and the last of the original so-called cement dust is captured by sprays of water which are in each chamber.

These sprays of water also bring into solution much of the gases, lime and alkalies. In connection with both the dry and the wet chambers there are means provided for the removal of the captured dust to the cement kilns.

The second paper of the evening, by Dr. J. C. Olsen of New York City, described "a new electrolytic method of sewage disposal," in operation at Elmhurst, in New York City, for more than a year. The C. P. Landreth process is used.

The principal novel features, which distinguish it from other electrolytic processes for sewage disposal, are, first, that lime is used together with electrolytic treatment, and, second, that a much smaller quantity of electricity per gallon is used than in other processes. A very thorough system of agitation is also employed.

We reserve publication in full of these two very interesting papers for a future issue.

On Thursday, Aug. 19, the party left Los Angeles to proceed to San Francisco. But several stops were made on the way. The main party left the train at Oxnard, to visit, under the guidance of Mr. H. E. Zitkowski, general chemist of the American Beet Sugar Company, the Oxnard sugar factory, which is the largest beet sugar factory in the world.

The ladies of the party, under the guidance of Prof. Edward Bartow, proceeded to Santa Barbara to enjoy the beauties of the "California Riviera."

The writer left the train at Surf, and was royally entertained by Mr. Krieger on a visit to the immense and unique high-grade kieselguhr deposits at Polnoc and to the extended mills which have grown up in the last three years to supply kieselguhr or celite in various forms to the most diversified industries—a new proof that the old creative California pioneer spirit is to-day as live as ever.

Roasting and Leaching Concentrator Slimes Tailings*

BY LAWRENCE ADDICKS

Through the courtesy of Dr. James Douglas I am permitted to give a summary of some of the results obtained in leaching slimes tailings in a series of experiments conducted under my direction at Douglas, Ariz., during the past year.

While the test run for which the data are given deals with a particular case, much of the work is general in its application and may therefore be of interest.

This work was done upon the ores of the Burro Mountain Copper Company. A description of the geology of the district will be found in the paper by R. E. Somers published in the May, 1915, *Bulletin* of the Institute.

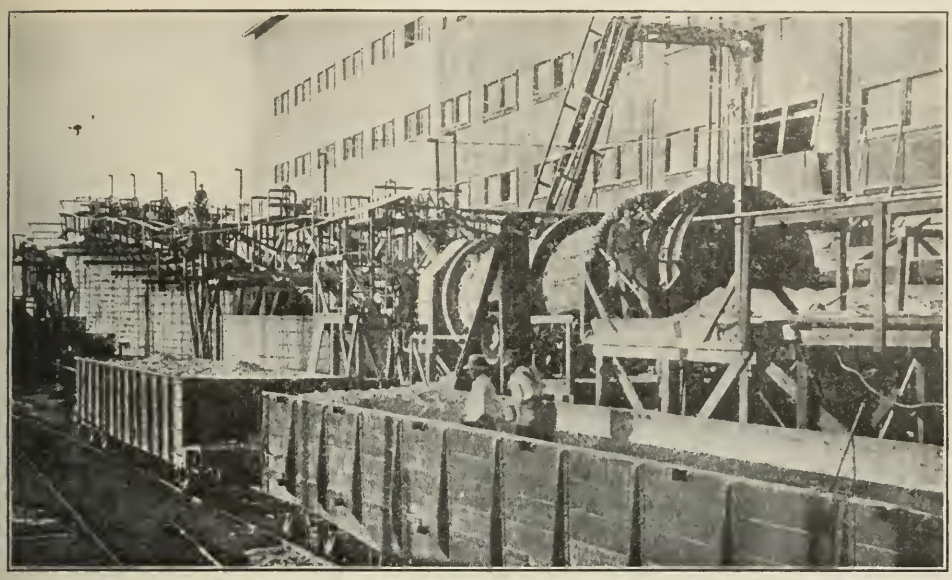

FIG. 1—GENERAL VIEW OF LEACHING PLANT

The mineral is pyrite and chalcocite very finely disseminated throughout the gangue and a characteristic of all the ores is the large amount of alumina present.

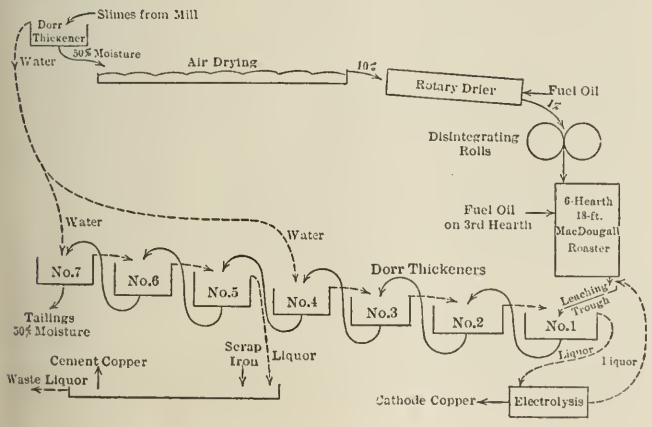

FIG. 2—FLOW-SHEET OF LEACHING PLANT

A representative analysis of the particular ore under consideration would be about as follows:

Cu, per cent	2.35	S, per cent	3.0
Ag, ounces per ton	0.05	CaO, per cent	0.5
Au	None	K_2O, per cent	4.0
Fe, per cent	1.5	SiO_2, per cent	70.0
Al_2O_3, per cent	13.0		

The leaching of the ore direct was early dismissed from consideration for the following reasons:

1. The ore would have to be quite finely crushed to liberate the mineral for leaching; concentrating after crushing would cost but a few cents a ton; and a higher total recovery would result from leaching tailings rather than ore.

2. Rough concentration would yield a suitable material for roasting to make sulphur dioxide or sulphuric acid in connection with the leaching scheme.

3. Such a program put the question of cost vs. recovery on a basis where flotation and discarding of tailings were directly comparable.

Concentrating experiments already available indicated that the tailings would consist of about 50 per cent of sands running about 0.3 per cent in copper, and therefore too low to justify retreatment, and 50 per cent of slimes running perhaps 1 per cent in copper, and it was on this latter material that the large-scale work was finally done.

At first flotation gave very unsatisfactory results, due primarily to the readiness with which the fine mineral particles became coated with a film of oxide upon exposure while concentrating, but later developments in this field overcame these difficulties and it became apparent just about the time the leaching plant was being started that the concentrator recovery was going to be so high that re-treatment of the tailings would not be justified. Nevertheless, for the sake of the data it was decided to carry through a representative run, the results of which are discussed below.

Fig. 1 is a view of the leaching plant, and the general scheme is shown in the flow sheet, Fig. 2. As the development of the electrolytic precipitation is really a subject apart from the leaching of the slimes, the results from this part of the work have been reserved for a separate paper. A part of the copper is shown recovered as cement in order to give a means of holding the iron and alumina in the liquor to be electrolyzed down to the desired point. A high ratio of washing can be used in the thickeners delivering to the cementation launder; in the remaining thickeners the ratio is governed by the evaporation loss, as there is no other outlet for liquor.

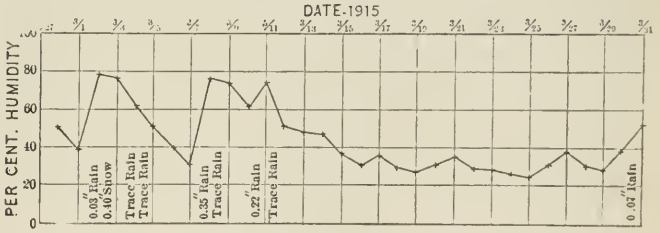

FIG. 3—MOISTURE IN AIR

The experiments will be taken up in detail under the headings of: (1) drying, (2) roasting, (3) leaching, and (4) washing.

Drying

As the slimes would be delivered from the concentrator in suspension as a thin pulp, it became necessary to consider carefully the question of drying.

*A paper to be presented at the San Francisco meeting of the American Institute of Mining Engineers, September, 1915.

Thickening experiments indicated that there was a critical degree of moisture of about 45 per cent, below which pumping the settled slimes resulted in further classification of the fine particles instead of delivering average pulp, so that thickening in a standard Dorr unit to 50 per cent of moisture was established as the first step.

As fuel is very expensive at the location in question and no waste heat can be counted on except that from the roaster gases, experiments were made with drying by exposure to the desert sun and winds. The heavy

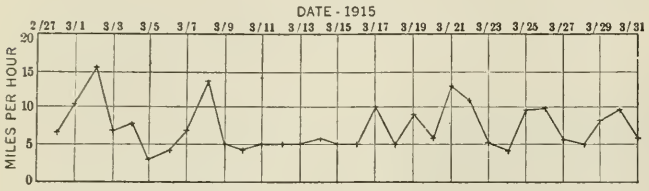

FIG. 4—WIND VELOCITY

pulp could well be poured into a shallow basin and the more or less dried slime reclaimed by some mechanical method for much less expense than an equivalent drying using artificial heat would cost. It was found that the pulp settled to about 30 per cent of moisture very readily when allowed to drain and that reasonable dry material could be obtained by a month's standing.

Figs. 3, 4, 5 and 6 give the measurements taken during the trial on three test beds, 10 ft. square, and respec-

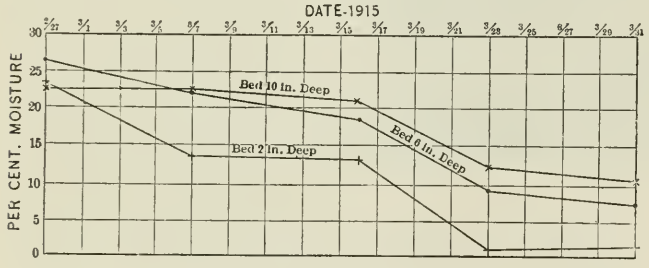

FIG. 5—MOISTURE IN SLIMES

tively 2, 6 and 10 in. deep, which were exposed to the atmosphere for about a month.

The climatic conditions are shown in Figs. 3, 4 and 6, and it will be noted that periods of both cold and wet weather were encountered during the first part of the run, much more favorable conditions following in the last two weeks. A bed only 2 in. deep would cost a good deal to reclaim, but the rate of drying, as shown in Fig. 5, was thought to indicate that a reasonably thick bed could be brought down to 10 per cent of moisture with-

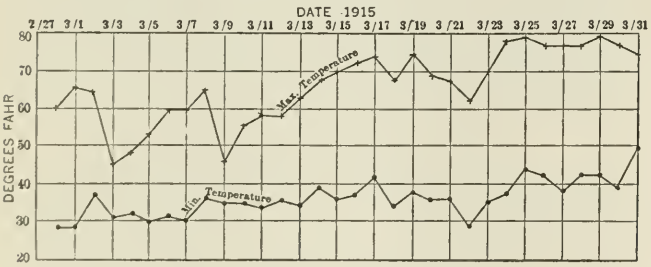

FIG. 6—TEMPERATURE OF AIR

out an excessive period of standing, and it seems probable that this will be the cheapest way to obtain this preliminary drying.

Up to this point the experiments were conducted on relatively small quantities of material, but starting with the following step—drying in the rotary kiln—large tonnages were handled. Instead of using atmospheric drying before feeding to the kiln, steam coils were buried in the cars of mushy slimes shipped to the experimental plant, bringing the moisture down to about 25 per cent, when it was shoveled directly to the drier.

This drier was one of the old Douglas roasters, 7 ft. in diameter and 31 ft. long. It was used as an ordinary unlined rotary kiln, with channel-iron spilling blades throughout the first two-thirds of its length, and cast-iron balls 3 in. in diameter feeding against a delivery screen made of sheet-iron plate with 1½-in. round holes. The idea was to dry and pulverize any caked nodules in the one apparatus. The outside was lagged with 1½-in. magnesia block, and heat was supplied by three oil burners at the delivery end. Two typical runs gave the following results:

Days run	23.0	12.0
Total tons dried	710.0	388.0
Tons per day	30.9	32.3
Per cent moisture entering	26.6	10.0
Per cent moisture leaving	1.1	2.0
Gallons fuel oil per day	404.0	154.0
Gallons fuel oil per ton dried	13.1	4.8

In general, it was concluded that about ½ gal. of fuel oil must be provided for each unit of moisture in the ore to be dried, so that 5 gal. would have to be charged against drying a 10 per cent product from the atmospheric drying beds, although this amount might be lowered in a properly designed drier. The capacity of the

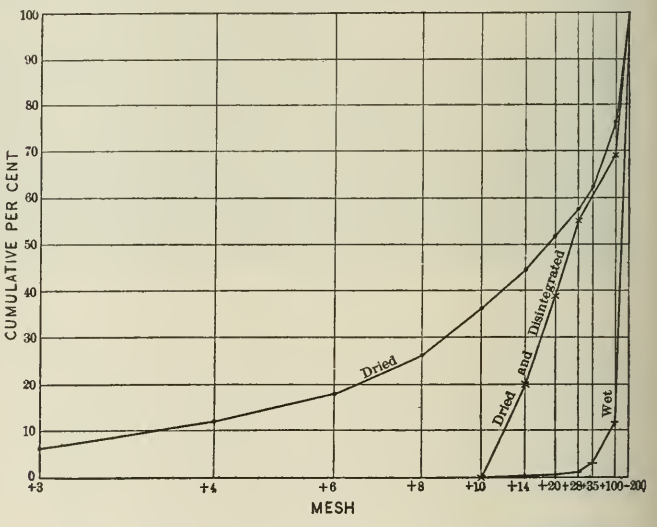

FIG. 7—CUMULATIVE SCREEN ANALYSIS OF SLIMES

drier was too low for the roaster used, and the pulverizing action of the iron balls inadequate, so the dried material was passed through a pair of disintegrating rolls, returning any oversize through a 10-mesh screen,

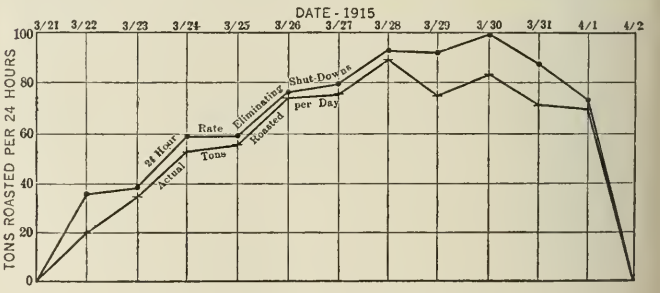

FIG. 8—TONS ORE TO ROASTER

and dried and disintegrated material was stored ahead of the roaster.

Fig. 7 shows cumulative screen analyses of the original wet slimes, the drier product, and the disintegrated material, made on the usual Tyler direct diagram. It must be remembered that the lumps formed in the kiln could be readily crushed between the thumb and forefinger, being merely caked clay. The danger was that

these lumps would be burned hard in the subsequent roasting.

The arrangement of the drier with skip feeding to roaster, and the row of Dorr thickeners can be readily seen in Fig. 1.

Roasting

The roasting was carried out in a standard six-hearth, 18-ft. MacDougall furnace with water-cooled arms, fuel oil being introduced on the third hearth. No change was made in the furnace for this work except to replace parts of the upper brickwork with firebrick. Fig. 8 shows the tonnage fed to the furnace daily during the particular run with which the remainder of this paper chiefly deals. When the arms began to be buried the

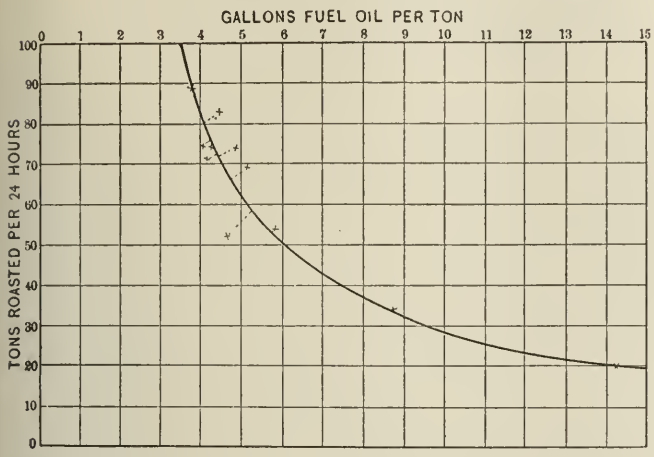

FIG. 9—ROASTER TONNAGE VS. FUEL-OIL CONSUMPTION

speed of rotation was increased from one revolution in 69 sec. to one in 60 sec. No trouble was experienced in the operation of the furnace.

Fig. 9 shows how the fuel-oil consumption was gradually cut down as the size of charge was increased. It is evident that 100 tons a day can be roasted with about 3.5 gal. of fuel oil per ton. The fuel oil burned was regulated so as to keep the maximum temperature on any hearth at about 950 deg. Fahr. Previous small-scale experiments had indicated that the proper roasting range lay between 900 deg. and 1100 deg. Fahr. Fig. 10 shows a log of the daily temperatures on the second, third, fourth and fifth hearths. It will be noted that the heat zone descended in the furnace as the tonnage

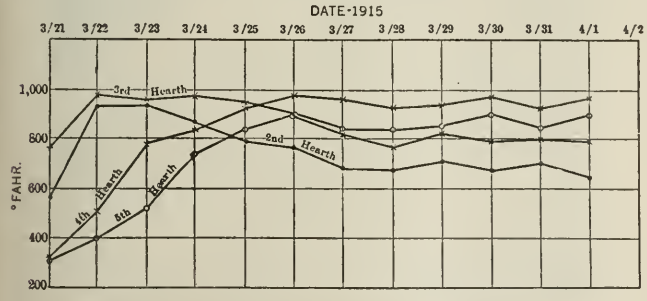

FIG. 10—ROASTER HEARTH TEMPERATURES

increased. This is shown diagrammatically in Fig. 11. At the same time the efficiency of the roast increased, as shown by Fig. 12. This is apparently due to the fact that at the higher rates, roasting temperatures were obtained on the fourth and fifth hearths, which were free from the more or less reducing atmosphere of the third and higher hearths due to the fuel oil.

Leaching

The hot calcines from the roaster were delivered through a spout casting made of Duriron into a rectangular trough about 30 ft. long, sloping 1¼ in. to the foot, which delivered directly into the first of the series of Dorr thickeners used for washing. This trough served three purposes: (1) that of leaching by agitation; (2) that of mechanically conveying the calcines from the roaster to the washing apparatus; and (3) that of absorbing the sensible heat of the calcines, thereby furnishing a warm liquor for electrolysis. A similar arrangement is described as doing excellent work in another field by Hofmann in his "Hydrometallurgy of Silver." A deep triangular trough was first constructed of common lumber. This was then lined with sheet lead

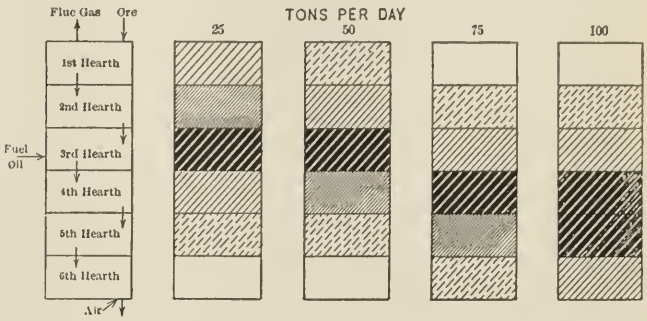

FIG. 11—ROASTER HEARTH TEMPERATURES

to make it liquor proof. Inside the lead lining, boards were loosely laid to prevent mechanical erosion of the lead by the calcines. A flat wooden cover was laid on top of the launder to keep down the steam and dust. This latter was not excessive, and would have been very slight had a more even delivery of calcines been made at the head of the sluice. The furnace arms alternated with light and heavy charges through the bottom drop hole and these were spread out over a reasonable time interval by placing an adjustable gate in the delivery spot, something on the plan of the classic hour glass. This worked fairly well, but it would have been better to have arranged some extra arms on the bottom hearth.

The copper content of the tailings at various points in their travel through the plant is shown in Fig. 13.

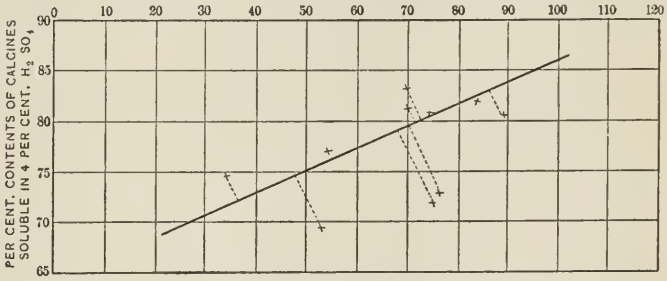

FIG. 12—VARIATION OF ROASTER EFFICIENCY WITH TONNAGE

The free sulphuric acid content of the liquor is shown in Fig. 14 and the effect of this strength of acid upon total extraction in Fig. 15.

The slimes as received assayed 0.84 per cent of copper. Fig. 15 shows that the calcines averaged about 0.74 per cent of copper, the grade falling as the furnace was gradually speeded up. This difference in assay was carefully investigated in the laboratory, and it seems very improbable that it was due to the formation of insoluble copper compounds during the roast, as three acids were used in the assay and various methods yielded but the merest traces of copper from the assay residue. The most probable explanation lies in the formation of particles of anhydrous copper sulphate during the roast, which blew over with the flue dust. No meas-

urements were made of the flue dust, as the furnace discharged into a common flue with other roasters treating concentrates.

The tails, as determined in the laboratory by heating samples of the calcines in 4 per cent sulphuric acid showed 0.2 per cent of copper, gradually dropping to 0.1 per cent as the furnace efficiency increased with the load. The actual final tails discharged from the last thickener ran about 0.1 per cent higher than the laboratory-leached calcines and laboratory tests showed this 0.1 per cent to be present as soluble copper. This same margin had been noted by Croasdale in his paper presented last year on his experiments at Ajo, and he there attributes it to the impossibility in practice of washing ore free from soluble salts. Fig. 15, however,

seems to indicate that the difference in this case is largely due to the stronger acid liquor used in the laboratory tests.

Fig. 14 shows that the run was started with over 3 per cent of free sulphuric acid at the leaching trough and that this strength was allowed to exhaust itself gradually upon the entering ore as the run proceeded,

the difference between final actual tails and laboratory tails increasing as the acid dropped. This same ratio is the basis of Fig. 14. It seems probable, therefore, that the strength of acid used will have to be considered in its bearing upon efficiency of extraction.

The leaching trough discharge ran but a few hundredths of a per cent higher in copper than the final tails after seven washings, showing that over 90 per cent of the leaching was done in the few seconds taken to travel down the trough. This high efficiency is due to the violent agitation when the hot calcines meet the relatively cool liquor, and to the fact that each particle of solid meets a fresh entering drop of liquor at the head of the trough, obtaining the full efficiency of the acid strength. An actual over-all extraction in practice somewhere in the seventies seems assured from these experiments.

Washing

The separation of the dissolved values from the exhausted slimes was one of the main problems presented. Any method of percolation was out of the question owing to the extremely fine state of subdivision of the material. The acid liquors employed, similarly ruled

out many of the mechanical filters. It was finally decided to try out continuous counter-current decantation with Dorr thickeners of the acid-proof type of construction, some experience with which had been gained at the installation at the Butte-Duluth Mining Co.'s plant. Two 30 by 10 ft. and five 24 x 10 ft. tanks with suitable mechanisms and wood-stave pipes and fittings for 4-in. air lifts were therefore ordered and connected after erection in accordance with the flow sheet shown in Fig. 2.

The acid proofing of these mechanisms consisted of the substitution of wood for iron in the under-liquor parts. In turn, this called for some changes in design, two arms being used in place of four and the inclination

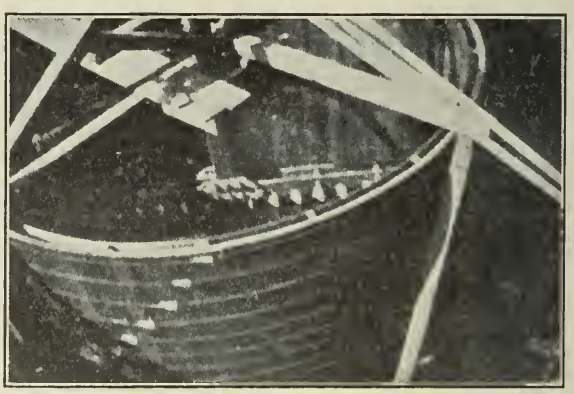

FIG. 16—THICKENER PADDLE

of the swept floor being lessened. Both these changes increased the digging load and the arms tended to ride rather than dig, extreme cases overstraining the unit. In spite of these difficulties the thickeners proved a practical apparatus. I believe, however, that the original metal construction properly protected by lead and equipped with Duriron rakes would be an improvement. An idea of the wooden construction can be obtained from Fig. 16.

The main difficulty was with the air lifts, and I am satisfied that these are not practical for the particular case. It must be remembered that it was desired to make an underflow of 50 per cent solids and that in the first thickeners many small lumps of slime had to be handled. When an air lift was gradually throttled until the desired thickness was obtained it no longer acted as a pump but more like a cannon, and a small capacity was obtained, finally resulting in one of two undesirable climaxes. Either a few small lumps settled out in the horizontal pipe under the tank, due to the slow flow, thereby choking it, or the lift would run thin for a moment followed by a rush as the normal pumping action was restored, stirring up the settled slimes and requiring constant attention for the next half hour in order to get the desired thickness of underflow. Also, the scouring action on the wood elbow at the point where the air was introduced was excessive, pipes sometimes wearing through in 24 hr.

Simple spigot discharge into a launder with some mechanical means of elevating was not promising, again due to obstructions making the flow of such a thick pulp very hard to regulate. Finally upon Mr. Dorr's suggestion two change were made: (1) a diaphragm pump was tried, and (2) the remaining air lifts were arranged to return a part of the underflow to the same tank, thereby increasing the solids moved and keeping the rate of flow in the horizontal feed pipe above the critical speed at which lumps settled out.

The diaphragm pump was an entire success. In the first place, the delivery depends almost entirely upon the stroke and speed and is not influenced by a momentary change in thickness as in the case of the air lift. Then the suction has the entire pressure of the atmosphere at its command and this is exerted whenever an obstruction is encountered. In fact, an ore sack and a pair of gloves were pumped up, to the surprise of the operator. It is astonishing how many things find their way into a system of this kind. A watch and fob and a brace and bit were among the articles added to our museum. Finally, the solids are moved steadily along and the scouring action is reduced to a degree which seems to make the use of wood pipe and fittings entirely practical. The pump was an ordinary 4-in. Gould contractor's pump with cast-iron body. The metal parts could readily be made of Duriron or other acid-resisting material.

During the run the temperature of the liquor in the first thickener gradually rose from 56 deg. Fahr. at the start until 100 deg. Fahr. was reached on the sixth day, at which point it was maintained by the sensible heat of the entering calcines. It was found possible to settle as high as 125 tons of solids in 24 hr. in one of the 30-ft. tanks. The overflow by actual test showed but 3 lb. of solids to the ton of liquor.

The liquors during the run accumulated sulphates corresponding to 10.0 lb. copper, 4.3 lb. iron, and 16.2 alumina per ton of slimes leached. The actual acid consumed was 49.0 lb. The acid equivalent of the corresponding metallic oxides is 70.5 lb., showing the presence of considerable sulphates in the calcines. A laboratory test on the calcines, using 4 per cent acid, showed a consumption of 68.9 lb. and a similar test on the product of a small-scale roast 69.1 lb. acid per ton. It appears, therefore, that less acid will be used in practice than in laboratory tests. Unfortunately, the run was not sufficiently prolonged to determine whether the proportion of impurities dissolved decreased as the liquors became more concentrated.

The Arizona Copper Co. produced 1758 tons of copper in May, 1915.

Metastability of Metals

BY A. VOSMAER

From more than one point of view it is important to recognize that metals are not always as stable substances as they appear to be. Professor E. Cohen of the Van't Hoff Laboratory, Utrecht, Holland, has carried out a large number of experiments bearing on the subject of metastability of metals and is continuing that work so that we may hope to have this difficult problem fully elucidated. It will be interesting and useful to the readers of this paper to be posted on the subject of allotropy of metals, since many a mystery in the world of metals has ceased to be such when the question of molecular transformation was considered.

The transformations of metalloids, such as carbon, phosphorus, sulphur from one modification into another are familiar to most people, but not so the transformations of metals which, by the way, are usually much less marked.

The man who, in a cold winter, buys a lot of block tin to store it away, runs the risk of finding a mass of grey powder after some time, instead of the solid white blocks. In fact, this did occur in Europe in the winter of 1858 and gave rise to the rather difficult question, whether or not tin in the white and in the grey state is one and the same substance. From a chemical standpoint it certainly is, but from a physical standpoint it certainly is not.

In fact, since we now have to admit that iron in the magnetized and the same in the nonmagnetized condition cannot be called one and the same substance, the problem of defining substances becomes a more and more difficult task for the scientist and it has also a practical importance in the industry. For it should be borne in mind that scientific research work can be of great benefit to the practical man, since the theory of metals and alloys not only explains mysteries and faults, but it also prevents mistakes and may even cure them.

The Van't Hoff Laboratory, through its head, Professor Cohen, has undertaken to study the question of metastability of metals and from the results published in the Royal Academy of Science of Amsterdam, we have prepared the following abstracts which give the gist of the results.

Allotropy of Bismuth[1]

Dilatometric research showed a sudden change in volume at a temperature of about 75 deg. C., when the alpha bismuth, stable at temperatures below 75 deg. C. changes into the beta bismuth, stable at temperatures above 75 deg. C. The alpha bismuth has a specific gravity of 9.732, the beta form 9.712. This is a considerable difference; it confirms the results of the dilatometric measurements which showed that the change from alpha to beta is accompanied by an increase in volume.

If we bear in mind that the beta bismuth differs in properties from the alpha modification and also that these molecular rearrangements take considerable time at temperatures lower than the transformation temperature proper, it is clear that as a rule commercial bismuth will always consist of a mixture of both modifications tending to reach equilibrium.

This explains why the physical constants of bismuth are as yet very far from being constant. Since the beta bismuth is a better electrical conductor than alpha bismuth, the specific conductivity of any sample of bismuth is bound to vary according to the ratio of alpha to beta bismuth in the sample.

Although the transition point is well defined at 75 deg. C., this does not mean that bismuth at a lower tem-

[1]Communication of June, 1913.

perature does not contain any beta metal. On the contrary, as a rule all bismuth will always contain some beta, as this form can very well exist in metastable condition.

On the other hand, it is noteworthy that the alpha bismuth may very well exist in metastable condition at temperatures above the transition point, even at temperatures as high as 150 deg. C.

In 1899 Perrot published his experience that the thermo electric potential of cast bismuth changes after some time without any apparent cause. Now we know from Cohen's investigation that this strange behavior of bismuth is not strange at all. Perrot's bismuth evidently contained some beta bismuth which slowly but surely turned to the stable alpha bismuth condition.

Determinations of the specific gravity, the melting point, the Hall effect, etc., have to be revised. All properties of bismuth hitherto determined except the atomic weight, must of necessity be corrected because not until 1913 was it known that all bismuth experimented upon may have consisted of a mixture—an undefined mixture —of alpha and beta bismuth.

We should remember the big difference between metals or alloys in the fluid state and in the solid state. It may very well be that in the fluid state all of the metal will be in the beta condition. On cooling down not all of the beta bismuth can find time to be converted to alpha bismuth and the beta condition is kept to a considerable extent in that form.

From a technical standpoint the change of specific gravity can be made use of. Every one familiar with castings knows the trouble caused by shrinkage; now bismuth and bismuth alloys possess the valuable property to expand on solidification, this, of course, gives rise to very sharp castings. It may be added that many of the fine Chinese metal castings of small objects for ornamental use contain bismuth. Unfortunately said change in volume—slight expansion on cooling—as observed by practical men in casting, cannot be explained by the allotropic change from beta to alpha bismuth at 75 deg. because it occurs at a much higher temperature and in a reverse sense.

It may be that there still is a third modification, gamma, of smaller specific volume than the beta and a second transition point a little below the melting point, but reports on bismuth do not mention this supposed third modification.

Allotropy of Antimony[2]

There have been four different forms of antimony known for some years, but the correlation of these has not yet been established.

Cohen investigated in how far commercial antimony, also known as metallic antimony, is to be considered as a metastable system and he came to the conclusion that it is metastable.

The four allotropic modifications of antimony are the ordinary or metallic, the black, the yellow and the explosive. The latter three are all metastable at ordinary temperatures.

Cohen's determinations of density led him to say that antimony after chilling, is in a form which changes at 100 deg. C., with a measurable velocity into a mass of different density. Probably about 96 deg. C. is the transition temperature.

The conclusion of this preliminary work is that antimony, as it is known in the familiar form, is a metastable system which consists of more than two allotropic forms. This is important in view of the extended use of antimony for alloys in technical arts.

Metals and alloys are judged, tested and paid for according to their properties and qualities. In case of dispute between buyer and seller in regard to quality the greatest embarrassment arises when authorities do not agree upon figures. But this will be unavoidable if metals are no longer what we think or thought them to be—definite substances. If a metal is a system of undefined composition as regards its own allotropic modifications, then we need not wonder about the discrepancies in physical constants and it is of the highest importance that the metal trade takes notice of the difficulties which may become traps in establishing definite figures.

[2]Communicated Oct., 1914.

Allotropy of Potassium[3]

Potassium is a metal of only very small importance for industrial uses and probably never will play an important rôle, but it is of interest to know that this metal also is subject to allotropic modification. The metal potassium as it has hitherto been known is at ordinary temperatures a metastable system in consequence of the simultaneous presence of two forms, alpha and beta potassium.

Allotropy of Copper[4]

It may surprise many people to learn that also in the case of copper we have a metal containing both alpha and beta copper, the transformation temperature being between 69.2 deg. and 71.7 deg. C.

In this, as in all cases, the transformation velocity depends largely on the presence of an electrolyte or of powdered metal which act as catalyzers. Under normal conditions the change of beta into alpha copper is so slow that it escapes notice unless specially looked for.

Remembering the changes undergone by tin and by zinc it is to be expected that bronzes and brasses will be subject to change as well.

Chemical Principles of the Blast Furnace

BY J. E. JOHNSON, JR.

This is a subject on which a number of large volumes have been written, but none of them have succeeded in elucidating the subject in such a way as to coordinate the accepted theories and the facts of practice to a profoundly useful extent. At the same time honor must be done to the work of some for their investigations which helped to lay the foundation, although not precisely for the structure which they had in mind.

Sir I. Lothian Bell in particular found time in a busy and highly successful commercial life to prosecute extensive investigations, to ponder at great length, and to record accurately the results of his labors in two large volumes in which I believe it is admitted that the first reasonably successful attempt was made to write a heat equation of the blast furnace. Most unfortunately for him and his disciples there are not one but two heat equations of the blast furnace, and in endeavoring to square all the conditions with this one equation he was led into errors which went far to vitiate the value of his work. But as a pioneer in applying chemistry and quantitative heat values to the operations of the furnace he is deserving of his high place in the esteem of furnacemen.

Gruner also set forth in 1879 the ideal condition of working of a blast furnace which has been too little heeded and has even been attacked in recent years as not universally correct, but I think I shall be able to show that Gruner is right and that his critic, through not realizing all the conditions, has fallen into error.

The action of the blast furnace must be considered in

[3]Communicated Feb., 1915.

[4]Communicated Dec., 1913; May, 1914.

three different aspects which sometimes merge into one another, but nevertheless can best be considered separately at first, the chemical, the thermal and the mechanical; in which order we shall consider them.

The Different Regions of the Furnace

An outline of a typical modern blast furnace is seen in Fig. 1. The cylindrical straight portion at the bottom is called the hearth or crucible or sometimes the well because it serves to contain the liquid iron and slag. The divergent cone above this is called the bosh. The short cylindrical portion and the long convergent cone above this, surmounted by another cylinder has so far as known to me no name established by universal custom, and I have been accustomed to call it the shaft, since the furnace as a whole is a "shaft" furnace and it is obviously this portion which gives it that name.

The furnace is expected to be kept filled to the line

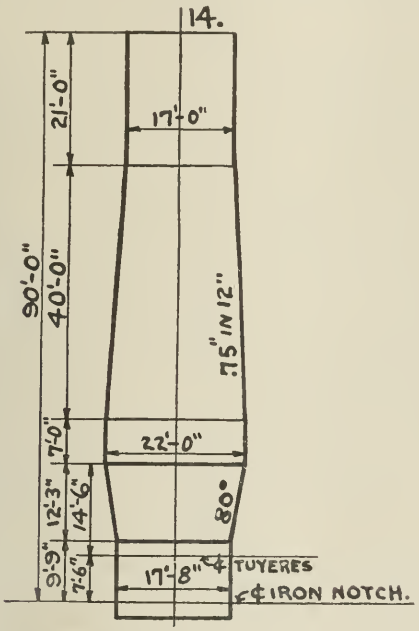

FIG. 1—LINES OF A MODERN BLAST FURNACE (SOUTH CHICAGO, NO. 4, 1914)

in the upper cylinder marked "stock line" and this is the diameter which is meant by the "stock-line diameter."

The height of furnaces, in the days of hand filling, was always measured from the hearth bottom to the top of the filling platform, but since the decline of hand filling the top platform is not quite such a definite and important level, having nothing to do with the level from which filling is done in mechanical charging, so it is better now to give the height to the bottom of the supporting collar on the hopper as that corresponds more nearly to the old top platform than any other equally definite point.

The size of furnaces is given by their height and diameter at the top of the bosh, very frequently the diameter of the hearth and stock line are added in the order given.

This terminology suffers from one defect. The word "hearth" denotes the level at which combustion takes place and connotes the laboratory of the apparatus in which the active work is done, but the region of the furnace which corresponds to this description is really the bosh, because the hearth, so-called, is generally filled (or largely so) with molten material, and combustion to any considerable extent cannot take place there in any event, since there is no outlet for the blast in any direction but upward, so that instantly on leaving the tuyeres the blast must pass up into the bosh, where it burns the coke and where most of the final work of the furnace is done. This should obviously be called the "hearth," if any region is to have that name. The habit of thinking and speaking of what goes on "in the hearth" is so universal among furnacemen that it is almost impossible to avoid using the word "hearth" in the sense of the laboratory of the furnace. I shall avoid confusion on this score to the best of my ability, but the reader should be on guard against the ever-present possibility of confusion from this source.

In the introductory chapter of this serial the general outlines and requirements of the process were set forth, and need not be repeated here. In operation the oxygen of the blast is burned by the fuel of the charge to CO in the bosh of the furnace. Theoretically oxygen first burns to CO_2 and then absorbs an additional atom of carbon which converts it into CO, since CO_2 cannot exist as such with carbon except at temperatures far lower than those in the hearth of a blast furnace. Practically the absorption of the additional atom of carbon takes place so quickly that no CO_2 has even been found excepting exceedingly close to the tuyeres and the physical difficulties of taking a correct sample of gas under the conditions existing are so great that little reliable work has ever been done to determine the limit within which the reaction occurs. I was formerly inclined to believe that for practical purposes the formation of CO_2 might be disregarded and the subject considered only on the basis of a direct formation of CO. Professor Howe, however, has pointed out to me that one of the observed facts of practice is well explained by assuming a zone of CO_2 formation at the tuyeres.

I shall later set forth the opinion that combustion of the oxygen to CO is not complete until the gas (blast) reaches the top of the bosh. If this be true and there were not a zone of CO_2 formation then the temperature would be virtually the same at the tuyeres as at the top of the bosh and this we know most positively is not true. There is a zone of intensest temperature right around the tuyeres which drops rapidly at first and then more slowly as we ascend.

These statements do not, unfortunately, depend greatly upon pyrometric measurements at different levels because the conditions of temperature, pressure and dripping iron and cinder within the furnace make such measurements in this zone almost if not quite impossible; the statements depend upon observation of the wear and the evidences of fusion at different levels in furnaces after they have been blown out, and general observation and experience with furnaces in operation.

The amount of heat developed by the combustion of a given quantity of oxygen to CO is only six-tenths of that developed by its combustion to CO_2 and the reaction $CO_2 + C = 2CO$ absorbs a large quantity of heat, hence combustion to CO_2 followed by instant conversion to CO would give a hot zone succeeded by a relatively much cooler one, the condition which we find in practice and for which we have no other adequate explanation. We are ,therefore, compelled to believe that at least part of the oxygen of the blast is converted to CO_2 and remains in that condition long enough to affect the temperature of the tuyere zone through the interval must be measured in hundredths if not thousandths of a second.

As far as the total heat developed in the hearth and the gas discharged into the shaft from the bosh is concerned the combustion to CO_2 has no effect, for in coming back from CO_2 to CO the heat absorbed is precisely the excess developed by consumption to CO_2 over that to CO, and the effect in the final result is therefore zero. Whether any effect of this narrow zone of high temper-

ature and relatively oxidizing condition can be determined may be left for later discussion and we need only say now that the ultimate reaction between the oxygen of the blast and the fuel in the bosh is to convert both to CO, with the development of a certain amount of heat, which is needed to complete the smelting operation, the nitrogen simply serving as a useless load to be carried.

The CO produced in the hearth and bosh passes up through the shaft of the furnace and with more or less help from the solid carbon of the charge reduces the iron from the oxide to the metallic state according to certain reactions which we may now discuss leaving for later discussion the question of heat development.

The functions of these two portions of the furnace, the shaft and the bosh, are quite separate and distinct so much so that we could substitute some other apparatus for one and leave the other unaffected.

For instance, we could produce iron sponge by reduction with a reducing flame in a rotary kiln and introduce it into the "bosh" of a furnace with no shaft above it and there melt the sponge to produce liquid iron and slag.

On the other hand, we could conceivably extract the iron sponge from the shaft of the blast furnace just above the bosh and then melt it down in an open-hearth or other melting furnace.

Many such processes have been tried and some of the attempts have succeeded technically although none of them have survived in actual use for they could not meet the commercial conditions.

They serve a useful purpose here by furnishing proof that the function of the blast furnace is not a single but a double one for the performance of two separate and distinct operations. There is in my opinion no such thing as a fundamentally correct understanding of blast-furnace principles without a full realization of this fact.

The Chemical Principles

The number of reactions which actually take place within the blast furnace is almost unlimited, but those which control its action are relatively few and simple.

These are the reactions between carbon, oxygen, and iron and its oxides, and the reactions which lead to the formation of slag, which are principally the formation of silicates and aluminate of bases, generally in fact almost universally lime and magnesia.

THE REACTIONS BETWEEN CARBON AND ITS OXIDES AND IRON AND ITS OXIDES

There are three well recognized oxides of iron which are in the order of their oxygen contents: Ferric oxide Fe_2O_3, ferric-ferrous, magnetic or black oxide Fe_3O_4, and ferrous oxide FeO.

The former is normally blood red in a color and very slightly magnetic under even the most powerful magnetic field, and is the commonest form in which iron occurs in nature. When hydrated it is brown in color and commonly known as limonite. The second is black and more highly magnetic than any other natural mineral, it is the second commonest form of iron oxide, and that to which iron oxidizes when heated.

The third, ferrous oxide FeO, is unstable under atmospheric conditions, and seizing oxygen from the air instantly returns to the form of ferric oxide.

The oxides of carbon are two, carbon monoxide CO and carbon dioxide CO_2, both gaseous at temperatures even far below that of the atmosphere.

These two elements and their five oxides react with one another at various temperatures according to the following equations in which the modern symbols are used to show that they are reversible:

$$3Fe_2O_3 + CO \rightleftarrows 2Fe_3O_4 + CO_2$$
$$Fe_3O_4 + CO \rightleftarrows 3FeO + CO_2$$
$$FeO + CO \rightleftarrows Fe + CO_2$$
$$3Fe_2O_3 + C \rightleftarrows 2Fe_3O_4 + CO$$
$$Fe_3O_4 + C \rightleftarrows 3FeO + CO$$
$$FeO + C \rightleftarrows Fe + CO$$

It may well be doubted whether the reduction of Fe_2O_3 to FeO takes place by way of Fe_3O_4, and I have always held the most serious doubts as to this point for two reasons: First, the relative complexity of the reaction involving three molecules of one oxide and two of the other, as compared with the extremely simple reactions

$$Fe_2O_3 + C = 2FeO + CO$$
$$Fe_2O_3 + CO = 2FeO + CO_2$$

which involve only one of each. Second, I have always found that the magnetic oxide is less reducible in the furnace than ferric oxide, and it is difficult for me to see how this could be so if ferric oxide has to pass through the magnetic oxide stage during reduction, and I have for several years past rejected that idea.

On the other hand, it is claimed that magnetic oxide is not irreducible in itself, but only because it is extremely dense and non-porous, so that the gas gets no opportunity to work on anything but its exposed surface. That magnetite is generally very dense is certainly true, but even in an extremely fine state of subdivision like roll scale or some of the Lake ores which are composed of flakes almost like graphite this oxide has a strong tendency to scour the furnace, that is, to come through only partly reduced and uniting with the slag forms a silicate of iron which always has an extremely scouring action.

On the other hand, again, Prof. H. O. Hofman of the Massachusetts Institute of Technology has told me that there are several arrests in the curve giving the relation between temperature and deoxidation of iron which indicate the existence of several intermediate oxides between those here noted, and the fact that iron in the course of reduction passes through these subordinate states of oxidation would indicate that it would also pass through the state of Fe_3O_4.

Testimony from such an authority cannot be questioned, but even admitting this as a laboratory condition it does not follow that the same thing takes place in the furnace, and certainly the reputation of magnetic oxide as an ore is not good among furnacemen on account of its well-recognized irreducibility, and I cannot believe that reduction of ferric oxide takes place principally by way of Fe_3O_4.

Carbon unites with oxygen according to three well-known equations as follows:

$$2C + O_2 \rightleftarrows 2CO$$
$$2CO + O_2 \rightleftarrows 2CO_2$$
$$CO_2 + C \rightleftarrows 2CO$$

all of which are reversible.

As the two oxides of carbon occur in the blast furnace in all concentrations from CO alone to CO and CO_2 in about equal proportions and through a very wide range of temperatures, we have the iron and its oxides exposed simultaneously to influences which tend to oxidize them and to those which reduce them.

The question of the temperatures and concentrations of the two oxides of carbon with which carbon is in equilibrium has been experimentally investigated by O. Boudouard in France, and the equilibrium condition of the iron and its oxides in the presence of varying percentages CO and CO_2 at different temperatures has been experimentally investigated by Baur and Glaessner in Germany and reported by them in *Stahl und Eisen* for May 1, 1903.

The work of Baur and Glaessner was extensive and ighly creditable. The data given are of great value, ut must not be used recklessly, as they cannot always e applied directly to the solution of practical problems hose conditions are frequently very different from hose which it is necessary to create in order to secure cientific results. In the present case the scientific nvestigation has sought equilibrium conditions which re only established after many hours, whereas in the last furnace the total time of passage of the gas from ts entrance at the tuyeres to its exit at the top is only few seconds, during which equilibrium in most reac- ions is not even approximated.

We can, therefore, use the valuable diagram of Baur nd Glaessner to show what *tends* to happen and what *annot* happen, but we should be led far astray if we ried to use its results to show the extent to which most f these reactions actually take place.

Their results are given by Sir William Ramsay in is work on "The Phase Rule," from which the follow- ng extract is taken as it is the only condensed and yet ogical statement extant with which I am familiar of very complex set of conditions:

"Some of the most important systems of three com- onents in which equilibrium exists between solid and as phases are those formed by the three components— ron, carbon monoxide, and carbon dioxide—and they re of importance especially for the study of the proc- sses occurring in the blast furnace.

"If carbon monoxide is passed over reduced iron owder at a temperature of about 600 deg., the iron is xidized and the carbon monoxide reduced with separa- ion of carbon in accordance with the equation

$$Fe + CO = FeO + C$$

his reaction is succeeded by the two reactions

$$FeO + CO = Fe + CO_2$$

$$CO_2 + C = 2CO$$

"The former of these reactions is not complete, but eads to a definite equilibrium. The result of the differ- nt reactions is therefore an equilibrium between the hree solid phases, carbon, iron, and ferrous oxide, and he gas phase consisting of carbon monoxide and dioxide. Ve have here four phases, and if the total pressure is aintained constant, equilibrium can occur only at a efinite temperature.

"Since, under certain conditions, we can also have the eaction

$$Fe_3O_4 + CO = 3FeO + CO_2$$

second series of equilibria can be obtained of a char- ter similar to the former. These various equilibria ave been investigated by Baur and Glaessner and ie following is a short account of the results of their ork.

"Mixtures of the solid phases in equilibrium with rbon monoxide and dioxide were heated in a porcelain ibe at a definite temperature until equilibrium was oduced, and the gas was then pumped off and ana- zed. The results which were obtained are given in ables I and II and represented graphically in Fig. 2.

"As is evident from Tables I and II and from the rves in Fig. 2, the curve of equilibrium in the case the reaction

$$Fe_3O_4 + CO = 3FeO + CO_2$$

hibits a maximum for the ratio $CO : CO_2$, at 490 deg., hile for the reaction

$$FeO + CO = Fe + CO_2$$

is ratio has a minimum value of 680 deg. From these rves can be derived the conditions under which the fferent solid phases can exist in contact with gas. hus, for example, at a temperature of 690 deg., FeO d Fe_3O_4 can coexist with a mixture of 65.5 per cent of CO_2 and 34.5 per cent of CO. If the partial pressure of CO_2 is increased, there occurs the reaction

$$3FeO + CO_2 = Fe_3O_4 + CO$$

and if carbon dioxide is added in sufficient amount, the ferrous oxide finally disappears completely. If, on the other hand, the partial pressure of CO is increased, there occurs the reaction

$$Fe_3O_4 + CO = 3FeO + CO_2$$

and all the ferric oxide can be made to disappear. We see, therefore, that Fe_3O_4 can only exist at temperatures and in contact with mixtures of carbon monoxide and dioxide, represented by the area which lies below the under curve in Fig. 2. Similarly, the region of existence of FeO is that represented by the area between the

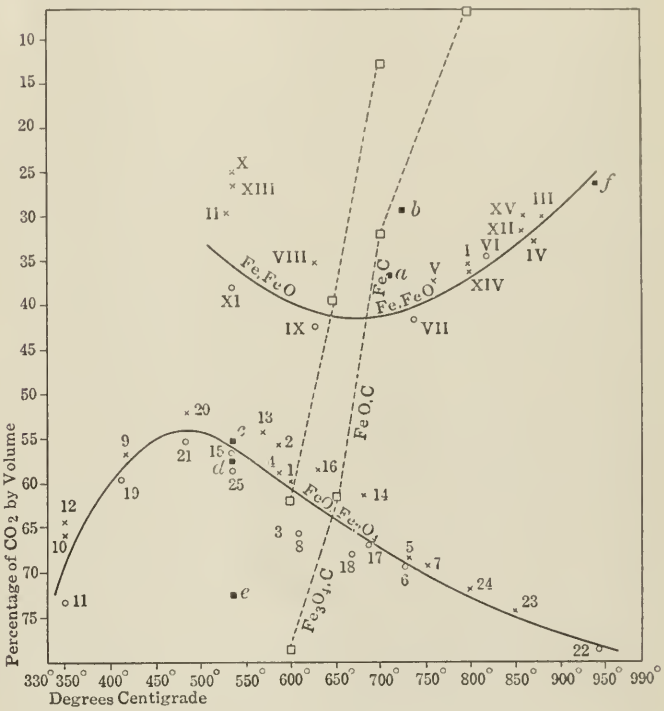

FIG. 2—EQUILIBRIUM CURVE

two curves, while metallic iron can exist under the conditions of temperature and composition of gas phase represented by the area above the upper curve in Fig. 2. If, therefore, ferric oxide or metallic iron is heated for a sufficiently long time at temperatures above 700 deg. (to the right of the dotted line, *vide infra*), complete transformation to ferrous oxide finally occurs.

"In another series of equilibria which can be obtained, carbon is one of the solid phases. In Fig. 2 the equilibria between carbon, carbon monoxide, and carbon dioxide under pressures of one and of a quarter atmosphere, are represented by dotted lines[1].

"If we consider only the dotted line on the right, representing the equilibria under atmospheric pressure, we see that the points in which the dotted line cuts the other two curves must represent systems in which carbon monoxide and carbon dioxide are in equilibrium with $FeO + Fe_3O_4 + C$, on the one hand, and with $Fe + FeO + C$ on the other. These systems can only exist at one definite temperature, if we make the restriction that the pressure is maintained constant (atmospheric pressure). Starting, therefore, with the equilibrium $FeO + Fe_3O_4 + CO + CO_2$ at a temperature of about 670 deg., and then add carbon to the system, the reaction

$$C + CO_2 = 2CO$$

will occur, because the concentration of CO_2 is greater

[1]These equilibria were obtained by Boudouard, *Annales chim. phys.*, 1901 [7], 24, 5. See also Hahn, *Zeitschr. physikal. Chem.*, 1903, 42, 705; 44, 513. Rhead and Wheeler, *Jour. Chem. Soc.*, 1910, 97, 2178.

than what corresponds with the system $FeO + Fe_2O_4 + C$ in equilibrium with carbon monoxide and dioxide. In consequence of this reaction, the equilibrium between $FeO + Fe_3O_4$ and the gas phase is disturbed, and the change in the composition of the gas phase is opposed by the reaction $Fe_3O_4 + CO = 3FeO + CO_2$, which continues until either all the carbon or all the ferric oxide is used up. If the ferric oxide first disappears, the equilibrium corresponds with a point on the dotted line in the middle area of Fig. 2, which represents equilibria between $FeO + C$ as solid phases, and a mixture of carbon monoxide and dioxide as gas phase. If the temperature is higher than 685 deg., at which temperature the curve for $C — CO — CO_2$ cuts that for $Fe — FeO — CO — CO_2$, then, when all the ferric oxide has disappeared, the concentration of CO_2 is still too great for the coexistence of FeO and C. Consequently, there occurs the reaction $C + CO_2 = 2CO$, and the composition of the gas phase alters until a point on the upper curve is reached. A further increase in the concentration of CO is opposed by the reaction $FeO + CO = Fe + CO_2$, and the pressure remains constant until all the ferrous oxide is reduced and only iron and carbon remain in equilibrium with gas. If the quantities of the substances have been rightly chosen, we ultimately reach a point on the dotted curve in the upper part of Fig. 2.

"Fig. 2 shows us, also, what are the conditions under which the reduction of ferric to ferrous oxide by carbon can occur. Let us suppose, for example, that we start with a mixture of carbon monoxide and dioxide at about 600 deg. (the lowest point on the dotted line), and maintain the total pressure constant and equal to one atmosphere. If the temperature is increased, the concentration of the carbon dioxide will diminish, owing to the reaction $C + CO_2 = 2CO$, but the ferric oxide will undergo no change until the temperature reaches 647 deg., the point of intersection of the dotted curve with the curve for FeO and Fe_3O_4. At this point further increase in the concentration of carbon monoxide is opposed by the reduction of ferric oxide in accordance with the equation $Fe_3O_4 + CO = 3FeO + CO_2$. The pressure, therefore, remains constant until all the ferric oxide has disappeared. If the temperature is still further raised, we again obtain a univariant system, $FeO + C$, in equilibrium with gas (univariant because the total pressure is constant), and if the temperature is raised the composition of the gas must undergo change. This is effected by the reaction $C + CO_2 = 2CO$. When the temperature rises to 685 deg., at which the dotted curve cuts the curve for $Fe — FeO$, further change is prevented by the reaction $FeO + CO = Fe + CO_2$, When all the ferrous oxide is used up, we obtain the system $Fe + C$ in equilibrium with gas. If the temperature is now raised, the composition of the gas undergoes change, as shown by the dotted line. The two temperatures, 647 deg. and 685 deg., give, evidently, the limits within which ferric or ferrous oxide can be reduced directly by carbon.

"It is further evident that at any temperature to the right of the dotted line, carbon is unstable in presence of iron or its oxides, while at temperatures lower than those represented by the dotted line it is stable. In the blast furnace, therefore, separation of carbon can occur only at lower temperatures, and the carbon must disappear on raising the temperature.

"Finally, it may be remarked that the equilibrium curves show that ferrous oxide is most easily reduced at 680 deg., since the concentration of the carbon monoxide required at this temperature is a minimum. On the other hand, ferric oxide is reduced with greatest difficulty at 490 deg., since at this temperature the requisite concentration of carbon monoxide is a maximum."

While the whole series of reactions between iron and carbon and their oxides are graphically portrayed in the chart of Fig. 2 and the accompanying explanation, the form in which the explanation exists is rather condensed and it may be well to run over some of the more important reactions in their relation to the more important phases of the operation of the furnace.

The reduction of iron oxide to iron is performed principally by carbon monoxide, but partly by solid carbon. The more complete is the reduction by CO the more efficient is the operation. The reason for this is not immediately apparent, but will be explained in detail in the next chapter. Part of the CO_2 so formed picks up carbon from the fuel and reconverts itself into CO; on the other hand, the CO is in part split up by what is supposed to be a catalytic action of the iron oxide according to the equation $2CO = CO_2 + C$. The carbon so deposited is in the form of an impalpable powder, which being a solid travels down with the stock, while the gas whose splitting up deposited it, passes on up and out of the furnace. At lower levels where the temperatures are higher and a smaller concentration of CO_2 can remain in equilibrium with carbon this carbon dust is dissolved by the reaction of $C + CO_2 = 2CO$ and passes up again with the gas. We have then a never-ending conflict of conditions in the shaft of the furnace with first one reaction occurring and then the opposite one wiping out its effects.

The effect of having deposited carbon carried down in the solid state through a given zone and carried up as gas to be redeposited again at the top of this zone is to produce an excess of this carbon dust in this zone, which tends to obstruct the openings in the stock through which the gas must pass and causes the furnace to work "tight" in this zone, and most furnaces which slip with more or less regularity in normal operation do so from about the same depth, as measured by the violence of the slip and the effect on the furnace. Such slips throw out huge clouds of black dust which travels high in the air; part of this is undoubtedly partly reduced iron, but much of it is the carbon dust which caused the slip in many cases.

While discussing the subject of the conflicting conditions existing in the shaft of the furnace it is well to call attention to the fact that the stock is charged in roughly horizontal layers, first one of fuel, then one of ore and stone, one of which tends to reduce the CO_2 already formed to CO, while the other tends to oxidize the CO to CO_2. These layers are only a foot or so in thickness, and the time of the passage of the gas through them must be measured in hundredths of a second so their effect is like that of waves of alternating forces, one set trying to hinder, the other to assist in bringing about the equilibrium which the broader conditions of temperature, etc., are trying to establish. This in itself would constitute a sufficient reason for the impossibility of predicting the conditions which will prevail under any given circumstances by the equilibrium diagram.

The Real Controlling Factor in the Composition of the Top Gas

After all the laborious and painstaking investigations of this subject which have been made we come now to the astonishing fact that the composition of the top gases is not a cause but an effect, and that important as are the detailed reactions I have so briefly described the composition of the top gas does not depend on them primarily at all, and at least three-fourths of all the work done on that subject has been wasted.

The reason for this will be clearer after we have discussed the heat equation of the furnace, but it will be well to explain it now and then return to it again later if desired. The reason is this: The ore to produce a ton of iron contains a certain definite quantity of oxygen; ferric oxide contains 70 per cent Fe and 30 per cent O, magnetic oxide Fe_3O_4 contains 72.4 per cent Fe and 27.6 per cent O, but commercial pig iron only contains about 94 cent Fe, and this being accompanied by 35.8 per cent of its weight of oxygen in the case of magnetite and 40.3 per cent in the case of ferric oxide, the oxygen per unit of pig iron is 33.7 per cent in the first case and 38 per cent in the second. These are perfectly definite relations not subject to furnace conditions or other qualifications.

We shall presently see that to keep the furnace hot enough in the hearth to run, a certain amount of fuel must be burned in the hearth for every unit of iron produced, the amount having nothing to do with reduction or in a general way with chemistry at all, but being a plain matter of heat, as the case of melting ice or any other solid. Now this carbon is burned to CO and nothing else; the CO_2 phase is, as I have explained, a transient one without effect on the final result. Thus we have a certain definite amount of carbon monoxide depending entirely upon hearth conditions and a certain definite quantity of oxygen added to it, as the oxygen is removed from the ore during the upward passage of the gas. It is obviously no problem in chemistry, but only a rudimentary one in arithmetic as to what the result will be in the composition of the gas at the furnace top.

But this statement which would settle so many problems if it were unreservedly true is subject to a certain limitation. The amount of carbon which must be burned in the hearth is not the same as the amount which is charged into the top, nor does it even bear a fixed relation with it, because the carbon charged, from the moment it enters the furnace, is subject to the solution by the CO_2 in the gas, and to direct oxidation by the oxygen of the ore and these influences, particularly the latter, as I shall presently show, are extremely variable, so that though the oxygen liberated and the carbon burned in the hearth per unit of iron produced are definite quantities which by themselves would give a top gas of a certain definite composition, they are not the sole determining factors; a secondary but none the less considerable influence is exerted by the carbon dissolved before it reached the tuyeres. This constitutes a variable addition of carbon to the definite composition of gas produced by the two main factors.

The Solution of the Carbon

The flux used for blast furnaces is universally either carbonate of lime, calcite or carbonate of lime and magnesia, dolomite, or a mixture of these two. These carbonates are broken up by heat, the carbon dioxide beginning to come off at a temperature of 800 deg. Fahr. or so, and not being all driven off, especially in the case of dolomite, until it reaches a temperature almost twice as high.

This is the range of temperature in which carbon dioxide attacks solid carbon very actively, and as a consequence the carbon dioxide liberated by the flux carries off enough carbon to restore approximately the equilibrium set by the conditions of temperature and the relative strength of the reducing and oxidizing influences in that zone.

This not only constitutes a loss of solid carbon, but a loss of heat as well, since the reaction $CO_2 + C = 2CO$ represents an absorption of heat of $14750 - 2 \times 4375 = 6000$ B.t.u. per pound of carbon dissolved. The carbon dissolved would obviously be equal to that in the limestone from whence the CO_2 comes, if all the CO_2 of the flux were reduced to CO, and as carbon constitutes 12 per cent of pure limestone (13.8 per cent of pure dolomite) and as the ratio of CO to CO_2 to which it is reduced is approximately 2:1 or two-thirds CO, we can see that 8 per cent to 9 per cent of the weight of the flux is the quantity of carbon dissolved and carried out the top of the furnace by the CO_2 of the flux. In proof of this fact gas samples taken from a point well below the stock line show a higher content of CO_2 than simultaneous samples from the furnace top showing that the CO_2 evolved by the flux was actually reduced to CO. I believe that this experiment has been made quite frequently, and I myself have made it with results which left no room for doubt.

The obvious suggestion is that the flux should be "burned" so as to drive off its CO_2 before charging into the furnace, and this has in fact often been proposed, but has never been done to any great extent. This failure may be due to inertia and the desire to avoid any additional operation at the blast furnace, but it has a certain justification in that most furnaces have a considerable excess of heat in the shaft and the limestone can be calcined with this without burning any fuel for this purpose. In many, if not most, cases this results in ultimate economy in dollars and cents in spite of the fuel dissolved by the CO_2. We can discuss this subject better when dealing with heat balance of the furnace in the next chapter.

A third source of solution loss is the contact of the ore and fuel and the direct reduction which results according to the equation $Fe_2O_3 + C = 2FeO + CO$ and $Fe_2O_3 + 3C = 2Fe + 3CO$.

These reactions take place freely throughout a wide range of temperature as shown by Fig. 2, and therefore every point of direct contact between ore and fuel is a possible point of direct reduction and solution loss. It would appear at first sight that this was precisely what we wanted, but when we come to deal with the thermal equations we shall see that it results in a very real loss, and I shall endeavor to show that the increase in the number of points of contact between ore and fuel accounts for the increase in the fuel consumption of fur-

naces which has resulted when their burden has been changed so largely to fine ore.

The conditions which lead to solution losses by any or all three of these methods are important and worthy of careful study, even though the theoretical laws of ore reduction do not control the action of the furnace to anything like the extent believed by some.

The Action of Hydrogen and Volatile Hydrocarbons

All furnace fuels contain a certain amount of combustible hydrocarbonaceous matter not driven off when the fuels were produced, but volatile at the temperature of the blast furnace, and as these frequently if not always contain considerable quantities of hydrogen their effect on the composition of the top gases is greater than their absolute quantity would lead one to suppose.

The quantity of volatile combustible matter in anthracite and coke is ordinarily 2 or 3 per cent, although it may go higher than this in some cases.

No analyses of this volatile combustible matter in anthracite and coke are at hand, and in ordinary cases and for ordinary purposes their quantity is not sufficient to exert an important influence. But in charcoal the case is very different; the volatile matter is about 30 per cent of the total weight of the fuel, and by far the larger proportion of it is combustible, about 50 per cent by volume hydrogen and about 15 to 20 per cent are methane or other hydrocarbon containing the same amount of carbon and hydrogen as that amount of methane in addition to some 10 or 15 per cent CO.

This is very important because the first two of these gases are extremely active reducing agents even at quite low temperatures, and the quantity of oxygen required to satisfy them is much greater than is required for CO or carbon. Hydrogen requires eight times its own weight of oxygen to convert it to water, and methane to convert it to water and CO_2 requires four times its weight of oxygen, as compared with one and a third times its weight to convert carbon to CO or two and two-thirds to convert it to CO_2. Moreover, about 30 per cent of the product of combustion of methane and all that of hydrogen is water vapor which mingles with the water vapor from the stock and completely disappears as a determinable quantity in the top gases.

Hydrogen is active as a reducing agent at temperatures lower than those required for much activity by carbon monoxide, and therefore the presence of this gas may be very beneficial in certain special cases. We have, unfortunately, no such reliable investigations of the reducing action of hydrogen as those of Baur and Glaessner for the oxides of carbon, but it is well known that the reaction is reversible; steam passed through a red-hot iron pipe is broken up, the oxygen attacking the iron of the pipe and hydrogen being set free. On the other hand, hydrogen will reduce iron oxide to metallic iron at quite a low temperature. But no data exist as far as known to me on the equilibrium percentages of hydrogen and water vapor at different temperatures in the presence of iron and carbon and their oxides.

The reversibility of the action of hydrogen will appear very strikingly in the next chapter; it will be seen that a chemical balance for the ingoing and outcoming materials of a charcoal furnace cannot be made unless the very considerable proportion of the total oxygen which disappears by combination with hydrogen be brought into account, while in coke furnaces it will be seen that hydrogen is produced by the decomposition of water, not only in the hearth of the furnace but also on a much more extensive scale in the shaft.

The reactions which are probably responsible for this result are

$$H_2O + Fe \rightleftarrows FeO + H_2$$

and

$$H_2O + CO \rightleftarrows CO_2 + H_2$$

both of which are reversible, as indicated.

The second is the typical reaction of the steam-blown gas producer.

The factors which control the direction in which these reactions take place are probably temperature and concentration of CO_2, but the indications are that temperature is the more important because hydrogen is consumed in the charcoal furnace, with its low top temperature, in spite of fairly high concentration of CO_2, while it is produced in the coke furnace, with its much higher top temperature, in spite of the low concentration of CO_2.

There is, however, much more ore and, therefore, more oxygen in proportion to the top gas in the charcoal furnace, and this may account for the oxidation of the hydrogen in that case.

These are some of the factors which affect the situation, but the conditions which control we frankly do not know.

The Carburization of the Iron

This is a subject of the details of which we know relatively little. Iron absorbs carbon eagerly up to between 1 and 2 per cent in the solid condition if exposed for a sufficient length of time at a high temperature, and in the liquid condition reasonable exposure to incandescent carbon will raise the latter element to about 2½ per cent in a neutral or slightly oxidizing atmosphere, but it is difficult to raise the carbon contents of a bath of steel beyond this limit by any means commonly available. Even in the electric furnace difficulty has been found in commercial operation in raising the carbon to the range which is commonly found in pig iron.

The explanation for this probably is that the conditions of exposure in the blast furnace are exceedingly favorable. The iron sponge, produced by the breaking up of the iron ore into powder under the action of the reducing gases and the removal of the oxygen from this powder, probably absorbs some carbon from the gas or the fine carbon precipitated from the gas before it reaches the zone of fusion, but not much is known about this.

After fusion the iron forms into drops presumably on the surface of the pieces of coke and then trickles down through the coke which constitutes the only solid contents of the bosh and hearth.

The progress of the iron is probably very slow at first, because until it is carbonized its temperature of fusion is that of steel, several hundred degrees higher than that of cast iron, while the temperature of the upper part of the bosh is much lower than that around the tuyeres. It may even be that the iron descends through the upper part of the bosh in the solid condition attached to the coke and is carried down by the latter in the solid condition. Then as it becomes more thoroughly carbonized and the temperature rises, it melts and completes the journey by trickling, but even this constitutes a slow descent because the surface of the coke is always porous and therefore rough, and the pieces of coke being in close contact with one another the path of the trickling iron is rough and tortuous.

Another important factor in retarding the progress of the iron and giving a chance for carburization is the high velocity of the gas upward, which must act to some extent like the up-blast through a shot tower in retarding the velocity of the liquid metal downward.

The conditions controlling carburization are not by any means thoroughly understood, and it is a lamentable fact that so little reliable work on the determination of carbon in cast iron has been done that our knowledge of the quantity of carbon in different irons made under different conditions is much less comprehensive than that of any other branch of the chemistry of iron.

We do know, however, that by the use of extremely high temperatures in the experimental electric furnace Moissan and more lately Witorff have succeeded in producing compounds of iron and carbon higher in the latter element than have ever been produced industrially. The compound Fe_2C seems to have been definitely identified as one of these products, and this contains 9.7 per cent of carbon. It is, therefore, probably safe to say that the higher the temperature, other things being equal, the more carbon will be absorbed. It is also probably safe to say that the more carbon in the hearth per unit of iron produced, other things being equal, the greater will be the carbon absorption.

The amount of excess heat in the hearth is probably a factor of much importance, and the nature of the fuel used may be of predominating importance since with charcoal fuel the carbons in the iron produced under certain circumstances rise to 4.50 per cent or more, although the temperature in the hearth is low relatively to that of a coke furnace which produces iron commonly running about 3.70 to 4.10 per cent carbon.

This subject will be further discussed in dealing with furnace operation and the quality of iron.

Manchester Meeting of the Society of Chemical Industry

The annual meeting of the Society of Chemical Industry was held in Manchester from July 14 to 16. According to the report of the Council, read by the secretary, Mr. C. G. Cresswell, the number of members is 4017.

There were less social functions than in former years, but more papers, mostly concerning the conditions and prospects of the British chemical industry and its relation to the chemical profession.

Presidential Address

Prof. G. G. HENDERSON, in his presidential address, said: "Since the outbreak of the war there has been much discussion concerning the present position and the future prospects of the chemical industries of this country, and I earnestly hope that the serious consideration which has been given to the subject will have at least one result—that we shall refrain from talk and proceed to action. We have been made to realize more clearly than ever before that during the last forty years chemical industry in Germany has made marvellous strides in advance, while in this country [England] it has by comparison stood still or even gone back. We have to admit that certain branches of applied chemistry, particularly the manufacture of dyestuffs, of synthetic drugs, and of organic compounds and fine chemicals in general have passed almost wholly out of our hands, or rather have never been taken up to any notable extent in this country. We cannot deny that the Germans have with energy and success developed on the industrial scale many scientific discoveries, such, for instance, as the various methods for the fixation of atmospheric nitrogen, while we have done little or nothing in that direction. Even our former supremacy in the manufacture of heavy chemicals has been seriously attacked. These are the facts."

Professor Henderson thinks there are two main causes of British lack of progress. "Firstly, we have failed to realize that 'scientific research work carried out in the laboratory, is the soul of industrial prosperity'—that modern chemical industry must of necessity be based upon research if it is to meet with success. This axiom may indeed have been tacitly accepted, but, speaking generally, it has not to a sufficient extent been made a guiding principle in our chemical industries. In the second place, there has not been in the past a sufficiently close and intimate interchange of information and opinions between manufacturers and professors of chemistry; in fact, most unfortunately for both manufacturer and teacher, the attitude has rather been one of mutual aloofness and reserve."

To rectify these errors Professor Henderson advocates the scheme of Industrial Fellowships, more or less on the lines of that successfully inaugurated by the late Kennedy Duncan in connection with the Universities of Kansas and Pittsburgh. "The essence of this eminently practical idea is that any manufacturer who desires to have some technical matter investigated applies to the chemistry department of a university or technical college for the service of a chemist qualified to prosecute research, and undertakes to provide adequate remuneration for a period of one or more years; the work is done in the chemistry department under the general superintendence of the professor, and, if necessary, facilities for large scale experiments are provided by the manufacturers."

As to the training of chemists for technical posts, Professor Henderson points out that opinions differ but may be grouped into three categories. "Some teachers appear unwilling to admit the possibility of the existence of the chemical engineer, and maintain that the chemical student requires nothing more than a sound scientific training to fit him for an industrial career, and that, if only he is a good chemist, he will be able after he enters a chemical factory to grapple with and overcome the special problems involved in the design and construction of apparatus and plant for chemical operations in any case. Others, again, hold that in addition to a thorough scientific training the student should receive such a course of instruction in chemical engineering as can be given in any teaching institution properly staffed and equipped for that purpose. Lastly, a few teachers apparently incline to the opinion that the student after acquiring a comparatively elementary knowledge of general chemistry should proceed at once to specialize in some branch of chemical technology."

This last method Professor Henderson considers to be wrong in principle and futile as regards results: any specialization in chemistry should be post-graduate work. The other two rival methods of training stand upon a different footing, and each can be defended by cogent arguments, but Professor Henderson's own experience leads him to advocate the second course.

Co-partnership in Chemical Industries

In a paper on this subject by Sir WILLIAM LEVER, it is pointed out that the present war has given Great Britain an awakening. British industries will be stimulated to organize efficiency as a result of the war. Yet the attainment of efficiency in mechanical appliances, in chemical knowledge, in banking arrangements, is not sufficient, but the human element must be taken care of. For this reason the author recommends co-partnership in the chemical industries—not simply profit-sharing, but also loss-sharing.

"Just as it is found in practice that the debenture holder, and to almost an equal extent the preference shareholder, take little or no interest in the undertaking in which their capital is invested, so it is found that the sole impulse and inspiration for development, growth, and activity in industries springs from direct interest in the results as represented by the holding of ordinary shares with possible profits or losses. When the board of directors are simultaneously ordinary shareholders, the greatest amount of efficiency, development and activity can be attained. The very fact that management and labor are often relegated solely to the position of debenture holder has reduced the efficiency

of management and labor and their interest in the undertaking in which they are engaged to the level of that of debenture holder, which, as we all know from experience, is, practically, a minus quantity." . . .

"I know of no industry to which the system of co-partnership applies with greater force than to the chemical industry. A British chemical industry, founded upon the principles of co-partnership, with employees trained and instructed as to what these co-partnership principles meant, and realizing the opportunities co-partnership offered them, would surely possess employees superior to those of competitors in Germany, or elsewhere, under mere wage and salary conditions."

It is more difficult in the chemical industry than in any other industry to assess the services of each member of the staff, whether as inventor, developer of the inventions of others, or organizer, or rank and file employee carrying on the routine process of production.

The following rules on co-partnership should be always kept in mind:

Profit sharing or co-partnership must not degenerate into charity or philanthropy. Its objects must be the increased success of the undertaking, with increased prosperity for all connected with it. It must not place management in the position of servant to labor through liability to criticism and censure. It must ensure to labor freedom from interference of management in the enjoyment of the benefits derived from profit sharing. It must possess greater stability than a mere system of bonus cash payment. Its benefits must be felt by the wives. It must have a distinctly elevating tendency on management and labor, raising them in the social and intellectual scale, and increasing their power for enjoyment and happiness as well as their power of usefulness. Control must remain with those who find the cash capital.

The whole basis of profit sharing or co-partnership cannot be other than enlightened self-interest for both capital and labor. Any other idea would be destructive to the self-respect of the employee, and lead to confusion from the point of view of capital. Philanthropy is own sister to charity, and charity is the mother of pauperism. There is no room for philanthropy in business, there is no room for maudlin sentiment; but there is ample room for a better and improved industrial relationship between capital and labor, one in which labor can become, equally with capital, interested in the results of the undertaking.

Research and Chemical Industry

Dr. M. O. Forster in a paper on this subject deplored the chasm between college and factory and pointed out that this estrangement proceeds in a vicious cycle. "If the manufacturer is not disposed to employ chemists on his premises, he could at least provide them with raw material or with problems which, if successfully handled and solved, would not only help him, but would give the instructors in that college the scent for technical inquiries. This would provide the first requirement in a course of genuine technology, a stimulus, and I am convinced that scores of chemists have been lost to industry from the absence of this connecting link. The young demonstrator, anxious and willing to work at anything useful, would be thrilled and exhilarated by a kilogram of waste material from Messrs. X and Y's manufacturing process, and a request to ascertain whether any valuable constituent was being thrown away; his mind would be directed forthwith into that particular field of industry, and whatever he found, even if it amounted to nothing, he would insensibly become potentially more useful to Messrs. X and Y, so that if these gentlemen ever did summon up courage to employ a chemist he, or the post-graduate student who had helped him, would be a suitable man to engage."

Dr. Forster said the first necessity for a closer union between research and industry is the development of a healthy public opinion on the subject of acquiring knowledge in general, scientific knowledge in particular, and more important than either, because it covers both, national wisdom. "In order to do this, speaking bluntly, our governments must advertise scientific methods of business and education by the employment of such methods in their own operations. In the establishment of such public opinion an important place should be given to the work which chemists do, the part which chemistry has played in the national economy, and the possibilities offered by a wider application of chemistry to industry, in order to attract to our ranks that type of young man which is able to use a chemical training as a weapon for making chemistry pay.

"Next, although many enlightened manufacturers already make good use of chemistry, their numbers must be increased, and the newcomers must not be too quickly discouraged by what may seem initially an unprofitable investment. It is not to be expected that when the war is over there will be any mitigation of Gottstrafe British Dyes, Ltd., and any other industry which ventures to raise its head, and the situation must be faced with resolute courage and all the resources of our people, both material and intellectual.

"In the next place, by some process which I cannot clearly foresee, but which must inevitably depend upon sympathetic pharmaceutical agreement, a means must be found by which the respective activities of chemistry and pharmacy may be differentiated in the public mind, so that existing vague ideas on this matter may be clarified. Concurrently with the removal of these motes from the eyes of other people, we must pay attention to the beam or two in our own. If the operation is carried out cheerfully, courageously, and conscientiously, our scientific descendants may have to bless this era as one of chemical regeneration, even if they do curse the ill-wind which wafted it to this country."

Finally Dr. Forster suggested the formation of a chemical intelligence department by the Board of Trade for the collection, tabulation, classification and distribution of chemical information, presentation of new problems, etc.

Development and Control of Industry by Public Influence

Prof. Henry E. Armstrong, in a paper on the subject, said: "The one chief lesson of this terrible war is the need of bringing home 'the idea of science' to the public at large; experts they can never be, but some respect for it they can acquire, and to insist that it be used regularly and systematically in the service of the country. It is clearly our duty to persist in urging its infinite value.

"All this by way of introduction—just to make clear my one thesis: that charity begins at home; that this body needs to wake chemical industry. Almost supine hitherto, you have allowed others to tinker with matters which primarily should be your concern."

Union is strength—is the motto of engineers. Medical men occupy a similar position; lawyers also; both professions are organized on trade-union lines. "But those who rate themselves scientific—the academic party as a whole—are an unorganized rabble, so individualistic, self-centered and unsympathetic that what is one man's meat is almost necessarily another man's poison. This is both our strength and our weakness, but we shall never win through until we can combine strength with

weakness. The lesson of the moment, the lesson a lifetime has taught me, is that chemists, too, must become professionals, and like others sell their services, not give them. We have not yet learned the lesson of the world; that people only appreciate that which they pay for; that the value of a thing is not appreciated until it has been sold freely. Academic chemists ought not merely to be allowed and encouraged, but almost required to work for payment, as consultants, like the engineers. The professor pure and simple should disappear." . . .

"One main reason why we are so much behind in some of the chemical industries is that the instruction given in our schools has been far too academic in character. It cannot be said too definitely, either too loudly or too widely, that chemistry has not attracted gentlemen—men of general mind, good presence, and real ability—in sufficient numbers into its ranks during many years past. We want much of the material that now degenerates into briefless barristers. Such material properly trained would be of worth, and command good pay."

Professor Armstrong criticized the work done by various committees appointed during the last year in Great Britain. The primary mistake was in appointing lawyers to controlling positions on these committees. Such men, however able and eminent, cannot have any real expert feeling on technical problems outside their own profession, and where there is no expert feeling, no proper sense of "technical effect"—to use Faraday's expression—there can be no "proportionate judgment" exercised.

"We have to bear in mind that the success of German chemical industry is due to two causes: Firstly, to the fact that the German universities are practical institutions—not collocations of compiling colleges—properly supported by the state and in touch with the educated community. The idea of science is abroad in Germany, though 'science' is not more taught in the schools than it is here. Science, however, is respected, and has acquired a money value in public eyes because it has been made real; the company promoter has been kept in subordination, and it has been shown that trust can be placed in those who undertake scientific ventures. . . . The second and true cause of German success is that the factories are in the hands of experts; moreover and especially ample provision is made for carrying out all necessary and desirable research work within the factories in well-formed laboratories, this being possible because a supply of properly trained men is to be had from the universities."

Professor Armstrong recommends that the government should levy an "insurance tax" on all industries in which the maintenance of research department is necessary and to apply the income from the tax to furthering research work.

"*Our plain duty in this society is to organize ourselves and when we are organized to claim the right to guide the government.* But unless the representatives of science subordinate their individualism, sink their differences and form a complete coalition of their forces, no public impression will be made. The task before us is indeed colossal. Before the war, Germany had control of the Russian market. It will be long before she will regain this, and here will be our opportunity—if our schools take Latin and Greek plays out of their bill and stage Russian instead, and if they add Spanish, we may have some chance in South America also, if meanwhile the Americans do not seal the market against us. The competition we shall have to meet outside Europe, especially in the East, will be greatly intensified, because this will be the chief market open to Germans. I have seen enough recently of German organization of trade in the East to realize that ours did not compare with it in efficiency."

Research in Technology

Dr. CHARLES C. CARPENTER, in a paper on this subject, emphasized that the chemical industry of to-day cannot make progress without research.

"That research must commence with the chemist goes without saying. Circumstances have, however, changed since the inception of the first great chemical processes. The technical demands made by modern manufacturers are much more extensive and exacting, and sole reliance upon the chemist would be fatal to the realization of success. Sooner or later the aid of the technologist must be called in. His equipment for the task is on a very different footing from that of his confrere, for it must be carried out on the large or working scale. Now surely here is an overwhelming case for localized centralization if one fact, and one fact only, is borne in mind. It is not from or among themselves that the greatest competition is to be feared, but from producers over the seas already organized. Let, then, every special industry build up its own schools or institutes of technology, not only to provide training for workers, but so fully equipped with resources that problems of all kinds can be submitted to them for research.

"It may be said that one manufacturer would be contributing to progress made by another. That may be true, but it would be better for him to put a small tax upon his profits for such a purpose than, by want of united effort, risk losing his trade altogether. It may be argued that the risk would be a great one in reposing so much confidence with the principals of such organizations. But if we distrusted our physicians we should run the risk of being decimated by disease. Is there one in a thousand who does distrust his adviser in sickness? Why should the physicians of industry be less honorable or disloyal? Such institutions as suggested would be clearing-houses for troubles to which manufacturers would automatically turn, whether perfecting an old process or working out a new.

"If as a nation we are to emerge successfully from the industrial battle which is awaiting us, we must pool not only our difficulties but their solution. When it is required to start new processes or adaptations, it will never do for each manufacturer to proceed as is now the case, viz., start *de novo* and work out for himself methods of its industrial application which are already known and used in other directions. He would get it from the institutes. If, as in some cases, the information as to certain methods of plant were confidential, he would be put into communication with the users, and matters might then be left to develop on ordinary business lines."

Chemical Engineering

Dr. G. T. BEILBY, in his paper on this subject, said that engineering has always had a definite place in chemical manufacturing, but the degree and kind of engineering skill which has found a place in the older chemical works has been frequently not of a very high order.

"One of the special features of large-scale chemical apparatus is the heavy depreciation to which it is subject and the need, therefore, for continual renewals and repairs. The skilled engineer who has been accustomed to the construction of high-class prime movers or mill machinery may be very ill-fitted to design and keep in repair the short-lived apparatus of the chemical works. A more adaptable but rougher type man is required, and these needs have produced a rather special kind of man, the 'chemical works engineer,' rather than the 'chemical

engineer.' If these facts are kept in mind we shall not find it at all surprising that a chemical works plant, especially in the older works, often has an improvised appearance which suggests either that the engineer in charge is actually slovenly or that he knows so well the temporary character of the work that he does not think it worth while to conform to the ordinary decencies of engineering design and construction! Tumble-down apparatus in only too apt to react on the processes which are carried on in it, and slipshod working is the outcome. The moral effect of rapid destruction of plant is certainly bad; hence the enlightened manufacturer is willing to make many sacrifices to secure more enduring forms of plant.

"Apart from the special characters which are due to the necessity for frequent renewal, there is no doubt that the influence of the chemist has had a definite effect on the design of chemical plant. A former colleague of my own, who had himself made splendid contributions to the improvements of the apparatus used in one particular industry, could find no more contemptuous way of expressing his opinion of any piece of apparatus of which he did not approve than to call it a 'chemist's job.' Of course, the chemist did sometimes get back on the engineer, if an elaborately designed piece of apparatus failed to give satisfactory results from a process point of view! In this case, unfortunately, any attempt at a *tu quoque* was more than ordinarily ineffective, as an 'engineer's job' was just the kind of job the constructor desired to make! It is not easy to define or characterize these two kinds of job by any simple definition. Chemists' apparatus is more the result of opportunism than of deliberately thought-out design. Contingencies are provided for as they arise, and initial mistakes in design are apt to be met in a partial or temporary way.

"The origin of the chemists' type of apparatus is found in the chemical laboratory, where it has generally been the aim of the professor to develop in his students a certain kind of individual resourcefulness. When the chemist needs to increase the scale of his apparatus, he naturally follows the type of construction to which he is accustomed, and even when the increased scale gets beyond the resources of the blowpipe table and the cork drawer, his ideas flow along the old laboratory lines. When the increase in scale is so considerable that it becomes necessary to call in the help of the engineer and his craftsmen, the designs proposed by the chemist still show their laboratory origin. The quick adaptability of the plumber's methods attract him rather than the engineer's carefully arranged series of steps from the drawing office through the pattern shop, the molding shed, and the foundry, to the machine shop. In pioneering work a 'chemist's job' is often the most suitable to use, but when the stage of steady manufacturing has been reached, all the resources of the drawing office and workshops should be devoted to the design and construction of suitable apparatus."

The procedure in the design of new apparatus in modern chemical works where sound engineering principle are allowed their proper might, is sketched by the author.

"In the modern organization there is room for the research chemist of high and wide attainments, for the scientifically trained engineer, also of wide attainments, and for a type of professionally trained man who is the natural medium of interchange between these two specialists. This intermediary is the chemical engineer. He must be a man of special aptitudes inasmuch as *he must have grasped the chemist's point of view as well as the engineer's.* The chemist thinks and works in terms of atoms and molecules and the laws which govern their combination. The engineer thinks of matter in masses which can be molded to his will by the craftsman, or of mechanical or electrical energy which can be generated, controlled and measured by machinery. The chemist is the master and director of his own operations, which he can, for the most part, carry out with his own hands. The engineer loses his direct hold on his operations whenever his ideas have been fully committed to paper in the drawing office. It is his special function to organize the labors of many workers.

"A certain number of men are able to enter fully into the spirit which actuates both types of expert, the chemist and the engineer; they can resist the particular exclusiveness of each, while giving to each its due weight. These are the naturally gifted chemical engineers who in one sense are 'born, not made.' In our colleges and universities the best that we can do for men of this gifted type is to give them the best possible opportunities for an all-round development of their powers. For the average men, we ought to provide a properly organized course of training in theoretical and practical chemistry, physics and mechanics, on professional, not on purely academic, lines.

"Our colleges have thus two distinct functions to perform, and it is best that this should be clearly recognized, first to allow the future leaders in applied science to come naturally to the top during their training, and second, to prepare a large number of well-trained professional men for the organization and development of industry. The ideal for these men must be a professional one. It is to be feared that the making of practical chemists has suffered severely from a fallacy—namely, that all students ought to aim at being pioneers in some branch of their science. Science and industry alike call aloud for *real pioneers,* for without these the highest type of progress cannot be realized. This call, however, cannot be met by the premature stimulation of 'originality' in men of very ordinary endowment. The effect of this stimulation is not merely futile, it is positively mischievous, for it raises an ideal which for the ordinary man is quite inappropriate during his preparation for a life of serious practical endeavor. In conclusion, I must repeat the statement of my belief that the phenomenal development of chemical industry in Germany has resulted much more from the large command of chemists and engineers of sound professional training and ability than from the possession also of an even larger supply of research chemists of mediocre ability."

A general program of the engineering society conventions and International Engineering Congress, to be held in San Francisco, Sept. 16-25, 1915, has been issued for the information of those expecting to attend. A copy may be had on application to W. A. Cattell, Secy., 417 Foxcroft Bldg., San Francisco. The program covers in outline the conventions of four of the national engineering societies, the meetings of the Congress, and the excursions planned.

The production of bauxite and the consumption of aluminium in the United States in 1914 were the largest ever recorded, according to the U. S. Geological Survey. The output of bauxite was 219,318 long tons, valued at $1,069,194, as compared with 210,241 long tons valued at $997,698 in 1913. The principal producing States were Alabama, Arkansas, Georgia and Tennessee. Arkansas produced more than 80 per cent of the output. The principal uses for bauxite are the production of aluminium, aluminium salts, bauxite bricks and such artificial abrasives as alundum. The quantity of aluminium consumed in the United States in 1914 was 79,129,000 lb., against 72,379,000 lb. in 1913. In 1884 the production was but 150 lb. The consumption of the metal is constantly expanding.

Industrial Energy as a Military Weapon*

BY J. R. FINLAY

At the beginning of the present European war I had believed that industrial energy would prove to be the decisive factor in this present struggle, and that this energy might be fairly represented by the use and production of coal and steel. Part of this proposition is now recognized by the public; the other part is not. It is now seen that the nations of Continental Europe that are facing Germany, namely, France, Russia and Italy, are no match for Germany in the production of the necessary equipment and munitions for fighting. I argue that it is equally probable that the whole combination of the Allies, including England, is deficient in the capacity for organizing and for utilizing equipment. I am disposed to believe that the second element is more important than the first, because it requires time to develop. You will understand that I am working on the supposition that military success arises from the same kind of development as industrial success. It will take some time longer to prove this.

The idea is abroad that Germany may be conquered by the Allies if the latter will buy enough copper and other munitions. The reality is that the buying of supplies is a comparatively insignificant part of the problem. To take an industrial comparison, let us suppose that the plants of the United States Steel Corporation were supplied, complete, to Russia, without the organization as it exists to-day. What use could Russia make of them?

I do not mean to imply that the individual Russian is necessarily inferior as a workman, or as a man, to the individual American. That is one of the difficulties in understanding this present situation. Each of the great nations and races of mankind is able to furnish human material that can compete on even terms with that of any other nation. But I think you will recognize quickly that it would take the Russians many years to make any adequate use of the plants of the United States Steel Corporation. It is hardly worth while to go into details. The operation of those plants. including mines, steamships, railroads, rolling mills and factories of all kinds, requires the development of a vast amount of specialized labor; it also requires a great deal more than that, namely, a slowly developed and highly organized control. The plans and the execution of them must be tested by competition with rivals. The organization must know the fields in which the products, when made, can be sold and utilized. It would be easy to dwell on this subject a long time, but I think you will soon conclude that the plants of the United States Steel Corporation would never reach anything like the effectiveness in Russia which they have in this country, until the Russian nation is developed industrially to such an extent that it can meet such an organization on even terms. In other words, other industries, all of the industries in the country, in fact, would have to be developed in a substantially equivalent manner. This certainly cannot be accomplished over night, nor during the probable continuance of any war. It is a matter that requires nothing short of the industrial organization and development of the nation. A generation, or even two generations, is a short time for such an accomplishment.

Dropping this subject for a moment, it seems to me that we should stop and discuss fundamentals a little.

One such fundamental is that our political ideas and most of our beliefs and prejudices date from the time when the steam engine was unknown. I believe that economic changes have taken place in the leading civilized nations without producing, as yet, the inevitable change in political and social ideas. We are facing facts which we do not recognize, or at least, which are not recognized by the public. We go through forms of thought and attach ourselves to certain prejudices that will not stand the analysis of modern actualities. Some of our political sentiments are like the buttons on a dress coat, which were put there originally to attach swords to, because gentlemen wore swords, and the dress coat is the coat of a gentleman; but there is no longer any actuality in the sword as a weapon, either social or military. The fact that we like to see buttons on a dress coat is a mere sentiment which does not change in the least the relative efficiency of the sword and its successor, the revolver.

What changes of a political, social and religious nature are to take place I do not know. One thing that the world is learning beyond doubt, is that individual effort, no matter how well developed the individual, is no longer a match for corporate effort. This is a lesson that the Frenchman and the Russian must be learning. We in the United States have learned it, but we hardly realize that we have learned it.

Let me try to explain what I mean. There are certain efforts that cannot be accomplished by the individual that require a combination of people such as was not contemplated at the time when our government was established. We can see plenty of examples in the mining industry and plenty more in the railroad business. In fact, we all know that the business of our country in general has reached a point where the large corporation is absolutely indispensable. Consider, for instance, the Utah Copper Company. Nothing but failure of such an undertaking could possibly have rewarded the efforts of any man or any group of men in this country 100 years, or even 20 years ago. Look at the organizations required to conduct the railroad business of this country. The railroads all started in a more or less individualistic manner. A little railroad was built from New York to Harlem; another from Harlem to Poughkeepsie; a third from Poughkeepsie to Albany; a dozen pieces of railroad were constructed to form a patchwork system of travel between New York and Chicago. The progress of our industry soon made it plain that such a system was absurdly less efficient than it might be; consequently these little roads were thrown into one system, and operated by one head, so that freight and passengers could be carried through with less expense and delay.

My belief is that the fundamental desire of the human race is to secure greater economy in the production of the necessities and luxuries of life. Any political system or any social idea which interferes with that economy will go to the wall, will be defeated and discarded. The demand for efficiency will finally triumph over any preconceived prejudices regarding personal and political liberty.

We were all born while a revolution was going on in human affairs, and we shall die before that revolution ends. This revolution is a fundamental accomplishment, such as the human race is not likely to repeat again for thousands of years. It is something that we are all familiar with, but which we do not think very much

*A paper read before the Mining and Metallurgical Society of America. In the informal introduction to his paper, which is published in full with the discussion that followed, in Bulletin 86 (Vol. 8, No. 7) of the Society, Mr. Finlay said: "I think the result of this war will be to arouse the entire world to the importance of the evolution through which we are going. We do not know the military situation in Europe. The nations do not give away their military secrets, but I had an idea last September that the outcome of the war could be predicted by a consideration of other than military factors. The ideas I intend to convey are, frankly, speculative, but after ten months of war it looks as if some of them were probably correct. I have formed one idea, the correctness of which remains to be proved, and I intend to call your attention to it."

about. It is the conquest of natural energy by the human brain.

One hundred and fifty years ago men had no resources for accomplishing their work except the muscular power of men and animals, with a little crude development of wind and water power. Now we use our hands and our brains to direct forces scores of times more energetic. The result is prodigious and it is causing a complete rearrangement of our mode of life. It is causing us to look upon nature itself in a different way, and it is altering profoundly the relations between men and between nations.

The source of this power at present is largely coal. The power of coal is developed through machines made of metals. This is not so much a chemical or material fact, as it is a human fact. The utilization of this power is made possible only by the development of human organizations to match it. A locomotive is no more the machine that accomplishes the work of a railroad than a statue is a living man. You cannot use a locomotive without a railroad, and you cannot have a railroad without work for it to do; you cannot have work for it without big industries. In short, you cannot have first-class mechanical service and efficiency except in a highly developed industrial nation. The mere existence of power-driven industry on a large scale proves in itself that a country which supports it possesses a different and more efficient organization than a country which does not support it.

When I learned some years ago that it took 10 to 15 Hindoo coolies to accomplish the work of one of our miners in this country, I could not understand it. The difference seemed preposterously great. It was all the more extraordinary because it occurred in a mine equipped with machinery just as thoroughly as the mines of this country. The reasoning I have offered you is an attempt to explain it. Industrial efficiency cannot exist in a population that neither understands nor demands it.

An adequate explanation must cover the improvements that are steadily made in our business. I know of mines in which each man is producing twice as much as he produced 10 years ago, without working any harder, and without any improvements in or additions to the machinery. I am satisfied that industrial efficiency means nothing less than national effort, produced by slow growth, by the habit of co-operation, and by a widespread recognition of the value of co-operation and a belief in its value.

It is a fact not generally recognized that to-day there are only three nations in which mechanical industry is widespread, namely, the United States, the British Empire, and Germany. It is not fair, of course, to say that industry has not been developed in other countries, but those nations are so far ahead of any rivals that they are very distinctly in a class by themselves. These three nations produce about 90 per cent of the coal of the world, and undoubtedly operate 90 per cent of its machinery. It is a remarkable fact—it may be an accident, but still it is a fact—that all of these nations are predominantly Teutonic. It may be an accident that this race of men happened to gain possession of the more important territories that contained coal; but whether an accident or not, it makes no difference as to the importance of the developments that have come from it.

It happens that one of these nations is the most highly developed military nation in the world. The other two, while developed industrially quite as highly as Germany, happen to be about the least military nations of the world. In my judgment, the unmilitariness of England and the United States is due to one cause only, namely, their isolation, their freedom from enemies capable of easily attacking them. If these nations felt compelled to do so, they could develop enormous military powers; but we may also believe, from our available sources of reasoning, that the development of such military power will take a long time and can be accomplished only by a thorough political and social organization on terms of military efficiency.

This is a long introduction to the concrete facts in Table I to which I now wish to call your attention.

Table I.—Comparison of Industrial Energy as Represented in Iron and Steel Plants of Russia, United States, and Germany

Russian Iron and Steel Plants, 1911.	
Number of plants	255
Workmen (Poland, 17,304)	263,653
Output of pig-iron, tons	3,943,000
Output of ready iron, tons	2,912,000
United States: U. S. Steel Corporation, 1910.	
Output of pig-iron, tons	11,831,000
Output of ready iron, tons	10,733,000
Employees manufacturing	154,563
Employees mining, coking, and transportation	60,000
Output per man:	
Russia: ready iron, tons	11
Pig-iron, tons	14
U. S. Steel Corporation, (total labor) ready iron, tons	50
Pig-iron, tons	55
Per manufacturer, ready iron, tons	70
Pig-iron, tons	76
United States: Rolling Mills and Blast Furnaces, 1909.	
Output of pig-iron, tons	25,600,000
Men employed	304,000
Output per man, tons	84
Germany: 1910.	
Metal workers of all ages	589,649
Output of pig-iron, tons	15,000,000

(If 400,000 are in ironworks, the output is 37 tons per man, about what we should expect by comparison with U. S.)

Data as to the production and consumption of fuels in the various countries are not so easy to procure without careful investigation. I take it that the main criterion of a nation's industrial activity is its consumption of coal, or any other form of mechanical energy, rather than its mere output. We shall have to make several tables to express what I mean.

Table II.—Production of Coal and Petroleum on the Continent of Europe and Elsewhere in 1912.

France:	
Production, tons	44,000,000
Imports, tons	19,000,000
Consumption, tons	63,000,000
Russia:	
Production of coal, tons	31,752,000
Imports of coal	Not given
Production of petroleum, tons	9,247,000
(If we assume that one ton of petroleum is equal in efficiency to 1.5 tons of coal, we might credit Russia with a total fuel consumption of about 45,000,000 tons.)	
Belgium:	
Production, tons	25,322,000
Servia:	
Production, tons	335,000
Total production for this group, tons, about	115,000,000
Probable consumption, tons, about	135,000,000
British Isles:	
Production in Great Britain, tons	291,666,000
Exports, tons	95,536,000
Consumption, tons, about	196,000,000
Canada:	
Production, tons	15,000,000
Imports, tons, about	10,000,000
Consumption, tons	25,000,000
Australia:	
Production, tons	15,000,000
India:	
Production, tons	16,000,000
Total output of the British Empire, tons, approx.	338,000,000
Consumption of the British Empire, tons, approx.	225,000,000

Total industrial energy, represented by coal production among the Allies, not including Japan, at the beginning of the war, approximately 473,000,000 tons produced, and approximately 387,000,000 tons consumed.

Production of Germany and Austria-Hungary in 1912.

Germany:	
Production, tons	282,000,000
Net exports, tons	24,000,000
Consumption, tons	258,000,000
Austria-Hungary:	
Production of coal, tons	57,000,000
Imports of coal, tons	5,000,000
Production of petroleum, tons	1,000,000
(Equal to 1,500,000 tons of coal).	
Total production of Austria-Hungary, tons	63,000,000
Total output of Teutonic combination at the beginning of war, tons	340,000,000
Total consumption, tons	322,000,000

TABLE III.—RELATIVE PRODUCTION AVAILABLE WITHIN AND WITHOUT THE GERMAN LINES TO-DAY (USING FIGURES OF 1912)

For this purpose we will consider only the amounts consumed in the various countries, as representing their manufacturing energy.

Originally consumed in Germany and Austria-Hungary, tons	322,000,000
Add production of Belgium, tons	25,000,000
Add production of Northern France, tons	27,000,000
Add production of Western Poland, tons	6,000,000
Add production of Turkey, tons	1,000,000
Total manufacturing energy available, tons	381,000,000

The manufacturing energy probably available on the side of the Allies on the Continent, is as follows:

Russia, tons	40,000,000
France, tons	36,000,000
Italy, tons	12,000,000
Servia, tons	335,000
Total on the Continent, tons	88,335,000

The industrial energy of the British Empire remains about as it was, and is represented by approximately 250,000,000 tons of coal, which, however, is scattered all over the world. Thus it appears that while the Teutonic group began the war with a manufacturing energy equal to about four-fifths of that of all the Allies, excluding Italy, it now has a clear preponderance over the entire combination, including Italy.

We will similarly compare the situation with respect to the production of iron.

At the beginning of the war, Germany had a production, using as before the figures for 1912, of about 20,000,000 tons, to which she has added the production of Belgium, 2,500,000 tons and approximately 65 per cent of that of France, say, 3,500,000 tons, besides whatever may be produced in Poland; making a total manufacturing equipment available to-day of some 26 to 27 million long tons.

At the beginning of the war the Allies had the following production:

United Kingdom, tons	8,800,000
France, tons	5,000,000
Belgium, tons	2,500,000
Russia, tons	2,500,000
Canada, tons	1,000,000
Total, tons	19,800,000

At present the manufacturing ability of the group of Allies, as represented by pig iron, is probably not over 14,000,000 tons, even including Italy. Thus we see that at the beginning of the war the Germans possessed equipment for iron manufacture approximately equal to that of the Allies, but has now converted it into a preponderance of two to one.

It is interesting to know that the occupation of Belgium and Northern France deprived the Allies of industries consuming more than 50,000,000 tons of coal and producing more than 6,000,000 tons of pig iron a year. In the production of iron the facilities thus taken away from the Allies was equal to two-thirds of the entire production of Great Britain, and there is every reason to believe that this capacity was better adapted, on the whole, for the production of military supplies than the equipment in the British Isles.

The Germans have explained that their invasion of Belgium was a matter of military necessity. I have seen no statement as to what that military necessity was, but if this equipment is as important as we may now suppose it to be, we can make a pretty good guess. They probably felt that if they did not occupy this manufacturing district its output would certainly be used against them, if not by the actual military participation of Belgium, at least by furnishing munitions.

Some further interesting comparisons may be made. In the consumption of fuels, the United States is easily the foremost nation, consuming an average of over 5 tons per capita. England, Belgium and Germany seem to be about on the same level with the consumption of approximately 4 tons per capita.

It is, I believe, conceded by all observers that the industrial output per man is greater in the United States than in any other country; probably about in proportion to the consumption of coal, that is to say, the use of mechanical energy.

A review of the consumption of fuels by the leading industrial nations shows some interesting figures. Russia is apparently in about the same condition that the United States was in about 1850. Wood is still largely used as fuel for locomotives, just as it was in this country at that time. The consumption of mineral fuel is about ¼ ton per capita, as it was in the United States in 1850. In the progress of the United States from 1850 to 1914 we find that to-day we are using twenty times as much coal per capita as we were then; and an estimate of the wealth per capita, as given in the World's Almanac, shows $300 in 1850 and $1,350 in 1914. If the productivity of a nation can be measured by this wealth, it would seem that the producing capacity of an American citizen is at least four times that of a Russian.

It seems also that, by the same comparison, France is now only as far advanced industrially as the United States was about 1875. This certainly does not mean that specialized industries are not fully as well developed in France as in this country. What it probably does mean is that the mass energy is much less. France consumes only about 1.6 tons per capita, which I think almost certainly means that most of the French people are at work on farms and small shops and not in the factories. They work more with their hands and less with machinery.

The whole population within the German lines, excluding Turkey, is approximately 135,000,000; including Turkey, about 155,000,000. The average productivity of this whole mass of people, as measured in coal and iron, is about equal to that of the United States in the year 1890. Coal consumption is 2.5 tons per capita.

In white population the Allies stand about as follows:

British Empire	60,000,000
France	35,000,000
Italy	35,000,000
Servia	5,000,000
Russia	150,000,000
Total	285,000,000
Coal consumption, tons	340,000,000
Coal consumption, per capita, 1.2 tons.	

This average is equal to that of the United States at about 1870. Thus the Germanic combination is about twenty years ahead of the average of its opponents in the use of machinery. They draw their men and resources from a total area of 1,000,000 square miles, while their opponents come from the ends of the earth and dwell in an area of 10,000,000 to 15,000,000 square miles.

The newspapers and the public have arrived at the importance of these facts, so far as they apply to munitions of war. The cry is broadcast that the Allies must be supported by the manufacturing resources of England and the United States.

I return now to my original suggestion, that manufacturing power is only one-half of the problem. It seems likely that the organizing ability in Germany has attained a superiority over that of the Continental Allies in some proportion to her superiority in industrial activity.

To illustrate the situation in Europe, let us suppose that the States of the Union should get into war against one another. Suppose the States of Illinois, Indiana,

Michigan, Ohio, Pennsylvania, New York, Connecticut and New Jersey should form a combination to resist the rest of the United States, and Canada thrown in. Suppose for full measure we throw in Mexico and South America as opponents of this bit of territory. We would then have a population of 40,000,000 in a territory of 285,000 square miles fighting a population of 150,000,000 occupying a territory of 15,000,000 square miles. Which would be likely to win? I may be foolish, but it seems to me that the group of States between New York and Chicago would probably win decisively. Why? Because in that area, producing 75 per cent of the coal and making 87 per cent of the iron of the country, there is almost a monopoly of the organized manufacturing and engineering energy of the Western hemisphere. The area contains practically all the plants capable of manufacturing arms, munitions and special devices. In this territory we have not only the plants, but the trained population, the trained leaders and organizers. If we permit ourselves to imagine that this group of States were organized under one efficient corporation which had the control of every citizen for the purpose of carrying on war, we should have in America something like the situation in Germany to-day. We could well reject the idea that the New Yorker or the Pennsylvanian was in the least superior to the Canadian or the Texan, but that would not alter the fact that the superiority of our group of States in the production of munitions, the transportation of supplies, the organization of effective effort, and its ability to strike quickly, would be very great indeed. If this group of States should make as its first move the occupation of West Virginia and of Missouri, it would add to its preponderance much as the Germans have added to theirs by the occupation of Belgium and Poland.

If, in addition to the enemies we were fighting in America, Great Britain should come in and use her command of the seas to help our neighbors out with supplies, what would be the result? I do not believe that it would be decisive. I still think that the problem of conquering such a unit would be insoluble. We might not be able to make extensive conquests, nor wrest the command of the seas from the English, but we could meet any probable attack with such a wall of mechanical energy that we could make expectant conquerors sick with hopes deferred.

War Consumption of Metals

In the discussion which followed Mr. W. R. Ingalls discussed the extraordinary consumption of metals by the war which is much greater than had been anticipated by experts. At the beginning of the war the consumption of copper by the Allies was estimated as 100,000 metric tons a year; independently the consumption by the Germans was also estimated as 100,000 metric tons a year. Both estimates are conservative and probably too low. Considering that the world's largest production in any year was about 1,000,000 metric tons, we begin to have a better perspective of the military demand.

"Most of the copper is used in the form of brass, which, of course, requires a corresponding proportion of spelter. In purchasing the spelter for this brass an extraordinary effect upon the market was produced. Ordinary brands of spelter rose to about 500 per cent of normal value, while high-grade spelter realized prices approaching the price of tin in ordinary times. Attention was chiefly centered on the special brands of spelter produced by the New Jersey Zinc Company. This is a metal in a class by itself, containing upward of 99.9 per cent zinc, and being free from undesirable impurities to an extent that is unmatched by any other spelter. This spelter is sold as the Bertha and Horsehead brands. Before the war such spelter had a rather limited use for special purposes. Inventors and promoters were always going to duplicate it, and in prospectuses they were always going to get the 2 cent or 3 cent premiums that these brands normally realized above the price for prime western. Those of us who knew something of conditions warned all of our friends who wanted to go into such enterprises that the addition of any important supply of this kind of metal, even if it could be produced, would break the margin, and in figuring upon a new zinc-smelting enterprise it was never safe to reckon on anything higher than the price for prime western, or good ordinary brands. Recent events have been directly contrary to our *antebellum* opinion and advice. We have seen it impossible for buyers to obtain all of the high-grade spelter they wanted, whence the premium for such spelter rose phenomenally. Almost anything that the New Jersey Zinc Company wanted to ask it could get. Other smelters were left to make a spelter by redistillation, almost, but not quite, as good. Impure spelter may be refined into pure spelter by redistillation, just as pure water may be obtained from brine, but there is difficulty with respect to the cadmium content, which is volatile, like zinc, and perhaps some difficulty with respect to lead also; wherefore it appears to have been impossible to raise the spelter redistilled from prime western above 99.75 to 99.85 per cent of zinc, which makes it a high-class intermediate spelter, rather than high-grade spelter properly speaking, according to the official classification. However, such spelter has been greatly in demand and has commanded very high prices.

"Now just why the military buying has been so insistent upon these superior brands is something of a mystery to me. Of course, I know that such spelter has always been required for the manufacture of cartridge cases, and there are good reasons why it should be, but apparently manufacturers who have been going to make ammunition of other kinds than cartridge cases have also insisted upon such spelter. I have wondered whether the military experts have not, in some cases, specified a purity that is not really necessary, having in mind only the idea of obtaining the very best. I have not heard that the German military authorities have exhibited any such crazy demands for high-grade spelter. What have they been doing for their supply of it? Other things are curious. Why should it have been necessary to produce a condition of spelter selling for £110 per ton in London, while it is selling for £29 in Germany in 1000-ton lots?

"Lately we have witnessed, also, a spectacular demand for lead. This metal is used for the cartridge bullets, for the shrapnel balls, etc.

"Other metals have experienced similar advances, which non-military persons did not foresee. Antimony is one of them. This is used for hardening the lead for the several bullets. Quicksilver is used in making the fulminates which go into the caps. The quicksilver market has been especially disturbed since Italy entered the war and thus cut off the supplies that we were heretofore able to draw from it. Aluminium is used largely in the construction of aeroplanes and dirigibles. There are rarer metals which also have had sensational advances. Such a one is magnesium, which doubtless is required for making the illuminating bombs, flares, etc., used in night attacks."

Mr. G. C. Stone (N. J. Zinc. Co.) explained that cartridge brass has to stand the severest strains in drawing presses and the zinc should be free from cadmium and contain not over 0.05 per cent lead and 0.15 per cent iron.

Condensers for Evaporating Apparatus

Principles, Types, Tests

In our August issue we gave an extensive account of the chapter on vacuum pans from the recent publication of Professor **E. W. Kerr**, assisted by J. F. Gunther and W. A. Rolston, on Sugar House Heating and Evaporating Apparatus (Louisiana Bulletin No. 149, Agricultural Experiment Station of the Lousiana State University and A. & M. College, Baton Rouge, La.). This same bulletin contains a very interesting chapter on sugar-house condensers from which we take the following extracts. Professor Kerr first considers the general principles of condensers for evaporating apparatus, then describes different types of condensers and finally gives the results of tests made by him.

General Principles of Condensers for Evaporating Apparatus

As a general thing, 26 in. of vacuum referred to a barometer of 30 in. is sufficient for vacuum pans and evaporators of the submerged tube type.

Film evaporators can use higher vacuum to advantage because there is no loss of temperature fall in them due to hydrostatic head. The loss due to hydrostatic head is much greater in the last body of a multiple effect than in a first body, and for this reason a high vacuum in the submerged tube types does not result in the increase of capacity that is possible in film evaporators.

High vacuum is also more desirable in triple and quadruple effects, especially of the film type, than in double effects. The rate of evaporation per square foot of heating surface per hour must be limited in order to prevent entrainment. With a given total temperature fall a double effect will naturally have greater temperature falls in each body than in triples or quadruples, resulting in higher rates of evaporation. For this reason the increased total temperature fall due to increasing the vacuum or the steam pressure is less likely to cause entrainment in triples and quadruples than in doubles.

The cost of high vacuum, 27 or 28 in., is greater than for ordinary amounts of vacuum for several reasons, among which may be mentioned more cooling water, more vacuum pump capacity, greater attention to providing against leakage from stuffing boxes, etc., larger vapor pipes and larger condensers. Most sugar-house condensers are of the barometric jet type, in which the vapors mix directly with the cooling water, being condensed and cooled down to the temperature of the water leaving the condenser. The cooling water required per pound of vapor condensed can be calculated by means of the formula:

$$W = \frac{H - (t_2 - 32)}{t_2 - t_1},$$

in which H is the total heat of steam at the pressure corresponding to the vacuum, t_1 is the initial temperature of the cooling water and t_2 the final temperature of the cooling water. Increasing the vacuum will naturally increase the value of t_2, which in turn will result in increasing the weight of cooling water per pound of vapor condensed.

This increased amount of cooling water means larger and more costly cooling water pumps, also increased steam consumption, wear and tear. Table I shows the increased amount of cooling water required with high vacuum.

The values in Table I were calculated according to the above formula, the final temperature of the cooling water being assumed to be 5 deg. lower than that corresponding to the vacuum.

Inspection of the above formula shows that in order to secure a given vacuum with the least amount of cooling water the value of t_2—that is, the leg pipe temperature—must be a maximum. In other words, the condenser must be the main factor in forming vacuum and not the vacuum pump, the object of the latter being to remove air and not vapors.

TABLE I—COOLING WATER AND VACUUM

Vacuum	Cooling Water Per Lb. Vapor, Lbs.
24.0	18.8
24.5	20.0
25.0	21.3
25.5	23.2
26.0	26.4
26.5	29.4
27.0	35.6

The pressure in a condenser is the air pressure plus the vapor pressure. According to Dalton's law, "The pressure of a mixture of a gas and a vapor is the same as the sum of the pressures each would possess if it occupied the same space alone."

In a vessel containing vapor only, with a vacuum of 27.99 in. of mercury, the temperature is 100 deg. F. In case there is some air mixed with the vapor, however, the pressure (1.926 in. of mercury) would be the sum of the pressures due to the air and to the vapor, and the pressure due to the vapor would be something less than 1.926 in., and the temperature in the vessel would correspond to this lower pressure. From this it is evident that the less air there is in a condenser, the nearer will the temperature approach that corresponding to its pressure, as given in steam tables.

Even in the best of condensers, the temperature of the discharge water (hot well) is lower than that corresponding to the vacuum. This is due to the presence of air with the vapor and a vapor pressure less than that shown by the gage, the temperature being due to the vapor pressure. If it were possible to exclude the air entirely, the temperature would be that due to the pressure shown by the gage. This would result beneficially in increasing the temperature of the hot well, and this in turn would decrease the weight of cooling water required to condense a pound of steam.

When pure steam in a condenser is cooled by contact with air-free water the original volume occupied by the steam and water is greatly reduced. For example, assume that one pound of steam under a pressure corresponding to 26 in. of mercury requires 30 lb. of water at 70 deg. F. to condense it. The volume of the steam is 175 cu. ft. and that of the water about ½ cu. ft., a total of 175½ cu. ft. Upon condensing, the volume of 1 lb. of steam becomes 1/60 of a cu. ft., so that the final volume of the mixture will be ½ + 1/60 = 0.5016 cu. ft. Thus, the volume is reduced from 175.5 cu. ft. to 0.5016 cu. ft. by perfect condensation, and the resulting void would give practically a perfect vacuum.

However, in actual condensing apparatus the above conditions are not fully carried out for the reason that there is air both in the steam and in the cooling water entering the condenser. In addition to the air in the condensing chamber, which decreases the vacuum—that is, increases the absolute pressure—there is also vapor from the warm water, the pressure of which depends upon the temperature of the water. Even if there were no air in the condensing chamber this vapor would be present. The figures in Table II taken from a steam table show the water vapor pressures for varying temperatures under vacuum.

Column 3 of Table II is obtained by subtracting the vapor pressure, column 2, from the pressure of the atmosphere which is assumed to be 29.92 in. mercury. The values in this table apply to water vapor only. If

it were practicable, a removal of the vapor formed, as explained above, could be resorted to for the purpose of increasing the vacuum. By thus removing vapor from the condenser with a pump, other fresh vapor would be formed from the water in the condenser to take the place of that removed and the absorption of heat required for this would cool the water and this in turn would result in an increase of vacuum.

Table II—Water Vapor Pressures for Varying Temperatures Under Vacuum

Temp. of Water, Degrees F.	Vapor Pressure, Inches Mercury	Vacuum Inches Mercury
32	.1804	29.7396
40	.2477	29.6723
50	.3625	29.5575
60	.5220	29.398
70	.739	29.181
80	1.029	28.891
90	1.417	28.503
100	1.926	28.994
110	2.589	27.331
120	3.438	26.482
126	4.057	25.863
134	5.02	24.90
152	7.95	21.97
162	10.12	19.80
170	12.20	17.72
182	15.98	13.94
190	19.02	10.90
200	23.47	6.45
212	29.92	0.00

Owing to the great volume of this vapor, however, a pump sufficiently large for this purpose would be impossible, as is shown in the following example. Assuming a condenser which requires 30 lb. of water to condense 1 lb. of steam and that the water is heated in the condenser to a temperature of 126 deg. F., corresponding to a vacuum of 26 in., let us determine the volume of vapor that must be removed by a pump in order to reduce the temperature to, say, 116 deg.—that is, to reduce the temperature 10 deg.

For each pound of steam to be condensed there would be required 10 x 30 = 300 B.t.u. to cool the water 10 deg. The latent heat of evaporization of water at 26 in. being 1026 B.t.u. $\frac{300}{1026}$ = 0.292 lb. vapor would be formed, and, therefore, removed by the pump in order to cool the water 10 deg. One pound of the vapor at this temperature has a volume of 175 cu. ft. Therefore, 175 x 0.292 = 51 cu. ft. of vapor would have to be removed for each pound of steam entering the condenser. An evaporator with 5000 sq. ft. of heating surface in the last body would deliver, say, 30,000 lb. of vapor to the condenser per hour, or 500 lb. per minute. The pump displacement of vapor to reduce the temperature 10 deg. would, therefore, be 51 x 500 = 25,500 cu. ft. per minute. The vacuum corresponding to 116 deg. is 27 in.; 25,500 cu. ft. of vapor would thus have to be removed per minute to increase the vacuum only 1 in. This would require a pump with dimensions entirely without the limits of practicability.

Larger vapor pipes are required with high vacuum because the specific volume of vapors—that is, the volume in cubic feet—occupied by 1 lb. of vapor increases rapidly as the vacuum increases. For example: the specific volume of vapor at 26 in. of vacuum is 175 cu. ft., for 28 in., 330 cu. ft., and for 29 in., 638 cu. ft. Thus the area of vapor pipes for 28 in. vacuum needs to be nearly twice that for 26 in. vacuum. The work to be done by condensers for evaporators depends upon the number of bodies. A condenser for a quadruple effect would have to handle about half the vapors that one for a double of the same capacity would have to handle.

Types of Condensers

Condensers of the kind used in sugar-house work are nearly all of the barometric type—that is, the vapor and the water mix in direct contact. The mixture of condensed vapors and cooling water passes to the hot well through the leg pipes by gravity, the condenser being located some 34 ft. or more above the surface of the water in the hot well. These condensers require injection water pumps for elevating the water to the condensers; also, in most cases, vacuum pumps of the rotary dry type, or of the slow speed water sealed type.

Generally a sugar house condenser consists essentially of a tall cylindrical vessel into which the vapors and the cooling water are led and mixed. The water enters at the top and is sprayed as it falls and mixes with the vapors. These condensers, according to the manner in which the steam is introduced, may be classified as parallel-current and counter-current; in parallel-current condensers the vapor enters the top, the cooling water and the vapors flowing in parallel currents at the bottom and out through the leg pipe; in counter-current condensers the vapors enter at the bottom and pass upward, their direction of movement being counter to that of the cooling water, hence the term counter-current.

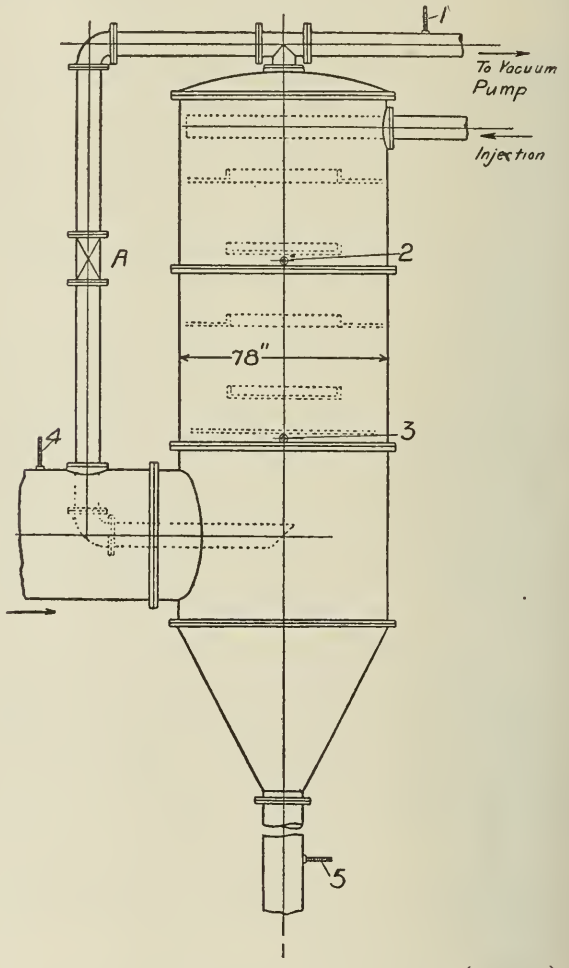

FIG. 1—COUNTER-CURRENT CONDENSER (TYPE I)

Fig. 1 illustrates a counter-current condenser upon which Professor Kerr made tests. Fig. 2 illustrates a parallel-current condenser which was also used in some of the tests. Referring to Fig. 2, it will be noted that the injection water enters the top, being controlled by a valve accessible to the operator. The water is sprayed and falls to one and then to another of two trays of semi-circular shape and finally to the bottom of the condenser and down the leg pipe. The trays are perforated with small holes, which cause a shower of water throughout the condenser. Vapors enter through the large pipe at the top and pass down-

ward. The air and other incondensable gases are swept toward the bottom, from there they are removed by the vacuum pump through the pipe shown, a conical thimble being placed so as to prevent water from entering the air pipe. The edges of the trays are serrated in sawtooth form to aid in dividing the overflow water into as finely divided a condition as possible, to facilitate an intimate mixture of water and vapor.

In the counter-current condenser of Fig. 1 the injection water pipe extends across the top and is perforated with small holes, thus spraying the water which falls from one to another of four circular trays with perforations and serrated edges. The vapors enter through the large pipe at the bottom and pass to the top, the air and other incondensable gases being drawn off by the vacuum pump through the connection shown. The

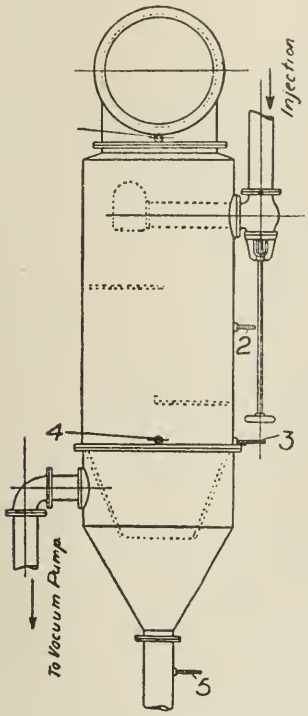

FIG. 2—PARALLEL-CURRENT CONDENSER (TYPE II)

valve A and its connecting pipe was put in for experimental purposes and was not a part of the original installation.

In the parallel-current condenser, Fig. 2, it will be noted that the air is drawn off near the bottom of the condenser, where the temperature is practically that of the leg pipe—that is, of the cooling water as it leaves. In Fig. 1, however, the air is drawn off from the top of the condenser just after having passed through the spray of cool injection water, and its temperature should be practically that of the entering injection. This is an advantage in that the vacuum pump will have a smaller volume of air to handle on account of its lower temperature. In other words, counter-current condensers should require a smaller vacuum pump displacement for a given amount of air handled than a parallel-current condenser on account of the reduced temperature. This difference in volume may amount to 10 per cent or more. An important consideration in condensers is that of the separation of vapors from incondensable gases so that the latter only will have to be handled by the vacuum pump. In this also the counter-current condenser seems to have the advantage.

Referring again to Fig. 1, it is evident that as the mixture of air and vapor move upward through the spray of cooling water, more and more of the vapor will be condensed, so that by the time the top is reached only air will be left, the injection with lowest temperature making it least possible for vapors to reach the air pump. On the other hand, with the parallel-current condenser, Fig. 2, the temperature of the water near the air discharge being relatively high, there is greater possibility of a mixture of vapor and air being drawn off by the air pump.

In any condenser the lowest pressure is at the coolest point, which is at the top in both the counter-current and the parallel-current types. In the counter-current condenser the air pipe is, therefore, at the point of least pressure, and the air should naturally move in that direction. In the parallel-current condenser, however, the air is taken off at the point of highest temperature, and, therefore, the highest pressure, a condition which does not facilitate separation of air from vapor. On account of the great specific volume of vapors under vacuum it is evidently of great importance to avoid handling vapors with the air pump.

In securing a good separation of vapors from air the size of the condenser plays an important part—in other words, the diameter of the condenser must be large in order to prevent excessive vapor velocities in it. If the velocity of the vapors is too high, there will not be sufficient time for complete admixture of water spray and vapors, and this will result in incomplete condensing

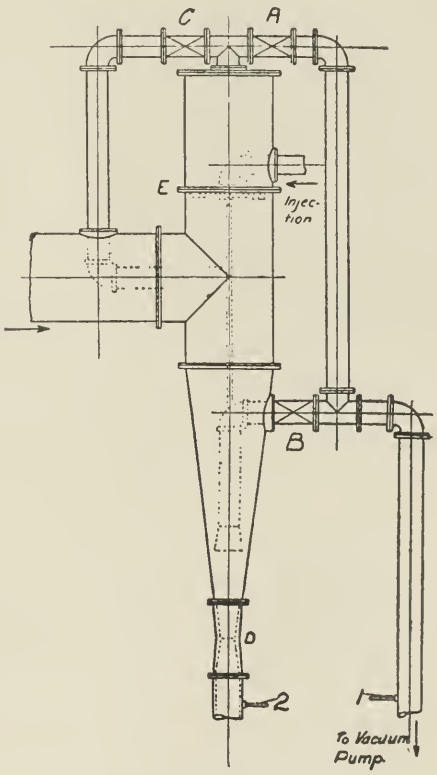

FIG. 3—CONDENSER (TYPE III)

of the vapors; in fact, the size has much to do with the results obtained from either parallel-current or counter-current condensers.

MIXING DEVICES

Attention has already been called to the use of trays having perforated bottoms and serrated edges, these trays being placed one above the other. In some cases only one tray is used, this being placed near the top, giving an uninterrupted shower from top to bottom. The latter would naturally give less time for contact of water and vapor, though it has the advantage of a

smoother flow of vapor through the condenser and a smaller velocity of the vapors. The trays naturally reduce the area of passage.

SUGAR HOUSE CONDENSERS WITHOUT VACUUM PUMPS

Fig. 3 illustrates a type of condenser in which the vacuum pump is often dispensed with. This condenser, as will be seen, is of the parallel-current type without trays, the original installation being that part below the flange *E*. The portion above *E*, including the valves *C* and *A* and their connecting pipes, were installed for experimental purposes. The vacuum pump connection belongs to the original installation, this being required for starting. Under normal operating conditions, however, the vacuum pump may be dispensed with, the air entering the condenser being entrained by the water passing through the restricted throat *D*. Even though the vacuum pump is used, its work is at least reduced by the aspirator *D*.

Tests of Condensers

With these different types of condensers Professor Kerr carried out a number of systematic tests. The condensers tested were of full size and used in the regular operation of evaporators or vacuum pans in sugar plants.

The object of the tests was to obtain especially first-hand information on the relative merits of the counter-current and parallel-current condenser types. In view of the fact that the advantages claimed for counter-current condensers are based on differences in temperature and pressure relation in the two types, the conditions of temperature and pressure were determined at different locations in the different types. Since the weight of cooling water required to condense a pound of vapor is an important consideration, attention was also given to this.

Tables III, IV, V give temperature observations from condenser types A, B, C respectively (Figs. 1, 2, 3). In each case thermometers were placed at points 1, 2, 3, etc., the observed temperatures being numbered to correspond in the tables. In all tests the temperature of the injection was constant and about 80 deg. Fahr.

Table III—Observations on Condenser Type I (Fig. 1)

Time	Temperature at 1	2	3	4	5	Vacuum, In. Mercury	Temp. Due to Vacuum, Kestner	Temp. Dif.	Conditions

5:15	86	81 5	140	142	118	23 9	141 0	23 0	Valve A open 3 turns.

The observations given in Table III were made on a counter-current condenser. The arrangement of trays was somewhat different from that of the original installation, a plate just above thermometer No. 3 having been substituted for an annular tray like the top tray. The plate is of brass with perforations and its diameter only 6 in. less than the inside diameter of the condenser shell.

This substitution was made with the hope of improving the condenser. After the change, however, it was noticed that the condenser did not work smoothly, there being considerable vibration and noise attended with rapid fluctuation of the vacuum as shown by the mercury column vacuum gage. The conditions given in Table III were found with the condenser thus changed.

It will be noted that the temperature at 2 was only slightly greater than the initial temperature of injection. The thermometer must have been directly under a shower of water which, being out of the vapor path, had not been heated to any extent.

The readings from thermometer No. 1 in the suction pipe of the vacuum pump show interesting information. The first four readings were taken with the valve A open, establishing a direct connection between the hot vapor space at the bottom and the vacuum pump. With

114	111	24.4	138	27	24.7	Injection same. A open. B closed.

this condition the temperatures in the vapor pipe were some 8 to 12 deg. lower than the temperature corresponding to the vacuum. These relatively high temperatures indicate that the vacuum pump was drawing over a large amount of vapors. It will be noted also that those temperatures were considerably higher than the leg pipe temperature taken at the same time.

The last eight readings were taken with the valve closed and the temperatures observed may be assumed to show the conditions that may be expected with the normal operation of counter-current condensers. Here it will be noted that the temperatures at thermometer No. 1 ranged from 86 to 99, though the former probably comes nearest normal, the higher temperatures having been obtained immediately after closing valve A. These temperatures are some 40 to 50 deg. lower than the temperatures corresponding to the vacuum and very slightly above the temperature of injection, indicating air with very little vapor mixed with it.

Thermometers 3 and 4 show temperatures practically the same as that corresponding to the vacuum, the former being slightly lower than the latter, which is to be expected.

The average reading at 4 is slightly higher than that corresponding to the vacuum. This may be due to an error in the barometer reading, which was assumed to

be 30 in. This, however, will not affect the general value of the observations given in the table.

The temperature difference given in the last column of figures is the excess of the temperature corresponding to the vacuum over the leg pipe temperature. It varies from a maximum of 25.8 to a minimum of 6.8 deg., the latter figure having been obtained by a considerable reduction in the amount of injection water used. As stated above, most of the observations were obtained with an amount of injection water considerably in excess of that required by the condenser for the vacuum maintained.

These observations were taken while the condenser was handling the vapors from a quadruple effect, which was handling juice at the rate of about 400,000 gal. per 24 hr. The valve *A* and its connecting pipe was installed to ascertain if such a connection would do away with the vibration and noise caused by the substitution of the brass plate at the bottom, which has been mentioned. In subsequent tests of this condenser it was found that it could be operated with much less injection water than was used when these observations were made without reducing the vacuum. Further observations relative to this will be given later.

The observations given in Table IV were made on condenser Type II, Fig. 2, which is of the parallel-current type. This condenser serves a 12-ft. coil vacuum pan. At the time the observations were made a mixed strike with corresponding low purity was being boiled. Here we have greatly varying temperatures showing a considerable irregularity of conditions in different portions of the condenser. It will be noted that thermometers 3 and 4 show average temperatures only slightly greater than in the leg pipe shown by thermometer 5. Both thermometers 3 and 4 were doubtless affected by a flow of water over them, though the latter was in a current of vapor.

The relations of the temperatures found at 1 to the temperatures corresponding to the vacuum are somewhat irregular. This is probably due to rapid fluctuations of the vacuum causing a change in the one to be shown before the change has affected the other. The temperature in the suction pipe of the vacuum pump was not observed, though it was probably somewhere between the temperatures at 4 and 5—that is, in the neighborhood of 108 deg., a temperature much higher than that obtained with the counter-current condenser as shown by thermometer 1 in the latter part of table III. This high temperature indicates the presence of much vapor along with the gases. The excess of the temperature due to the vacuum over the leg pipe temperature varies from 13.8 deg. to 39.2 deg., the average being 22.8 deg. During most of the time the injection water valve was about as close as it was possible to have it without decreasing the vacuum.

Table V gives the results of observations on condenser Type III, Fig. 3. By means of the valves A and B and connection pipes it was possible to operate this condenser either counter-current or parallel-current—that is, with B closed and A open it operated counter-current and with B open and A closed it worked parallel-current. In the tests recorded in Table V the condenser was operated both ways, also while gradually changing from one condition to the other. The condenser was connected to the vacuum pump in all cases, though as heretofore explained the aspirator D did service in removing a portion of the incondensable gases.

In these observations only two temperature readings were obtained, namely, in the leg pipe and in the air pipe to the vacuum pump. The first three readings were taken while operating parallel-current, the injection being varied. It will be noted that the temperature in the leg pipe varied from 15 to 29 deg. above the temperature corresponding to the vacuum. The temperature in the air pipe for these three readings varied in the opposite direction with an average of about 120 deg., indicating a considerable quantity of vapors mixed with the air. The last three or four readings were taken with the condenser operating practically counter-current. In general there seems to be little difference in the results as regards temperatures when worked counter-current or parallel-current.

Pressure Relations

In comparing parallel-current and counter-current condensers it was stated that as a parallel-current condenser is hotter at the bottom than at the top, theoretically the pressure should be lower at the top—in other words, the pressure would vary at different points in condensers of either type. In order to ascertain if this difference of pressures actually existed, pressure observations were made in several different condensers.

In one counter-current condenser 5 ft. in diameter, serving a quadruple effect which delivered about 230 lb. of vapor to the condenser per minute, it was found that the pressure at the top was exactly the same as at the bottom. The comparison of pressures was made by means of a mercury manometer, one side of which was connected to the lower end of the condenser, and the other side to the top of the condenser, holes having been tapped into the bottom and top for the connection.

Another counter-current condenser 4 ft. in diameter serving a double effect and condensing about 180 lb. of vapor per minute gave a reading of 23.95 in. vacuum at the top and 22.5 in. at the bottom; that is, the vacuum at the top was 1.45 in. greater than at the bottom. This condenser had only one spray plate at the top, the water below it having an uninterrupted fall to the bottom.

A parallel-current condenser, with trays arranged practically as in Fig. 2 and handling vapors at the rate of about 110 lb. per minute, shows the same vacuum at the bottom as at the top, the vacuum being 22.46 in.

A parallel-current condenser, with three trays 2 ft. apart arranged as in Fig. 2, serving an 8-ft. vacuum pan, showed ¾ in. greater vacuum at the bottom at one time with three coils on and 1¼ in. greater vacuum at the bottom later with five coils on. The diameter of the condenser was 42 in. and it was condensing vapors at the rate of about 170 lb. per minute with a vacuum of 26 in.

At first sight it would appear that the results of these observations were quite contradictory. On investigation, however, it will be seen that the two condensers which have different vacuums at the top and bottom were relatively small and were handling larger volumes of vapor than in the case of the other two. It will be noted, also, that the higher vacuum in the parallel-current condenser was at the bottom, whereas in the counter-current condenser the higher vacuum was at the top. This seems reasonable as regards the counter-current condenser, though why there should be a higher pressure at the bottom of a parallel-current condenser is not so apparent, unless it be due to the pull of the vacuum pump.

Attention has already been called to the substitution of a plate instead of the original bottom tray in Fig. 1. It has been stated, also, that after this change there was considerable noise and vibration. After full consideration, it was thought that this might be due to a surging of vapors back and forth above and below this plate. On one occasion it was noted that there were twelve fluctuations at the vacuum gage of 1 in. every five minutes, the upward movement being much quicker

than the downward movement, the noise and vibration occurring at the beginning of the upward movement of the vacuum gage. The vacuum gage, which was of the mercury-column type, was connected to the space below the plate.

In order to get some data regarding this a mercury manometer was rigged up and one side connected to the space above the plate and the other side to the space below the plate. Upon operating the condenser again it was found that the mercury would vary, being first higher in one leg of the manometer and then suddenly reversing, showing that there was actual reversal of pressures in the condenser above and below the plate. This would naturally react upon the last body of the evaporator itself and cause unsteady action thereof.

It may be well to state here that the noise and vibrations spoken of usually occurred when the supply of injection water was reduced to a point where the leg pipe temperature was very near that of the temperature due to the vacuum. After the fact of these pressures reversals was established the plate was gradually reduced in diameter from time to time until a space of 9 in. was left between the plate and the shell, at which point the vibration ceased and the condenser worked smoothly.

All of the pressure observations seem to be of value mainly in pointing out the desirability of liberal size and careful designing of trays, both as to size and location, in order to secure steady action and the prevention of pockets.

Quantity of Injection Water

The unit assumed for measuring injection water is, "pounds of injection water per pound of vapor condensed." The point has already been brought out that for a given absolute pressure in the condenser the amount of cooling water depends mainly upon the amount of air or other incondensable gases mixed with the gases in the condenser. The presence of air results in a higher leg-pipe temperature than there would be if no air were present. Theoretically, the greater the amount of cooling water the greater the vacuum due to the cooling effect. Actually, however, there is a limit to this because the water brings in air with it which offsets the reduction in pressure due to cooling. This is especially so in condensers with a poor separation of air from vapor. The weight of cooling water per pound of vapor has to be calculated from temperature and vacuum data, as it is not practicable to actually weigh the water; however, the calculated values are quite accurate.

Tables III and IV give data bearing upon the weight of cooling water per pound of vapor, though indirectly. Other conditions being the same, the weight of cooling water per pound of vapor is almost proportional to the difference between the temperature corresponding to the vacuum and the leg-pipe temperature. It will be noted that in Table III this value varies from a minimum of 6.8 deg. to a maximum of 25.8 deg—that is, the maximum is nearly four times the minimum. It will be noted, also, that the vacuum was less with a large temperature difference than with a small temperature difference. These observations were made on a counter-current condenser handling in the neighborhood of 550 lb. of vapor per minute. The minimum difference shows something of what can be done with careful manipulation of the injection water.

Table IV, giving the observations on a parallel-current condenser serving a vacuum pan, shows a minimum difference of 13.8 deg. and a maximum of 39.2 deg. The temperature difference in all cases is much higher than is considered good in practice. A minimum difference of 13.8 deg. is probably about the best that could be done with this condenser. It will be noted, also, that this was obtained with the highest vacuum observed in the series.

Table V gives values of injection per pound of vapor varying from 24.7 to 31.4 lb. The temperature difference is in all cases very high.

Table VI—Observations on Condenser Type IV

Vacuum	Temp. Due to Vacuum	Temp. Leg Pipe	Temp. Difference	Injection Water per Lb. of Vapor, Lbs.	Conditions
24.5	137.5	120	17.5	26.5	
24.5	137.5	120	17.5	26.5	Injection valve open an additional turn
24.6	137	119	18.0	27.2	Same.
24.65	136.5	116.5	20.0	29.2	Same.
24.5	137.5	120	17.5	26.5	As at first.
24.25	139	124	15.0	23.8	Injection valve closed one turn.
23.8	142	127	15.0	22.3	Injection valve closed two turns.

Note.—In no case could the injection valve be altered without affecting the vacuum. Type IV condenser is the same as that part of Type III condenser below flange E.

Table VII—Observations on Condenser Type V

Vacuum	Temp. Due to Vacuum	Temp. Leg Pipe	Temp. Difference	Injection Water per Lb. of Vapor, Lbs.	Conditions
25.0	134	118	16.0	28.2	
24.9	134	120	14.0	26.4	Injection valve closed one turn.
24.8	135	123	12.0	24.4	Injection valve closed 2 turns.
24.65	136.5	126	10.5	22.8	Injection valve closed 2½ turns.
24.5	137.5	130	7.5	20.8	Injection valve closed 3 turns.

Note.—In no case could the injection valve be altered without affecting the vacuum. Type V condenser is the same as that part of Type III condenser below flange E.

Table VIII—Observations on Condenser Type I

Vacuum	Temp. Due to Vacuum	Temp. Leg Pipe	Temp. Difference	Injection Water per Lb. of Vapor, Lbs.	Remarks
25.5	130	130	0	20.8	
26.5	121	120	1	26.2	
25.75	128	125	3	23.2	
26.25	123	120	3	26.5	
25.5	130	130	0	20.8	
24.8	135	130.3	5.2	19.9	Average during evaporation test. See test 3, Table 14.
24.8	135	112.9	22.6	35.0	Average during evaporation test. See test 1, Table 14.
25.1	133	114.2	19.3	32.6	Average during evaporation test. See test 2, Table 14.

Note.—During the time the first five observations were made the injection valve was not changed, the five observations being made within a space of about two minutes.

Tables VI, VII and VIII give data which may be used for comparing the amount of cooling water required with the two types of condensers shown in Figs. 1 and 3.

It will be noted that in Table VI the amount of injection water used was varied, though the amount of vacuum in the first five readings remained practically the same. In the last two observations, however, with reduced injection the vacuum decreased, the temperature difference remaining at 15 deg. In other words, we may be assured that with this condition the minimum possible temperature difference was obtained.

The observations shown in Table VII give temperature differences ranging from 16 down to 7.5, with greatly decreasing vacuum. Here, also, the equilibrium point was obtained, the average temperature difference being something like 12. Condenser Type V is exactly like condenser III, Fig. 3.

The first five observations of Table VIII were obtained in an attempt to ascertain the lowest possible injection water requirement for condenser A, which is of the counter-current type. It will be noted that the

average temperature difference for these five observations was a little less than 15.

With the minimum temperature difference of 7.5 for condenser Type V the weight of cooling water for a vacuum of 26 in. and the injection temperature of 80 deg. would be 27.07 lb. With a temperature difference of 14, the weight of cooling water for the same standard conditions would be 23.24 lb. In other words, the counter-current condenser would seem to be capable of operating with some 17 per cent less cooling water than is required for condenser Type V.

The last three horizontal lines of Table VIII give the averages obtained during evaporator tests using condenser Type I. It will be noted that the weight of cooling water per pound of vapor varies from 19.9 to 35.0 lb. with the same vacuum, the difference being doubtless due to carelessness in handling the injection valve.

Table IX gives condenser data obtained by Professor Kerr while making various evaporator and vacuum pan tests. This table gives data of considerable interest, though it is not very definite as regards a comparison of counter-current and parallel-current condensers.

The actual injection per pound of vapor is given in column 11. These values, however, were obtained with varying vacuums and varying temperatures of injection water, for which reason they are not directly comparable. For this reason the weight of injection water per pound of vapor has been corrected to a standard vacuum of 26 in. and an injection temperature of 80 deg. These corrected values are given in column 12.

The values in column 13—namely, vapor velocities in condenser—are based on the assumption that a condenser is a cylinder without trays, and equal to the cubic feet of vapors per second divided by the cross-sectional area of the condenser shell. The results, though, are somewhat erratic, and this is quite natural in view of the careless operation of many of them.

A general inspection of column 12, however, shows considerable advantage for the counter-current type of condenser. The average of ten tests made on the counter-current condenser shows 33.06 lb. of injection per pound of vapor condensed. An average of eight tests made on parallel-current condenser shows 56.3 lb. of injection per pound of vapor condensed. Condensers Type I and Type V were in the same factory and observations were made throughout several weeks in order to get a comparison of the actual weight of the cooling water required per pound of vapor in the regular operation of the factory. The average temperature difference for condenser Type I was 16.5 deg. and for condenser Type V 25.5 deg. With standard conditions—that is, with 26-in. vacuum and 80-deg. injection water—these temperature differences would correspond to 35.8 lb. of injection per pound of vapor in the case of condenser I and 52.3 lb. for condenser V; in other words, condenser V required 43 per cent more injection water than condenser I. This shows a greater difference than was shown in the observation referred to above.

Anaconda Notes.—From the June issue of *The Anode*, the safety bulletin published by the Anaconda Copper Mining Co., we note that No. 1 section of the concentrator, which was recently remodeled to provide for the installation of the oil flotation process, is successfully treating ore at the rate of 2000 tons per day and is making a tailing that assays well within the limits expected. No. 2 section is now being changed to provide for the use of the same process and rapid progress is being made with the work. It is expected that the entire task of tearing out the old machinery and constructing the new 2000-ton section, ready for operation, will be accomplished by August. All four furnaces in the East Reverberatory Building are now operating on pulverized coal. Three of them are 143 ft. in length and the fourth, which was the first furnace to be equipped for coal dust firing, is 124 ft. long. These four are running nicely and are smelting a greater amount of material than the eight grate-fired furnaces formerly did. All furnaces in the West Building are now being rebuilt and will be ready for operation when the No. 2 Roaster Plant is completed. In the Coal Pulverizer Plant the Pulverizer Building is now completed and work is progressing on the installation of the balance of the crushing, storage and drying equipment.

The Morse Bros. Machinery and Supply Company, of Denver, Col., has purchased the entire power plant recently erected at Wilkenburg, Ariz. This plant was built to furnish power for the Octave Mining Company, fourteen miles distant, the power being generated at the railroad and transmitted to the mine. The plant consisted of 200 and 550-kw. Westinghouse alternators driven by Corliss engines. The steam plant consists of B. and W. Boilers, fired with oil. The transmission line was operated at 22,000 volts and is fourteen miles long. All of this material will be dismantled and sold, or removed to Denver. The smaller unit was in use three weeks and the larger one was never used.

The Electric Furnace for Reheating, Heat Treating and Annealing*

BY T. F. BAILY

More than a quarter of a century ago the first commercial electric furnace was put into operation for the melting of steel. This furnace, of less than 100 kw. capacity, showed on its preliminary operation a current consumption of 7000 kw.-hr. per ton of metal melted. Had this furnace been operated in America at the then commonly prevailing rate for electricity, at, say, 10 cents per kilowatt-hour, there would have been little hope that such a process requiring a heating medium of such great cost would ever become commercial. In the twenty-five years that have passed since this early and crude development of electric melting and refining furnaces, there have been put into service more than 100 of these furnaces, ranging in commercial capacity from 1 to 20 tons, and in electrical capacity from 100 to 3000 kw. Central stations that twenty-five years ago considered 10 cents per kilowatt-hour a low rate are now, with modern equipments of power generation, furnishing electric furnaces with current for less than ¾ cent. Electric furnace loads running into thousands of kilowatts, where now there are but hundreds, operating continuously and with power factors closely approaching unity, will undoubtedly cause central stations advantageously located to look with favor upon rates of ½ cent a kilowatt for such loads. As the dominating factor in electric furnace operation costs must always be the cost per kilowatt-hour, the gradual reduction in the cost of electric current will greatly add to the growth of electric furnace loads for re-heating, heat-treating and annealing.

Early Methods of Re-Heating by Electricity

One of the earliest attempts at electric heating was by direct resistance, wherein the materials to be heated were clamped between two massive terminals of an electric circuit, or, as in the water pail forge for small material, where one end of the bar was connected to a suitable terminal while the free end of the bar was plunged into a bath of water and other suitable liquid conducting material which was in turn connected to the other terminal of the electric circuit.

Both of these methods have two distinct disadvantages which prevented them ever becoming commercially feasible. The first and most serious is the matter of obtaining a suitable contact between the material to be heated and the electric terminal. The other inherent disadvantage is that at the point where the electric connection is made that part of the material to be heated must of necessity be of a different temperature than the rest of the bar.

From an operating standpoint, this method of heating is very inconvenient, as electrical connection must be made for each piece to be heated, and on account of the enormous current involved these contacts must be carefully made or there will be serious burning of the metal at this point, which would not only destroy the electrical terminal itself, but also burn the bar.

In any event, this method of heating could not be adapted to any but material of uniform cross-section, and in all probability there would be a much higher temperature in the interior of the bar than on the surface, due to the peculiar heating effect of an electric current flowing in a conductor.

Re-Heating Furnaces with Granular Resistors

The type of furnace that seems best adapted for reheating operations is the resistance type, in which the material to be heated is entirely separate from, and independent of, the resistance elements in which the heat is generated by the electric current. This arrangement makes for the maximum simplicity and convenience in operation. A general description of this type of furnace is as follows:

Through the side walls of a furnace shell made of suitable refractories are inserted two carbon or graphite electrodes. The inner ends of these electrodes extend into a trough of highly refractory material. This trough is filled with the resistance material itself, usually some form of broken carbon, and makes contact at each end with the electrodes. The outside ends of the electrodes are connected by means of suitable copper terminals and cables to the regulating transformer and switch, by means of which the voltage impressed across the furnace is regulated, the voltage thrown on the furnace having a definite relation to the current flow and heat input. The material to be heated is placed conveniently adjacent, at the side or above or underneath the resistance material and its containers, as the case may be.

In some heating operations the actual cost of heating per ton is less with electric furnaces than with combustion furnaces, while in some heat-treating and annealing operations the precision with which the operations are carried on must be the justification for the higher cost of heating in the electric furnace. In a general way it may be stated that the higher the temperature at which the heating operation is conducted the higher the relative economy in the use of electric furnaces. At the lower temperature there is less difference in the thermal efficiency of electric and combustion furnaces, but here the electric furnace shows great superiority in the way of temperature control.

The principal advantages of electric furnaces over combustion furnaces for re-heating are more accurate temperature control, non-oxidizing atmosphere, saving in space, elimination of blast or stack, evenness of temperature throughout the heating space, simplicity of control, small amount of heat lost to the surrounding atmosphere, and cleanliness of surroundings.

Electric furnaces of the character described may be controlled with great precision, for the reason that a given input of electric current liberates a given quantity of heat units within the furnace, the transfer of electric current to heat being at 100 per cent efficiency. The walls and doors of the furnaces are the only means for the escape of heat from the furnace in other than useful work, and this loss remains constant for any given temperature and operating conditions. For a given tonnage of metal to be heated to a certain temperature in a given time, it is only necessary to know the heat absorbed by the metal in coming to the temperature and the heat lost by conduction and radiation from the furnace. The voltage across the furnace terminals is then adjusted so that the kilowatts per hour required to deliver the necessary heat are just sufficient to deliver this heat.

In contrast with this simple method of delivering heat into the furnace, the combustion furnace requires that a given quantity of air be mixed with the fuel, and this process of converting chemical energy into heat is not usually conducted at an efficiency closely approaching 100 per cent, as in the conversion of electricity into heat. Besides this, the stack or discharge flues to the combustion furnace are an ever present means of carrying out what should have been useful heat under ideal operating conditions. Any variation in the supply of air or the supply of fuel in a combustion furnace quickly

*A paper presented before the Engineers' Society of Western Pennsylvania. In connection with this paper former papers by Mr. Baily may be compared in our Vol. 9, page 262 (May, 1911), and Vol. 10, page 291 (May, 1912), where illustrations of this furnace type may be found. An illustrated description of a Baily annealing furnace for brass and German silverware was given in our Vol. 12, page 483 (July, 1914).—Editor.

affects the temperature, and both of these do continually vary, both in volume and pressure.

In order to obtain good commercial efficiency in a combustion furnace, an excess of air over the theoretical amount is required. This excess of air creates an oxidizing atmosphere in the furnace chamber which results in scaling the metal under treatment, resulting in a loss of from 1 to 5 per cent, depending upon the type of combustion furnace, the temperature, and the man operating the furnace. The smaller of these figures applies to annealing furnaces of large capacity, while the larger figure is not uncommon in oil or gas-fired heating furnaces for forging stock running at high temperatures. One of the factors contributing to the reliability of electric furnace operation is that electric current supply, whether from central station or from isolated plants, is much more dependable than either oil or gas, and under more ready control than even direct firing.

The space required for electric furnaces is considerably smaller than that required by combustion furnaces, due to the fact that no stack nor combustion chamber is required, and the electric cables carrying current to the furnace require much less space and are far safer than gas or oil lines, and much more readily located.

As the heat from the resistance units is thrown on the hearth almost entirely by radiation, the temperature of the furnace is more readily kept uniform over the entire area than in combustion furnaces where the heat is delivered to the hearth by the impinging heated gases or products of combustion. Another feature leading to evenness of temperature throughout the electric furnace is that the resistors of the electric furnace may be run at only a comparatively small temperature above that of the hearth of the furnace, while the combustion furnace, for instance in an annealing operation, requires that the incoming gases from the combustion chamber must of necessity be several hundred degrees higher than the desired ruling temperature of the furnace.

Mention has already been made of the precision with which electric current may be supplied to the furnace. It should be noted further, however, that the instruments for indicating and recording electricity are far more accurate than those available for indicating and recording the flow of fuels to combustion furnaces. Thus the heating costs of electric furnaces may be very readily obtained on any particular class of work, as the kilowatt-hours registered over a given run are readily ascertained.

In the summer months the heat given off by combustion furnaces, either by radiation through the walls of the furnace itself or from the waste products of combustion, if small furnaces are used, produces such extreme room temperature around the furnaces as to seriously affect the operator and markedly reduce the output of the furnaces. In contrast with this the loss of heat through the walls of an electric furnace is so small as to be almost negligible.

The actual theoretical heat required expressed in kilowatt-hours per ton of metal is given in Table I for heating to the temperature given.

The thermal efficiencies of electric furnaces vary greatly with the size and capacity in tons per hour. The wall loss on a forging furnace of 60-kw. capacity heating 250 lb. of steel per hour to 2200 deg. Fahr., will be approximately 30 kw., showing a thermal efficiency of 50 per cent. A furnace of 1 ton per hour capacity for 2200 deg. will show an efficiency of 75 per cent.

In annealing work a furnace of 100-kw. per hour capacity will heat 600 lb. of metal to 1650 deg. with an efficiency of 50 per cent, while a furnace of 600-kw. capacity heating 3 tons of steel per hour will show an efficiency as high as 90 per cent. All the above figures are typical for the usual classes of work handled in the capacity named.

First Commercial Furnace for Re-Heating

The first type of these granular resistor furnaces for re-heating was designed for heating small bars and billets such as are used for small forgings, and for temperatures up to 2300 deg. The general construction of these furnaces was as follows: The furnace proper was constructed of firebrick much after the method of prevailing oil-fired furnaces. Through the sides of the furnace were inserted large electrodes, the inner ends protruding into the furnace chamber. Foundry coke crushed to pea size was placed in the space between the electrodes and formed the resistor of the furnace. The opening to the furnace was in front, and the bars of metal to be heated were placed directly over the resistance body but not in contact with it. The necessary variable voltage supply to this furnace was regulated by the field rheostat of a small single-phase alternator. This furnace was run commercially for several weeks in place of the oil-fired furnace usually used for the hammer and on various sizes of material, as shown by the data given in Tables 2 to 5.

TABLE I

Material	Deg. Fahr.	Kw.-Hr. per Ton

Some of the difficulties encountered in this furnace besides its rather low thermal efficiency were burning off of the electrodes at the point where they emerged from the furnace; the burning out of the refractory materials supporting the resistance material itself; trouble with electrical connections between furnace cables and electrodes, and great variation in the electrical resistance of the resistance material itself.

The Electric Furnace for Re-Heating

In the six years that have elapsed since the construction of this early furnace, these difficulties have been well overcome. By the use of a steel shell for the outside wall of the furnace instead of brick, and with this space filled with suitable insulating material, the thermal efficiency of the small furnaces has been very materially increased, as is shown by the accompanying test sheet on a 30-kw. furnace. The burning off of the electrodes at the place where they leave the furnace walls has been entirely eliminated, one set of electrodes lasting for months at a time in continuous service.

Table VI—Test of a 30-K.W. Electric Furnace

Duration of test, 5 hrs., 5 min.
No resistance material used. Current left on at 20 volts.
11,138−10,971=167 kw.-hr. power used.
½×⅝×16×0.2834=4.25 lb. weight per bar of steel.
15×12=180, total number of bars heated to 2200 deg. Fahr.
4.25×180=765, total number of lb. of steel heated to 2200 deg. Fahr.

$$167 \div \frac{765}{100} = 21.83 \text{ kw.-hr. per 100 lb. of metal heated.}$$

20×21.83=436.6 kw.-hr. per ton of metal heated.
Temperature difference, 2150 deg.
Specific heat of steel, 0.199 approx.
2150×0.199×765=327.305 B.t.u. required to heat metal.
167×3412=569.804 B.t.u. used in furnace.

$$\frac{327.305}{569.804} = 0.575 \text{ efficiency.}$$

*One piece removed that had obtained required temperature.

The troubles encountered in connecting the electric cables to the electrodes have been eliminated, so that no trouble is experienced now from this source. For furnace temperatures not exceeding 2500 deg. Fahr. this type of furnace will answer every reasonable requirement, and in operating cost will compare very favorably with oil furnaces, figuring electrical energy at 1 cent per kilowatt-hour and oil at 4 cents per gallon, so far as actual fuel cost alone is concerned, while there is an additional saving due to the non-oxidizing of the metal amounting to a saving of from 2 to 5 per cent of the metal heated. This type of furnace is suitable for tonnages up to 1 ton per hour capacity, and billets not exceeding 4 ft. in length.

Continuous Furnaces

For furnaces in capacities of 1 ton per hour and above, the continuous type of billet heating furnace offers some advantage in economy as well as in mechanical operation, as in the continuous type only the discharge end of the furnace reaches the full ruling temperature, the lower temperature of the feeding end reducing wall loss of the furnace very materially. The following calculation of a heat balance sheet may be taken as typical for this type of continuous billet heating furnace heating material to 2000 deg.:

Capacity, 10 tons per hour; temperature, 2000 deg.; wall loss in kilowatt-hour, 250; theoretical heat required per hour by metal in kilowatt, 2150; kilowatt-hours per ton of metal heated, 240; cost of heating per ton with current at ½ cent per kilowatt, $1.20.

This figure of cost per ton of metal heated becomes prohibitive unless account is taken of the metal loss due to the oxidizing influence of the flame in gas-fired billet heating furnaces. Even making allowances of 2 per cent on $20 steel, this type of furnace seems to have no prospect of competition for large tonnages unless the cost of electric current is under the rate named in the above tabulation. In heating higher grades of steel, especially steel of crucible quality, the saving in scale over any combustion furnace practice will far outweigh the higher cost of heating by the electric furnace.

Combination Gas and Electric Furnaces

In large tonnages of heavy billets a combustion furnace using producer gas firing to, say, 1500 deg. Fahr., or above, and heating from this temperature to the desired rolling temperature by electricity, offers advantages of low fuel cost per ton of metal heated, at the same time a minimum amount of oxidation of the metal, as the low ruling temperature of the gas end will permit a high thermal efficiency even with a non-oxidizing flame, while the final heating is done in the electric end of the unit which is readily maintained under a reducing atmosphere.

Such a furnace as this can be expected to show a thermal efficiency in the gas end of 50 per cent and in the electric end 75 per cent. With coal at $2 per ton and electricity at ½ cent per kilowatt, the total cost of heating should not exceed for coal alone 10 cents and electricity 32½ cents, making a total cost of 42½ cents per ton.

This cost compared with a direct-fired heating furnace having a coal consumption of 200 lb. per ton of metal heated, would show an excess cost for the combination gas and electric furnace of 22½ cents per ton. But with a saving of 2 per cent in metal worth $20 per ton, the combination gas and electric furnace would show an actual saving of 17½ cents per ton of metal heated, besides giving to the metal all the advantages of the precision in uniform temperature throughout the billets, as well as a uniform rolling temperature.

Soaking Pits

The type of electric furnace which seems, however, to be destined to have the largest commercial application in rolling mill operations is the soaking pit, and it is doubtful whether any gas-fired pits of large size can compete in cost of operation with electric pits where

current is supplied at the usual rates of electric current available for this service, provided the ingots are charged hot into the furnace. A heat balance sheet for an hour-hole soaking pit holding sixteen 3½-ton ingots and having passed through it 648 tons per twenty-four hours would be as follows, assuming a wall loss of 500 kw. per hour:

With ingots stripped hot, interiors molten, no heat required for the metal itself, the current consumption would then be 500 kw.-hr. per 27 tons of ingots, or less than 20 kw.-hr. per ton of ingots soaked. With ingots averaging 1650 deg., the current consumption for 27 tons per hour would amount to 1620 kw. per hour, or a current consumption of 60 kw.-hr. per ton absorbed by the metal. To this should be added 40 kw.-hr. per ton as wall loss. This higher figure for wall loss per ton of metal heated being due to the reduced capacity of the pit in tons per hour when handling the cold ingots on account of the longer time required for heating and soaking. Thus the current consumption for ingots charged at 1650 deg. would be 100 kw.-hr. per ton.

With cold ingots the heat absorbed by the metal will be 230 kw.-hr. per ton, and with a wall loss under this condition of 185 kw.-hr. per ton 315 kw.-hr. per ton would be the current required for cold ingots. But as cold ingots are a rather small percentage of the total ingots handled in a modern steel mill, these high figures are of no serious consequence in considering electric furnaces for soaking pit operations.

It is apparent from these calculations that electric soaking pits can compete with gas-fired pits, even where moderately hot stripping and charging is practised. Besides this, the electric pit, as in the heating furnaces mentioned before, has the advantage of a non-oxidizing atmosphere, which will mean a saving of from 1 to 2 per cent of the weight of ingots put through the pit. Another advantage worthy of note is that an electric pit will take only one-third the space of a gas-fired pit of the same capacity. A feature of even greater importance than almost any other is the elimination of surface defects in the ingots, due to scale or oxidation, a matter now receiving considerable attention by steel makers.

Electric Furnaces for Heat Treating and Annealing

The rapid growth of the practice of heat-treating and a realization of the precision with which this treatment must be carried on in order to secure uniform results, has opened a particularly desirable field for the electric furnace, especially as the electric furnace can be more accurately controlled and a greater uniformity of heat throughout the furnace maintained in commercial operation than with combustion furnaces. A comparatively slight variation in either blast pressure or fuel supply in a combustion furnace very quickly affects the ruling temperature, while in the electric furnace, owing to the comparatively great mass of heated refractory material of walls and roof acting as a heat storage or accumulator, the variation in temperature is reduced to a minimum. In practice the current may be off for periods of an hour at a time without affecting the temperature more than a few degrees.

This type of furnace may be described as follows: In the usual steel sheet is constructed an arched roof of firebrick, so arranged as to reflect the heat radiated from the resistor troughs onto the hearth located between the two resistor units running lengthwise of the furnace. The material to be heated is handled through the doors of the furnace located in the end walls. The hearth, if not subject to mechanical abrasion, is made of suitable firebrick. Where the abrasion is likely to be severe, cast-iron plates replace the firebrick.

A heat balance sheet of a furnace of this type of 100-kw. capacity and the hearth area 5 by 6 ft. and heating 600 lb. per hour to 1650 deg. Fahr., will show the following efficiencies:

Heat absorbed by the metal, 50 kw.
Heat lost through the walls, 35 kw.
Heat lost through the doors and door openings, due to the frequent charging and withdrawing, 15 kw.

Continuous Furnaces

For furnaces of more than ½ ton per hour capacity, and for higher thermal efficiencies, the continuous type of furnace is desirable. The material, if of uniform section, is pushed through the furnace by direct application of the pusher to the material to be heated. If the parts are small or liable to buckle if direct pressure is exerted on them, they are placed in pans or steel boxes, these containers being pushed through one at a time. If the material is in the form of rods that may be handled through the furnace lengthwise, as, for instance, copper and brass rods or tubes, this material may be placed on steel pans and drawn through the furnace by means of hook and chain, as is common in brass mill practice.

A typical furnace of the continuous type for annealing German silver or brass stampings in steel pans has a hearth 15 ft. long by 2 ft. wide, and a rated electrical capacity of 200 kw. A mechanical charger operated by a motor-driven winch with hand-operated clutch pushes the pans in through the charging door one after another, seven pans being in the furnace at one time. The pans passing through the furnace are supported by a hearth made of cast-iron grids each 2 ft. square. The pan when discharged is dumped automatically into a water-sealed discharge hood. The metal under treatment falls into a tank of either clear water or pickling solution, depending upon the cleanliness of the material before it is charged. The pan is caught by two rails and held suspended above the trough. It may be taken out from under the water-sealed hood through the counterbalanced swing door.

In operating the furnace, a pan filled with material to be treated is placed on the runway in front of the pusher. The small hand lever near the top of the furnace frame operates the clutch on the motor-driven winch on top of the furnace. The first movement of the cylinder raises both doors enough to admit the pans, which are 3 in. high; a stop on the cable holds the doors at this height while the pan of fresh material is pushed into the furnace. As the fresh pan enters, the pan at the discharge end is pushed onto a dumping carriage, its own weight automatically tips the pan dumping the contents into a hopper, the lower end of which is submerged in the quenching tank; the annealed material falls into a perforated copper basket, which at intervals is lifted out of the quenching tank. As the pan starts to tilt, the pusher carriage is pulled out of the charging end and the doors are dropped. Thus in this furnace the material is not exposed to the atmosphere at any time after entering until taken cold from the quenching tank. This entirely eliminates the possibility of oxidation as the furnace itself has a reducing atmosphere. A heat balance sheet of this furnace annealing German silver at 1400 deg. Fahr. shows the following:

Heat absorbed by 2000 lbs. of metal, 80 kw.
Heat absorbed by 400 lbs. of steel pans, 28 kw.
Heat lost through walls and doors, 24 kw.

A heat balance sheet of this furnace heating 1500 lb. of steel per hour to 1650 deg. will show the following:

Heat absorbed by 400 lbs. of pans, 34 kw.
Heat absorbed by 1500 lbs. of metal, 127½ kw.
Heat lost through walls and doors, 30 kw.

The advantage of this type of furnace over the non-continuous furnace is a lower labor cost and the fact

that the material when brought to the desired temperature may be more quickly removed, eliminating largely the danger of over-heating, and at the same time allowing the material under treatment to be brought to temperature more gradually.

Automatic Continuous Furnaces

The type of furnace best adapted to heat-treating which requires precision is the automatic continuous type, wherein the material under treatment, when brought to the predetermined temperature, is automatically discharged either into the air or into some quenching medium. This method of operation reduces the human element and the chance of error to a minimum. The only part of the operation dependent on the operator is the placing of the material to be heated on the charging platform. When the material at the discharge end of the furnace reaches the maximum temperature, a special pyrometer closes an electrical circuit, which in turn closes, through a suitable relay, the solenoid operated radial dial switch; the various electrical circuits in turn operate the doors, pusher and quenching apparatus.

A typical two-furnace equipment of this type having three operations, heating above the critical point, quenching and re-heating for drawing, consists of the following parts: Two furnaces, a quenching tank, a quenching machine, a control pulpit and two contact-making pyrometers. As all the motions of the equipment are controlled from one radial dial switch, the equipment, when once adjusted, is so interlocked that no material can get through the furnace unless it is first heated to the exact temperature (a maximum of 5 deg. Fahr. is allowed). Immediately upon reaching this temperature it is quenched and allowed to remain in the quenching bath a stipulated time; at the end of this time it is withdrawn from the bath and placed on the charging platform of the drawing furnace. When the material at the discharge end of the drawing furnace reaches the desired temperature, the pyrometer of this furnace sets in operation the operating mechanism, pushing into the furnace the material just brought out of the quenching bath and at the same time discharging the material that has come to temperature.

It is only by this automatic method that the highest class of work in heat-treating can be done, as the only part of the operation depending on the human factor is, as mentioned above, the placing of the material to be heated on the charging platform of the first furnace.

The greatest feature and one that cannot be emphasized too greatly is that when the material is delivered at the discharge end of the equipment it has received the treatment as per the setting of the control equipment, and nothing else. The greatest objection to heat-treatment as generally practiced to-day with combustion furnaces is due to the inability to obtain duplicate results. The automatic equipment just described eliminates the uncertainties of non-automatic equipments and enables heat-treating to be done with as great a precision as it is possible to measure. While with hand operation it is possible to obtain excellent results in actual practice at times, a considerable portion of the material treated will fall below the standard as determined by physical tests. The automatic equipment gives every piece exactly the same treatment.

A tabulation of the results that may be obtained with costs of such a treatment as has just been described is given in Table 7:

It will thus be seen that for a comparatively small cost, steel of much better physical qualities is obtained.

Table VII

Carbon per cent	Treated or Untreated	Ultimate Strength	Elastic Limit	Elongation	Reduction in Area	Per Ton Cost of Electric Heat Treatment Current at ½c per Kw.-Hr.	Increase in Ultimate Strength	Increase in Elastic Limit	Increase in Cost for Heat Treating Steel Costing $30 per Ton

Treatment consisting of heating to 850 deg. C., quenching in water, reheating to 550 deg. C.

Data taken from Harbord & Hall.

Conclusion

In conclusion it may be stated that the small electric re-heating furnaces are commercially feasible from a fuel standpoint alone, where the current consumption per ton is 400 kw.-hr. and the rate is 1 cent per kilowatt-hour, compared with oil where the consumption per ton is 100 gal. at a cost of 4 cents per gallon, or natural gas where the consumption per ton is 12,000 cu. ft. at 33 cents per 1000 cu. ft. With an allowance made for the saving of metal due to absence of scaling in the electric furnace, the saving in heating cost per ton on the above will be that percentage of saving multiplied by the cost of steel per ton; as, for instance, 5 per cent saving on an automobile steel worth $50 per ton, or a net saving of $2.50 per ton of metal heated. On this basis of metal saving and with a consumption of 100 gal. of fuel oil per ton, in order to compete with electricity at 1 cent, oil would have to cost not to exceed 1½ cents per gallon, or with oil at 3 cents the fuel consumption would have to be under 50 gal. per ton.

Electric furnaces of the continuous type of 5 tons per hour capacity will show commercial economy over coal-fired furnaces of the same capacity which require 200 lb. of coal per ton of steel, with coal at $2 per ton, while the electric furnace requires an electric current consumption of 250 kw.-hr. per ton, current at ½ cent per kilowatt-hour, with a metal saving of 3 per cent over coal-firing, heating a steel worth $35 per ton.

The further advantage of electric furnaces will be, evenness in temperature throughout the billet, and uniformity of temperature one billet with another.

The combination gas and electric furnace will show commercial efficiency compared with producer-gas-fired furnaces using 200 lb. of $2 coal per ton, while the combination gas and electric furnace uses 100 lb. of coal per ton of metal for heating to 1400 deg. Fahr., and 100 kw.-hr. per ton in heating from 1400 deg. to 2000 deg., current at ½ cent per kilowatt-hour, coal at $2, and with a metal savings of 2 per cent on steel valued at $20 per ton.

In the case of soaking pits, the advantage in favor of electric pits is more marked in the way of commercial saving than any of the other electric heating furnaces mentioned, on account of the elimination of the usual metal loss by oxidation of 2 per cent which occurs in producer-gas-fired pits. With steel valued at $20 this item alone is 40 cents per ton. To this add a fuel cost of 5 cents per ton, making a total cost of 45 cents per ton of ingots soaked in producer-gas-fired pits. Electric soaking would cost only 10 cents per ton, current consumption being 20 kw.-hr. per ton of ingots, and the current at ½ cent per kilowatt-hour. This would mean a saving of 35 cents per ton over the prevailing method of operation, besides giving the additional advantage of saving in space, and ingots with surfaces as clean as when charged into the pit.

In heat-treating, the saving in operating cost of electric furnaces over combustion furnaces in most cases

must come in the elimination of oxidation, as, for instance, on high-grade steel, brass and non-ferrous metals, eliminating large expense in acid, and in labor for the pickling operation. In addition to this, the advantage which outweighs, perhaps, all others is the precision with which electric heat-treating may be done. It is obvious that it is useless to heat-treat a series of parts that may go to make up a steel structure, as a bridge, a line of rails, or a set of springs or axles of a locomotive, if the method of heat-treatment is such that dependence cannot be fully made on the gain in physical properties. The failure of a single member of the bridge or a single rail or a spring or axle is almost certain to cause a catastrophe, hence without absolute precision in temperature and method for producing that temperature in every piece alike vital parts of a structure or a machine must be figured on the basis of untreated parts, necessitating a greatly increased weight over that of a design relying on the greater strength of heat-treated parts.

The automatic electric furnaces described above give this precision, and when the material to be treated has come through the furnace it is certain that it has had the prescribed treatment, and nothing else.

The user of steel to-day is willing to pay the additional cost for the additional physical qualities to be obtained by proper heat-treatment, but he has never been willing and never will be willing to pay for the so-called heat-treatment that has in too many cases consisted of simply putting the material through a furnace. Physical qualities of the highest character have been obtained from time to time by treatment in combustion furnaces, but it is almost impossible to obtain duplicate results from day to day, owing to the many variables, including the greatest of all, the human element. The automatic electric furnace requires the minimum of attention in its regulation, and the human element is eliminated completely in the cycle of operation, excepting in placing the material on the charging platform of the furnace.

When the engineer realizes that for an additional cost of from $2 to $3 per ton he can with certainty get the full value of results possible with heat-treatment, the demand for heat-treated material will be a great many times larger than it is to-day.

Electric furnaces have come to stay, and while in the past a great deal of bad steel has been made in all classes of electric furnaces, it must be realized that the same sort of operators would probably have made a great deal worse steel in any other kind of furnace. The application of electric furnaces in melting and refining, and in heating and heat-treating, has only begun, and while the total current now used in this country in electric steel furnaces is only a few thousand kilowatts at this time, within the next ten years it should be several hundred thousand kilowatts. With the growth of electric furnace loads, with their high-load factor and power-factor, the cost of current per kilowatt-hour will be materially reduced, so that even electric smelting, when the high quality of pig iron thus produced is taken into consideration, may become, even in this district, commercially feasible for the better grades of iron to be used in the manufacture of high-grade steels, while electric furnaces for heat-treating, re-heating and the soaking of ingots will have come to hold the same relation and importance in industrial heating operations as the electric motor now holds in the field of industrial power.

* * *

In the extended discussion which followed Mr. Baily's paper, and which is given in full in the April issue of the *Proceedings* of the Engineers' Society of Western Pennsylvania, Dr. C. G. Schluederberg, Mr. Frank Thornton, Jr., Mr. T. D. Lynch, Mr. E. D. Leland and Mr. A. Stucki asked various questions.

Dr. J. W. Richards said for the sake of heat insulation that kieselguhr bricks should be used next the shell or casing, and the latter should be of a polished white metal, such as Monel metal.

Mr. William Hoopes said that "the Aluminum Company of America has lately installed one of the Baily furnaces, and it works. . . . This type of furnace is more flexible than any other type of furnace, i.e., the resistance type of furnace is capable of a more general application. It can be built in almost any size, and the resistance material is cheap and easily used."

With respect to the cost of electrical energy at ½ cent per kilowatt-hour, Mr. Baily said he thought that this "in large capacities includes all the charges, for instance, the investment charge as well as fuel. We have some furnaces now in operation that are operating under 2/3 cent per kilowatt-hour. This is from a central station, of course."

Prof. S. L. Goodale referred to a peculiar point which had come to his attention in heat-treatment experiments, from which it would seem to have been better to have an oxide scale formed than not. "I cannot say the effect is always found, but it certainly happens at times that when no oxide scale is formed the metal itself is decarbonized to a slight extent on the surface, resulting in a soft skin."

In reply to questions of Mr. Thomas S. Perkins on the cost of electrodes and maintenance cost, Mr. Baily said that "a typical furnace, 200 kw., has had two $4 electrodes, and in the way of repairs to brickwork has had about twelve silica brick. It has run about 6000 hours. By a little carelessness the electrodes burned off owing to the resistor material over the electrodes becoming too thin.

"As to the adjustment of the control of the furnace, this will not need any changing for over a period of eight to ten hours or longer; the quantity of material going through the furnace is practically constant. If you have a lower capacity you have to reduce the flow of current into the furnace or the temperature of the furnace will, of course, increase. As to the voltage, take a forging furnace of 250 lb. per hour capacity, the voltage would be about 60 across the furnace. In a furnace of 600-kw. capacity, probably 18 ft. long, the voltage would be about 250. In some cases the two cores of the heat-treating furnace are run in parallel, thus doubling the voltage, cutting the amperage and cables in two by that method.

"The cost of the furnaces themselves will be roughly four or five times the cost of a combustion furnace of the same capacity. Take a typical forging furnace handling 250 lb. per hour would cost about $1,200. A heat-treating furnace of 600-lb. capacity per hour would cost about $2,500. A furnace of 2000-kw. capacity runs about $25,000. These figures may be taken as typical for standard designs. . . .

"The control is obtained through special transformers called regulating transformers, controlling by special switches connected to the special taps of either the primary or secondary of the transformers. If we have to handle a primary voltage of 22,000 we control on the low-tension side. If we have a primary of only 440 volts we control on the high-tension side. All these furnaces are alternating-current furnaces. It is possible to use direct current, but in order to get voltage control a motor-generator set is required."

Single-phase furnaces are usually cheaper to build than two or three phase. A furnace of considerable size, say 1000 kw., would probably be built two-phase.

The voltage depends on the particular furnace, the highest used by Mr. Baily in an actual furnace is 400 volts. Above that there is danger of trouble with electric insulation.

Mr. Baily concluded his reply as follows: "The highest temperature we have ever operated furnaces at is 2700 deg. Fahr., and those furnaces run as long as three weeks without any repairs. At that time they required new linings, which cost about $4.00 and take half a day to renew, counting the time of cooling the furnace down.

"I think I have answered most of the questions that have been mentioned here. Some one has mentioned metal resistors. These seem to be quite feasible for temperatures up to 1500 deg. Fahr. About 2000 deg. they seem to go to pieces pretty rapidly, and are not really commercial at that temperature.

"The upkeep of the furnaces was asked for. We have recently put in operation some furnaces where the upkeep, renewals, etc., were guaranteed to be within 10 cents per ton of metal heated. That is a heat-treating operation. In small forging furnaces the cost will probably run as high as 50 cents a ton, using regular forging furnaces with ruling temperatures of the metal of 2300 deg. Fahr. in the small furnaces. The larger the furnace the less the cost per ton."

The Current Status of the Borax Industry

BY SAMUEL H. DOLBEAR.

The effect of political conditions in Europe has been felt less in the American borax industry than in almost any other branch of the chemical and mineral industry. Possibly this statement would be more clearly correct if it said that the net effect has been a normal production during the past year. On account of depressed business in the United States, local demand has, as a matter of fact, fallen off very considerably. On the other hand European refiners of borax and boracic acid, particularly those of Austria and Germany, have been badly crippled in their operations, and this has resulted in a large increase in American export trade. Canada, which has hitherto been supplied by England, has purchased large quantities from American refiners.

The world's commerce in boron compounds is practically controlled by Borax Consolidated, Limited, an English syndicate with headquarters at London. This company, in addition to its French and English refineries, also has refineries in Austria, and has supplied the German refiners with ore from its Chilean mines.

In Asia Minor the borax mines on the Sea of Marmosa normally produce about 14,000 tons per year. These mines are controlled by the British syndicate and have been for years an important source of ore for French and Austrian refiners. The mines at this point were worked many years before the development of the South American deposits. The participation of Turkey in the war has effectually shut off this source of supply.

In the United States, the mines of California are the only producers of borate ores. The largest production is from the deposits of the Pacific Coast Borax Company, which is now a subsidiary of Borax Consolidated. During the past year this company completed a narrow gage railroad connecting its Biddy McCarthy and Monte Blanco deposits with the Tonapah & Tidewater Railroad at Death Valley Junction. This work represents an expenditure of about $400,000 and opens up some of the best deposits in the Death Valley region. These deposits have hitherto been inaccessible on account of a long rough wagon haul. At Death Valley Junction this company has also built a large roasting plant in which the lower grade ores are calcined before shipment to the refineries.

The Sterling Borax Company, whose mines are located 6 miles from Lang, in Los Angeles County, ranks as second largest producer in California. During 1914 this company is reported to have mined about 15,000 tons of borate ore. This is divided into two grades, the first containing about 31 per cent anhydrous boracic acid; the second about 20 per cent. All of the ore is roasted at the mine before shipment, thereby eliminating impurities which consist of clay, pandermite and water. On roasting, the colemanite content disintegrates into a fine powder, while the pandermite and clay retain their original form. This makes it possible to separate the valuable portion very easily by screening. A branch railroad connects the mine with the Southern Pacific Railroad.

After a period of idleness lasting several years, the Russell Borax Mining Company is again working its mines in the Ventura fields, the control of the company having been acquired by the Stauffer Chemical Company of San Francisco. During the past year fifteen men were employed during the seven months' operating season and a production of 3800 tons was made. The ore mined was colemanite and averaged 37 to 38 per cent A. B. A.

The possibility of the development of an entirely new colemanite field is suggested by the discovery of this mineral in the Kramer section in San Bernadino County. While drilling for water on a ranch four miles from Rich Station on the Santa Fe Railroad, colemanite ore was encountered, the extent of which has been variously reported up to a thickness of forty feet. Little information is yet available regarding this occurrence, but the fact that the land has been purchased by the Pacific Coast Borax Company may be regarded as indicative, in a measure, of its importance.

The borate mines in Chili have been the principal source of this ore for many years, about 75 per cent of the world's supply being normally produced here. Ascotan, near Antofagasta, is the chief producing district. The Chilean mines, as well as those of Peru and Argentine Republic, are controlled by the British syndicate.

It is expected that Peru will become a producer shortly through an arrangement effected by Borax Consolidated with the Peruvian government. This agreement provides for the continuous operation of the mines situated near Arequipa, the construction of reduction furnaces capable of treating 40,000 metric tons annually, and the provision of either a railroad or other transportation facilities.

Although some borates are produced each year in Argentine Republic, none of the product is shipped, and only enough work is done to comply with the mining laws of that country. At Tres Morros the sun dried ore carries about 38 per cent A. B. A., and 1800 tons of such material was produced in 1913. The expense of production is high on account of the scarcity of fuel and distance from rail or water. It is not likely that borates from this country will be produced commercially until cheaper sources have been exhausted.

Borax prices are somewhat higher now than before the war. During the past year quotations for carload lots were at 4 to 4¼ cents per pound as compared to 3¾ to 4 cents in 1913.

Practically all of the borax and boracic acid consumed in the United States is refined in this country. Refineries are located at Bayonne, N. J.; Brooklyn, N. Y.; New Brighton, Pa.; Chicago, Ill., and San Francisco. The product of the San Francisco refineries is sold largely to Pacific Coast and Japanese consumers.

The Electric Furnace in the Foundry*

BY WILLIAM G. KRANZ.

The increased service demands on some of the products of the National Malleable Castings Company prompted it about eight years ago to investigate the electric furnace, both in America and in Europe. The process had already been sufficiently developed in Europe to lead us to believe that the electric furnace would most nearly meet our requirements.

After further investigation and consultation with the highest authorities on the subject, we decided upon the Heroult type as the simplest and most practicable.

In 1910, we built a furnace of this type, of 300 lb. capacity, for experimental purposes, and although it was crudely constructed the quality of the material we were able to make justified the installation of a 6-ton Heroult furnace in 1912.

This furnace has three electrodes, 17 in. in diameter, uses three-phase, 60-cycle current, and is equipped with Thury regulators, which give us good regulation and a uniform load on the line even when cold melting. The power factor of the furnace is 94 per cent.

Since July, 1912, the furnace has been in continuous operation, producing up to the present time over 20,000 tons of both carbon and alloy steels of varying analyses and of exceptional quality. Both cold and hot-metal charges have been used, with a power consumption of about 150 kw.-hr. per ton in the case of hot-metal charges and from 500 to 600 kw.-hr. per ton in the case of cold charges.

The electric energy consumed varies according to the final analysis of the steel and the amount of refining required. Too much cannot be said about the refining possibilities of the electric furnace, for no other method of steel manufacture can compete with the electric in this respect.

In proper operation lies the whole secret of success. That steel has been made electrically means nothing, for when the furnace is operated under oxidizing conditions the quality is no better than that of open-hearth material; but when properly made, electric steel is as good as that made in the crucible, and very much less expensive. The operation of the furnace is simple and the resultant composition is scientifically accurate. I might cite an example in this connection:

On a heat of steel treated under a slag of high-silica content some metallic aluminum was added in order to reduce the silicon from the slag in accordance with the following chemical equation: $3SiO_2 + 4Al = 3Si + 2Al_2O_3$. Analysis showed that the amount reduced was theoretically correct according to this equation.

The most important of the many advantages of electric steel castings over those made by the ordinary processes are briefly summarized below, and it should be kept in mind that these apply not only to carbon steels but to the alloy steels as well.

1. Absence of segregation, elimination of oxides, and absolute uniformity of composition regardless of atmospheric conditions which affect open-hearth furnaces.

2. Almost entire elimination of sulphur is possible (an important consideration in steel castings) and complete control of the other elements.

3. Great tenacity, giving ability to withstand much more abuse and fatigue without rupture.

4. High ratio of elastic limit to ultimate strength.

5. A more ready response to heat treatment and with much more uniform results.

6. Perfect control of pouring temperature, combined with ability to obtain very hot metal, so that light and intricate shapes are readily cast.

Let us take up the advantages of the more important of these qualities of electric steel, and investigate them more fully.

First.—Absence of segregation and oxides has been firmly established by a great many investigations in our chemical and microscopical laboratories. As a more practical proof of the elimination of oxides, we know that additions of any of the ferro-alloys to the bath will be found alloyed with the steel in their theoretical amounts. This is even the case with elements, such as aluminium and titanium, which are so susceptible to oxidation, proving conclusively in our minds that there could be no oxygen present in the steel. Leading authorities have agreed for some time that the electric steel furnace is the one means of preventing segregation.

W. R. Walker, in May, 1912, read a paper on "Electric Steel Rails" before the American Iron and Steel Institute, in which he stated that "Ingots of even eight tons had been produced electrically which were practically free from segregation."

Second.—We know of no authority who doubts the practical elimination of sulphur in electric-furnace operation. We have repeatedly reduced the sulphur to a trace in irons containing as high as 0.30 sulphur. The rapidity with which this reduction takes place depends somewhat upon the carbon content of the material, the sulphur reducing very much more rapidly in the higher carbon materials.

Third.—To illustrate the great tenacity of electric steel we submit (Fig. 1) exact reproductions (reduced) from two tests of two similarly treated specimens of steel, which are typical of a large number made on an Upton-Lewis toughness testing machine. One of these is electric and the other open-hearth, of almost identical analysis, as shown below. The marked superiority of the electric steel specimen, especially as to its tenacity, is shown in Table I.

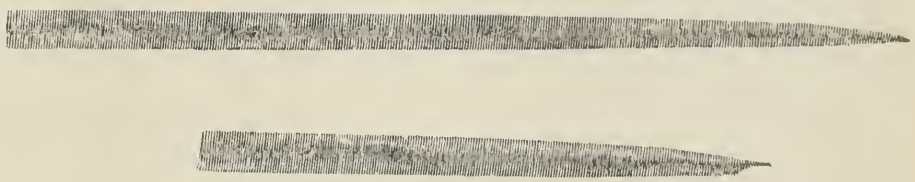

FIG. 1—TESTS WITH BASIC OPEN-HEARTH STEEL, ANNEALED, 213 CYCLES (UPPER PICTURE) AND ELECTRIC STEEL, ANNEALED, 345 CYCLES (LOWER PICTURE)

Table I.—Comparative Properties of Electric Steel and Basic Open-Hearth Steel.

Electric Steel.

C, 0.24; Mn, 0.52; Si, 0.25; P, 0.010; S, 0.019.

Elastic limit	36,400 lb.
Ultimate strength	65,300 lb.
Elongation	36 per cent
Reduction	55 per cent
Toughness test (fatigue) to break	345 cycles

Basic Open-Hearth Steel.

C, 0.23; Mn, 0.53; Si, 0.24; P, 0.011; S, 0.038.

Elastic limit	34,800 lb.
Ultimate strength	63,000 lb.
Elongation	29½ per cent
Reduction	35 per cent
Toughness test (fatigue) to break	213 cycles

*A paper to be presented at the San Francisco meeting of the American Institute of Mining Engineers.

Fourth.—During the past year we have developed an electric steel having remarkable physical qualities after heat treatment. This was accomplished without resorting to any of the high-priced alloys. The steel, when subjected to shock or static pull, will stand from four to five times as much stress without distortion as the ordinary open-hearth product. This assertion is not based on a few tests, but on over 3000 made up to the present time.

We have made a great many similar tests of heat-treated open-hearth material, and have invariably found that in certain specimens the physical properties are impaired by the treatment rather than benefited. This is not, however, the case with the electric-furnace product. The old saying: "In order to make good bread you must start with good dough," we believe applies to the steel industry as well.

CONCLUSIONS

The greatest advantage of the electric-furnace process over all others is its uniformity of product. The open-hearth under certain conditions will, we know, produce steel of very good quality, but there are so many contingencies, such as atmospheric conditions, stack-draft, fuel and furnace variations, beyond the control of the operator, that absolutely uniform results are impossible.

Electric-furnace products are looked upon by some with skepticism, due to those who have adopted the process thinking it a panacea for all of their ills, and who have furnished the trade with products not worthy the name. The lack of knowledge and the inexperience of the operator should in no way condemn the process. The production of perfect castings does not entirely depend upon the quality of material of which they are made, but upon the foundry practice to a very great extent. Frequently excellent material is ruined by bad foundry practice. Nevertheless we feel that the electric furnace, with its perfect control of composition and temperature, fills a long-felt want in the industry.

National Malleable Castings Co.,
Sharon, Pa.

Synopsis of Recent Chemical and Metallurgical Literature

Crushing and Grinding

Hardinge Mill Data.—In a paper to be presented by Mr. A. F. Taggart at the San Francisco meeting of the A. I. M. E. in September, the author presents numerous data on Hardinge mill operation at different plants, and gives a summary, as follows:

	6 ft. by 16 in. Ball Mill	8 ft. by 22 in. Pebble Mill
Average maximum size of feed, mm	44.5	9.7
Average size of feed, mm	9.0	1.26
Average maximum size of product, mm	6.0	1.5
Average size of product, mm	0.37	0.14
Average per cent of—200 mesh in product	28.9	37.0
Average per cent of—200 mesh in product, no slope	.....	44.3
Average per cent of—200 mesh in product, 0.5 to 4 in. slope	.....	31.6
Reduction ratio, range	7 to 67	6 to 15
Reduction ratio, average	39.6	8
Average size of product, no slope, mm	.....	0.10
Average size of product, slope 0.5 to 4 in.	.....	0.17
Average tonnage	203	110
Average tonnage at no slope	.....	85
Average tonnage at 0.5 to 4 in. slope	.....	128
Average horsepower	35.06	35.6
Average charge, balls or pebbles, tons	4	4.5
Average ball or pebble consumption, pounds per ton	0.51	1.94
Average relative mechanical efficiency	53.2	20.5
Average percentage of water in feed	60	58.7
Average revolutions per minute	28	27.8

Gold

Gold Refining with an Electric Furnace.—At the Alaska-Treadwell cyanide plant an electric furnace has been substituted for a blast furnace for treating the by-products from the Tavener refining process. The by-products consist of slag, matte, flue-dust and refinery refuse. The operation is described by Mr. W. P. Lass in a paper to be read at the meeting of the A. I. M. E. in San Francisco next September.

A sectional view of the furnace is shown in Fig. 1. The body of the furnace was constructed from an old steel drum by cutting off the top and introducing a cable, made from strands of bare copper wire, through the bottom and spreading the strands out fan-shaped on the inside of the drum.

Powdered graphite, obtained by grinding up old crucibles, mixed with 10 per cent cement, was tamped wet into the bottom of the drum, around and completely covering the copper wires. The graphite was carried up to the bottom of the furnace, or lead-well, and acted as the lower electrode. The sides were built up of ordinary firebrick forming a melting chamber 14 in. in diameter by 20 in. high.

The upper electrodes, of graphite or carbon, are 3 in. in diameter and 40 in. long, arranged with joints enabling new electrodes to be connected without shutting down or wasting stubs. A screw feed was arranged for raising and lowering the upper electrode.

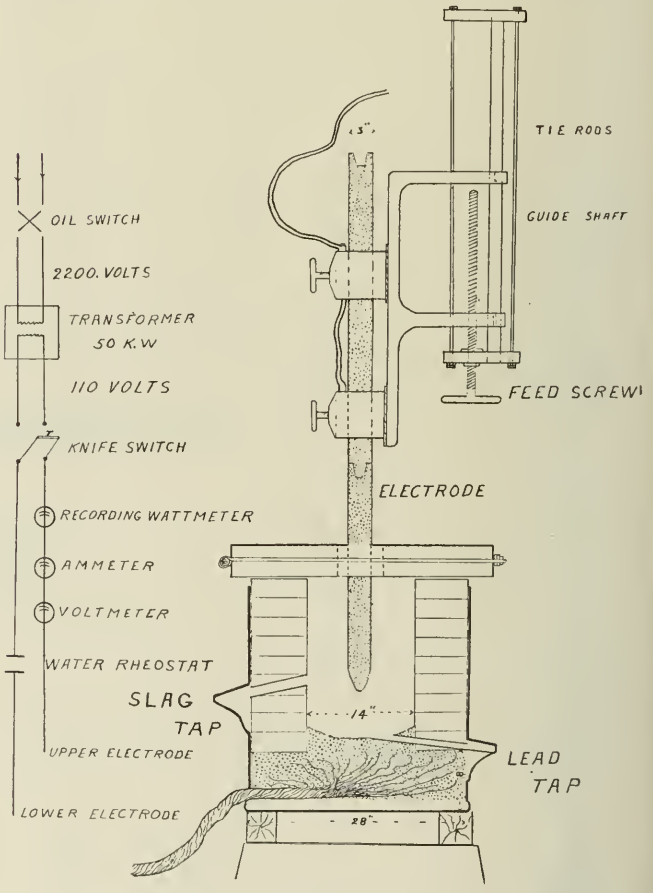

FIG. 1—SECTIONAL VIEW OF ELECTRIC FURNACE

The cover for the furnace had three openings, one for feeding the charge, one for the escape of gases, and one in the center for the introduction of the electrode. It was later found more practical to enlarge this center opening to 6 in. in diameter, to allow of a central feeding of the charge around the electrode.

A 4-in. pipe connected to a ventilating fan carries off the escaping gases.

The furnace is operated on the lighting circuit through a 50-kw. transformer, 60 cycles, 110 volts.

Later, a water rheostat, operated by raising and lowering one disk on another submerged in a barrel of water, was constructed to lower the voltage for use

when starting the furnace, or when there was a bath of metal in the bottom of the furnace that would otherwise allow too much current to pass and thereby cause short circuiting.

The material to be treated in the furnace is mixed in the following proportions: Refinery by-products, 100 lb.; old reverberatory hearths, containing 60 per cent CaO, 20 lb.; litharge, 20 lb.; coke, 2 lb.; scrap iron, 3 lb. About 160 lb. of the mixture is added for a charge. The total amount of material added during the melt is 8507 lb., of which 5870 lb. is by-product material (old slag, the residue from burning old mill launders, sweepings, etc.) of the following composition:

	Per Cent
SiO_2	40.1
Fe	16.0
CaO	16.1
Cu	5.9
Pb	3.0
Zn	5.7
Al_2O_3	2.0
S	3.6
Moisture	1.0
	96.4
Gold	$1,096.60 per ton

Coke is added to the charge as a reducing agent, only a quantity sufficient to throw down the lead being used.

The charge is introduced into the top of the furnace through the central opening around the electrode without removing the slab cover.

In starting, the furnace is operated as an arc furnace, until it has become thoroughly hot, when the charge, consisting of slag, brick dust, etc., is added, the electrodes being raised as the load in amperes increases, until the entire chamber is filled with the charge and the upper electrode extends into the melt almost a foot. As the charge continues to melt the electrode is moved down or up, keeping the amperage reading as nearly constant as possible. The raising or lowering of the upper electrode decreases or increases the power consumption and thereby affects the amount of heat generated.

At this stage the furnace is no longer operating as a simple arc furnace, but has automatically transformed itself into a resistance type of furnace, the semi-fluid or molten charge acting as the resistor, the current passing from one electrode through the center of the charge to the other.

After the charge is in quiet fusion, which takes on an average 2 hr. 10 min., the power is turned off and the charge allowed to settle for 15 min. before tapping the slag. This allows the lead to settle out, the furnace acting as a forehearth.

In operation, the molten lead and slag are tapped, as in the blast furnace. If the lead freezes it is melted by diverting current from the upper electrode and letting it pass through the lead, the tapping rod playing as an arc on the side of the furnace or into the lead tap.

The operators use colored or amber glasses to protect their eyes from the glare of the electric arc.

Operating Data	
Total running time	128 hr. 40 min.
Average weight of charge added	160.5
Average fusion time of charge	2 hr. 25 min.
Total number of charges	53
Graphite electrodes used	1 per 24 hr.
Total power for 128 hr. 40 min., kilowatt-hours	4,440
Power used per hour, kilowatts	34.50
Power used per pound of material fed, kilowatt-hours	0.52
Power used per ton of material fed, kilowatt-hours	1,044.0
Acheson graphite used per hour, feet	0.15
Material melted per hour, pounds	67.7
Material melted for 24-hr., pounds	1,625.0

The only item of cost for flux is the coke, 2 lb. per 100 lb. of by-product material or 118 lb. total being used, since the old reverberatory hearths furnish the lime; the cupels from bullion refining, the litharge, and mill scrap, the iron.

Both graphite and carbon electrodes are used, the former costing $2.95 each, and the latter $1.20. Power cost is less than 1c. per killowatt-hour.

The labor required for the operation of the furnace, including the work of charging and tapping, is one-half one man's time, when melting 1 ton in 24 hr.

The furnace was constructed and put into operation by the regular cyanide-plant crew, without the aid of special electricians. The operation is so simple as to require no special training. Although the operators were unaccustomed to handling electrical equipment, no trouble has been experienced from electrical shocks, since the bottom of the furnace acts as the lower electrode, or grounded circuit.

The advantages of the electric furnace compared to the blast furnace for melting high-grade gold slags are: A saving in mechanical loss of gold in flue dust, because the melting is done in a quiet neutral atmosphere, instead of in a rising blast of air; the obtaining of a lower-grade slag, free from shot, by reason of the quieter melting action and the higher temperature obtainable, making a more fluid slag; the nicety of regulation of the melting temperature; the benefit to the general health of the operators.

Chemical Engineering

Hydrogen Manufacture.—In an article on the manuture of hydrogen for the inflation of baloons, in *Revue générale des Sciences* of June 15, 1915, Mr. A. FOURNIOLS gives a history of the development of hydrogen-generating processes and describes some methods of producing this gas for inflating purposes.

The problem of transportation presented the greatest difficulties in connection with the utilization of the hydrogen gas set free in large quantities as a by-product in electrolytic, caustic and chlorine plants. In compressing and transporting this hydrogen a problem presented itself in the great weight which must be moved to get a small amount of hydrogen to a certain point. This gave rise to the development of other processes in which not the hydrogen but the apparatus and material for its production were placed on carriages. A few of these processes are the hydrolitic or calcium hydride process, the silicon and ferro-silicon process, and the coke and oil process used in Germany. The calcium hydride process depends upon the reaction $CaH_2 + 2H_2O = Ca(OH)_2 + 2H_2$. The apparatus consists of a generator, water reservoir, purifier, and various other minor attachments, mounted on a carriage. A comparison of the price of transporting gas in this way with the compressed hydrogen method follows (1 franc = about 20 cents):

Cylinders with Compressed Hydrogen	Francs	Hydrolytic	Francs
8000 tubes at 80 fr.	640,000	48 tons at 5 fr. per kg.	240,000
50,000 cubic meters of hydrogen at 0.40 fr.	20,000	Apparatus for generating	40,000
Carriers for tubes	60,000	Carriers for reagents	4,000
12 carriages of 3 tons	240,000	2 carriages of 3 tons	40,000
	960,000		324,000

This table is only intended to compare transportation cost, as the hydrolytic process is expensive as a stationary means of production.

The silicon process consists in decomposing a compound of silicon by a concentrated soda solution. The apparatus required is a generator containing the soda, a spraying apparatus containing ferrosilicon, a washer and dryer for the gas. The standard stationary apparatus furnishes 1500 cubic meters per hour, while the movable apparatus, using two wagons, furnishes only 400 cubic meters per hour. The latest German process used for both lighting and inflating purposes, using coke and oil, is also capable of being transported ready for generating purposes. For a description of this process and other information on hydrogen production see this journal, Vol. IX, page 157.

Glass Melting.—Methods of manufacturing glass, descriptions of furnaces and the properties of glass in the molten condition are discussed in an article by Hugo Knoblauch, in *Zeitschrift für angewandte Chemie*, June 22, 1915. The characteristics of molten glass mixtures are illustrated by drawings of cross-sections of crucibles containing characteristic charges. The fact that the temperature at which our very best fireproof clay weakens lies near the temperature needed to produce a good melt is shown to make the pyrometer very useful in glass making.

Investigation of Fusible Tin Boiler Plugs.—The failure and deterioriation of fusible tin boiler plugs in service has been investigated by G. K. Burgess and P. D. Merica of the Bureau of Standards. The complete investigation will be published in a Bulletin shortly to be issued by the Bureau of Standards. In some cases such plugs have failed to melt and so give warning of dangerous boiler conditions, and investigation has shown that the tin filling in these cases had become oxidized to tin oxide (SnO_2), which has a melting point above 1600 deg. C. (2900 deg. Fahr.). About 1050 plugs, of which 100 were plugs which had been in service, were obtained through the courtesy of the Steamboat-Inspection Service, Department of Commerce, and subjected to examination. This included inspection of design and construction, condition and purity of the tin filling, and in the case of the used plugs their classification according to the type of deterioration undergone by them in service.

One pronounced and dangerous type of deterioration is the oxidation of the tin along the grain boundaries by which is formed a network of oxide throughout the tin. The plugs showing deterioration of this type all came from the same manufacturer and contained zinc in amounts varying from 0.3 to 4 per cent. It is shown that this type of oxidation is due to the presence of this zinc. The latter metal is not soluble in the solid state in tin, and when a tin with small amounts of zinc is heated as in a boiler to about 180 deg. C (340 deg. Fahr.) this zinc coalesces as a network enveloping the tin crystals or grains. The boiler water, particularly if it contains alkali, will attack the zinc, eating its way into the alloy along the zinc network, and finally form the oxide network described.

Lead and zinc are found to be the principal impurities in tin plug fillings, and since all "failed" plugs contained these or other impurities the conclusion is reached that if these impurities are eliminated by strict specifications and inspection, which will allow only admittedly superior qualities of tin such as Banca and some others, the danger of failures of these plugs will no longer exist. In order to test quickly the purity of a tin sample a determination of its freezing point may be made. This can be done conveniently with two or three grams of the sample, and requires only inexpensive apparatus, including a high resistance millivoltmeter and a copper-constantan thermo-couple.

Electroanalysis and Electrodeposition

Procedure in Electroanalysis.—Two papers by E. P. Schoch presented at the New Orleans meeting of the American Chemical Society are interesting. They are abstracted in *Science* of July 16. The first of these, a paper by E. P. Schoch and Denton J. Brown, deals with a "systematic, rapid, electroanalytical procedure for the separation and determination of silver, arsenic, copper, bismuth, antimony, tin, lead, and cadmium.

In earlier work the authors have shown that copper, tin, lead, bismuth, and antimony can be determined accurately by electrodeposition out of acidified chloride electrolytes which contain suitable reducing agents such as hydroxylamine or formalin. They have found since that copper, bismuth, and antimony can be deposited simultaneously, and can be separated from tin and lead; that tin and lead can be deposited simultaneously and separated from cadmium; that copper or bismuth can be separated from antimony by dissolving alloys of these metals in nitric acid plus tartaric acid and electrolyzing the solutions with a limited cathode potential; that bismuth phosphate can be precipitated quantitatively out of the same solution; that tin may be separated completely from lead by dissolving an alloy of these two metals in nitric acid plus potassium nitrate, and that silver in silver chloride may be determined by dissolving the latter in ammonia, adding ammonium nitrate and electrolyzing.

These facts are all combined in the following systematic procedure for the rapid electroanalytical determination of all the common metals the potentials of which are more noble than that of cadmium.

(A) Dissolve sample in hydrochloric acid or in aqua regia; an insoluble residue—silver chloride—is dissolved in ammonia plus ammonium nitrate, and the silver determined electrolytically.

(B) Treat solution A with hydroxylamine—mercury, gold and platinum will be precipitated and can be determined by well-known methods.

(C) Out of filtrate B remove arsenic by distillation with hydrochloric acid, and determine arsenic iodometrically.

(D) Electrolyze retort residue C—copper, antimony and bismuth will be deposited with a cathode potential limited to 0.45 volts (against the normal calomel electrode).

(E) Dissolve metal deposit B in nitric acid plus tartaric acid, and precipitate bismuth as bismuth phosphate.

(F) Electrolyze filtrate E with a limited cathode potential—copper alone will be deposited. Antimony is obtained by difference.

(G) Electrolyze residue D with a cathode potential limited to 0.7 volt against the normal calomel electrode —tin and lead will be deposited. Treat the deposit with nitric acid plus potassium nitrate; the solution contains all the lead, and this metal may be deposited as lead peroxide, or the residue of tin oxide may be dissolved in hydrochloric acid plus hydroxylamine and the tin determined by electrolysis.

(H) Electrolyze residue G to obtain cadmium or other metals.

The second paper, by E. P. Schoch and W. A. Felsing, deals with the influence of the potassium ion upon the **potential of the ferrocyanide-ferricyanide electrode.**

The potential of the ferrocyanide-ferricyanide electrode is made more noble by the addition of potassium salts to the electrolyte, but the amount of this change in potential is much greater than the amount calculated from the change in the ratio of ferrocyanide to ferricyanide ions when the concentrations of the latter are calculated from the conductivity ratio and with the aid of the rule of mixtures as set forth by Sherrill. It was suggested by Lewis that this extra effect may be due to the potassium ion taking part in the pole reaction. Thus, with the undissociated salts, the reaction would be $K_3Fe(CN)_6$ plus K-ion plus one electron gives $K_4Fe(CN)_6$, and it has been shown recently by Mueller that with concentrations of potassium ion ranging from 0.2 normal to 0.8 normal the amount of change in potential corresponds to the amount of change in the potassium ion if the concentration relations of the other substances remain constant. Since the latter is not likely to be true, and since the potassium ion shows the

same influence even in the most dilute solutions tried, the authors sought to ascertain whether or not concentration influence of the potassium ion is constant with a particular power of its concentration. This was found to be the case with the 0.75 power of the potassium ion concentration, and if the ferrocyanide and the ferricyanide ion concentrations are calculated from the conductivity ratio and the rule of mixtures. The various mixtures tried present a range of total potassium ion concentration from 7.8 millimol to 395 millimol per liter. In some mixtures the potassium ion was derived wholly from the iron cyanides, in others almost wholly from potassium chloride, and in others still partly from both sources. The different potentials thus reduced to unit concentrations present a maximum range of 8 millivolts with this large variation of concentrations, and hence the result may be considered to be constant. Furthermore, it is likely that on reptition, measurements will be obtained which will show considerably less variation.

Since the calculation of the above potentials involve the general dilution law of strong electrolytes and the rule of mixtures, it was desirable to test these calculations in some way, hence the conductivities of these mixtures were measured and compared with their calculated values. When allowance is made for the influence of the viscosities of the solutions, then the observed and the calculated conductivities agree to 1 per cent and less.

The work is now being repeated with calcium salts in place of potassium salts. Although the immediate result of this work is the establishing of an empiric relation between concentrations and pole potentials, yet it is likely that the results will throw some light on the manner of ionization of salts with polyvalent ions—particularly because other electrodes, such as the thallous-thallic, the ferrous-ferric and the mercurous-mercuric, show similar relations.

Recent Chemical and Metallurgical Patents

Gold

Vacuum Filter.—A modification of the revolving vacuum filter is shown in Fig. 1, being the patented invention of Mr. HENRY B. FABER of New York City. It consists of a skeleton wheel structure in which are mounted filter pockets 10 which are connected, through a suitable valve in the hub, with a source of vacuum. In operation the wheel is revolved slowly and each pocket

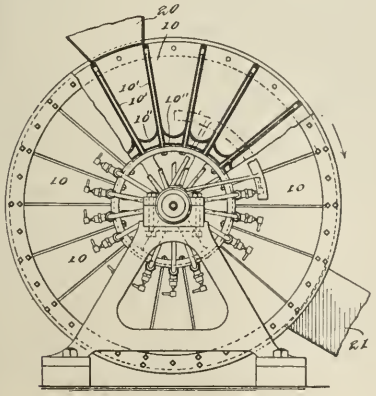

FIG. 1—FILTER

receives a charge from the hopper 20. Being under vacuum, the fluid is withdrawn from the pocket and the solid material forms a cake on the filter surface. As the filter continues to revolve, the cake is discharged by gravity at a predetermined point, as in the hopper 21. As no provision is made for washing the cake, the machine is adapted for use only as a dewaterer and not in cases where complete displacement of the liquor from the solid is required. (1,133,944, March 30, 1915.)

Copper and Zinc

Hydrometallurgy of Copper Ores.—In a patent granted to Mr. N. V. HYBINETTE of Christiansand, Norway, the inventor discloses his process for roasting copper ores and extracting the copper therefrom. An improvement in the ordinary roasting process is claimed in the addition of a quantity of sodium sulphate to the ore. The effect is to form double sulphate of sodium and copper which is decomposed only at temperatures higher than those prevailing in the roasting furnace. The addition of from 2 per cent to 5 per cent sodium sulphate forms a fusible double sulphate which has the property of dissolving sulphides and which forms a spongy mass easily leached with dilute sulphuric acid. The solution resulting from subsequent electrolysis contains sulphuric acid and ferric sulphate and is used for further leaching. Ultimately this solution will contain so much sodium sulphate that it can no longer be used for leaching. When this point has been reached and the solution contains about 450 gr. sodium sulphate per litre, the solution itself is added to the ore in order to supply the sodium sulphate for roasting. The iron salt in solution is decomposed in the roasting furnace, exerting a solvent effect on copper sulphide remaining in the ore as a result of incomplete roasting. (1,140,682, May 25, 1915.)

Electrolysis of Copper Solutions.—In the electrolytic reduction of copper solutions, the presence of certain compounds of metals other than copper exercises a solvent effect on the deposited metal, which is often detrimental. Thus ferric compounds in an electrolyte would act to dissolve deposited copper. Mr. LAWRENCE ADDICKS of Douglas, Ariz., has discovered that the presence in solution of a quantity of aluminum sulphate retards the corrosion rate at the cathode to a small proportion of the quantity of copper deposited per unit of time at the current density used. As a practical illustration of conditions suitable for good work, the inventor gives the following: A solution containing copper, iron and aluminum sulphates, containing 3 per cent copper, 3 per cent ferrous iron and 3 per cent alumina, some free sulphuric acid to prevent the formation of basic salts. This is electrolyzed with a current density of 13.5 amp. per square feet, at a temperature of 115 deg. Fahr., and with a circulation sufficient to keep the average concentration of ferric iron at about 0.25 per cent. Under such conditions a cathode deposit equivalent to from 70 per cent to 90 per cent of the theoretical can be obtained. (1,138,921, May 11, 1915.)

Metallurgical Furnaces

Reducing Aluminium Sulphate to Alumina.—A furnace adapted to the preparation of alumina suitable for electrolytic reduction to aluminium is shown in Fig. 2,

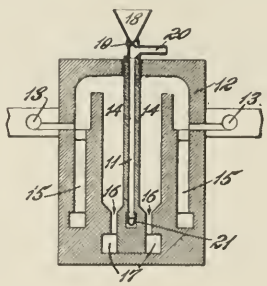

FIG. 2—FURNACE FOR PRODUCING ALUMINA

being the patented invention of Mr. GUSTAVE SCHWAN of St. Louis, Mo. It consists of a retort 11 arranged in a furnace 12. The retort is constructed of refractory material capable of withstanding temperatures up to

1200 deg. C., and is separate from the furnace. Inside measurements of the retort are 8 in. wide and 8 ft. or more in height. The furnace is heated by gas which enters by pipes 13 which convey the gas to the upper portion of the combustion chamber 14. Preheated air is conveyed to the same point by pipes 15. The Products of combustion flow through passages 16 to a flue 17. The material to be treated may be fed into the retort from a hopper 18 by means of a feeding device 19. The gaseous products from the retort pass out through pipe 20, and the solid product is removed by a screw arranged at 21. (1,132,738, March 23, 1915.)

Roasting Furnace.—A method of heating the charge in a roasting furnace of the superposed-hearth type, without subjecting the rabbles to excessive heat, is patented by Mr. Utley Wedge of Ardmore, Pa. Gas, oil or electric current may be used as the heating medium. The rabble arms and means for heating, either oil or gas burners or electric heaters, are all attached to the same central rotating shaft, but are disposed at right angles with each other, so that the rabbles are at some distance on the hearth from the heaters. (1,133,829, March 30, 1915.)

Iron

Process for Dephosphorizing Pig Iron.—According to a method of removing the phosphorous from pig iron, patented by Amand Francois Pasquier of Dijon, France, iron oxide and lime in a finely pulverized condition are blown through the tuyeres by the air blast. The iron oxide is claimed to rapidly transform the phosphorus into phosphoric acid, which combines with the lime and passes into the slag as calcium phosphate. The phosphorus is thus eliminated without the usual overblasting or recarburation. Instead of lime, magnesia, dolomite, or similar bases could be used and the oxide of iron might be added in the form of hammer scale or force scale (1,145,506, July 6, 1915).

Aluminium

Treatment of Surfaces of Aluminium for Plating.—A process for preparing aluminium surfaces for plating is patented by Francois Auguste Roux of Paris, France, and assigned to Société L'Aluminium Français. In this process the aluminium surface is first cleansed by any common method, then it is rinsed and immersed in a dilute acid or alkaline hydrate solution to which 1 per cent of tin chloride is added. This gives a coating of tin on the surface. The surface is then rinsed and immersed into hot saturated solution of ammonia alum. This is claimed to cause any inclosed hydrogen to escape and to prevent the oxidation of aluminium which has been the greatest hindrance to aluminium plating. It also gives tenacity to the tin deposit. The surface is then rinsed and dipped into dilute sulphuric or nitric acid and finally placed in the plating bath (1,140,000, June 22, 1915).

Process of Plating Aluminium.—Another process of plating aluminium is patented by Joseph A. Hall of New Britain, Conn. In this process the aluminium is first cleansed in the usual manner, then given a bright dip in a solution made up of 2 parts nitric acid and 1 part oil of vitriol. This is to remove iron, which is claimed to be found usually on the surface of commercial aluminium and which is believed to hinder successful plating. The surface is then electroplated with zinc for a few seconds and is then ready to receive the plate of brass, copper or silver. In the case of nickel plating a preliminary coating of copper is first given for twenty to thirty minutes and then the nickel is applied. The process is claimed to be particularly applicable to plating the material used for making die castings, which is high in aluminium (1,147,718, July 27, 1915).

Oil

Dehydrating Petroleum Oil.—Apparatus for the separation of water and petroleum oil when mixed in the form of emulsion is described in three patents issued to Robert E. Laird and Joseph H. Raney of Taft, Cal. A general outline of the process is as follows: In the treater, Fig. 3, the emulsion enters at 23 into chamber 16, which surrounds the outer electrodes 21. It is heated here by steam coils to any desired temperature, and then passes through openings 22 into chamber 17, and upwardly between the outer electrodes 21 and inner electrodes 19. When an alternating current is impressed on the electrodes, it tends to change the trapped water into free water and to coalesce the free water. The emulsion flowing upward is fairly free from water at the top and no extra insulation is required at the surface. The freed oil passes upward into pan 12 and down through pipe 231 into another final separator. The electrical apparatus, which is a distinct feature of the invention, consists of a condenser placed across the electrode terminals, and a "distributer" which is so adjusted that only the peaks of the alternating wave are utilized, which during the other parts of each period the current charges the condenser which subsequently discharges through the oil along with the high-voltage current represented by the peaks. This gives maximum power economy. Means are also provided to allow escape of gases and to prevent combustion. The process is described fully in *San Joaquin Light and Power Magazine* for May, 1915, where it is said to be in successful use on the property of the Traders' Oil Company in the Midway Field (1,142,759, 1,142,760 and 1,142,861, June 8, 1915).

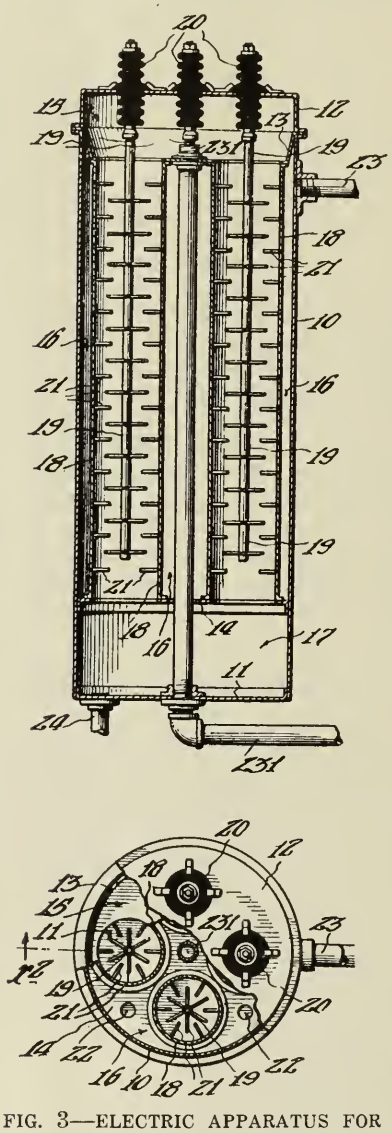

FIG. 3—ELECTRIC APPARATUS FOR DEHYDRATING OIL

An aluminium alloy, patented by Alfred Wilm, of Schlachtensee, near Berlin, Germany, contains about 95.5 per cent aluminium, 0.5 per cent magnesium, 3 per cent copper and 1 per cent manganese.

The inventor claims to have discovered an alloy that retains the advantage of aluminium as to light weight, in addition to other advantages which are not possessed by that metal.

Thus it is claimed that this alloy can be bored, drilled, planed, filed and ground successfully.

Callow Pneumatic Process of Flotation

The diagram, Fig. 1, indicates the various elements which compose the scheme.

A is an agitator operating by compressed air for the purpose of mixing or emulsifying the oil, the air and the water. The same type of apparatus as is in common use in cyanide works. In cases where the oil or frothing agent can be fed into a crushing machine or tube mill, this agitator or Pachuca tank can be dispensed with and the ore fed direct from tube mill into the separatory cell.

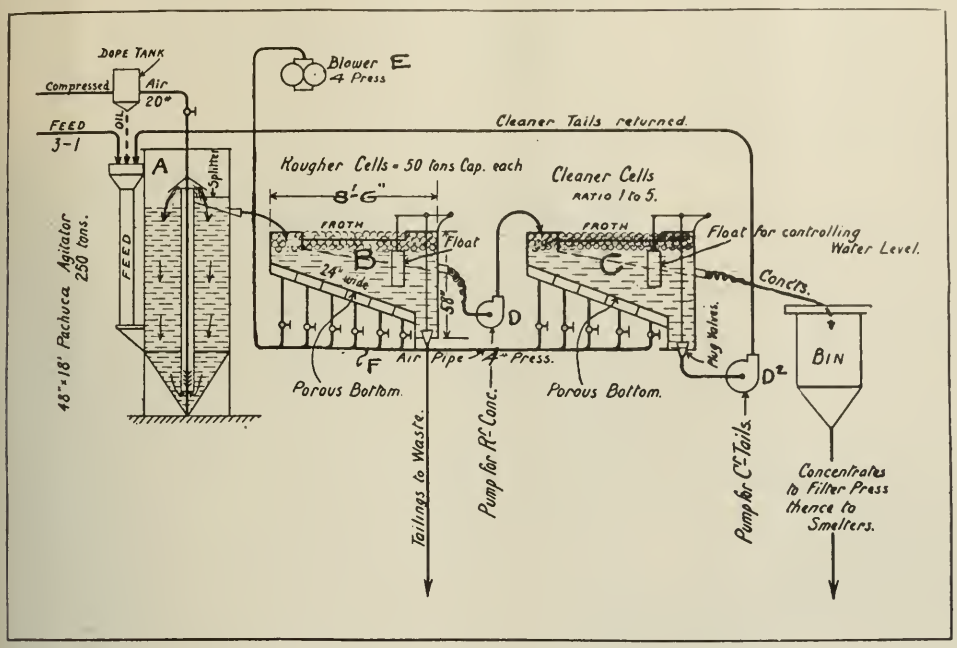

FIG. 1—CALLOW PNEUMATIC FLOTATION PROCESS

Separatory Cell

B is the initial or roughing separatory cell; it consists of a tank about 9 ft. long over all and 24 in. wide, with bottom inclined at from 2 to 3 in. of fall per foot; it is 15 in. deep at the shallow end and 37 in. deep at the deepest end. It may be built of either steel or wood, preferably wood.

The bottom of the tank consists of a porous medium made of four thicknesses of loosely woven canvas-twill properly supported by a backing of perforated metal to prevent its bulging when under air pressure. Through this porous medium, compressed air at from 4 to 6 lb. pressure is forced by the blower *E*. Porous brick or any other ceramic material may be used that will give the necessary fine subdivision to the air. Some of these have been tried out, but for practical and mechanical reasons the loosely woven canvas-twill seems to better serve all purposes than anything else and has been adopted as a standard porous bottom construction.

The space underneath this porous medium or bottom is subdivided into eight compartments, each connected by an individual pipe and valve with the main air pipe *F*. By this means the air pressure to each compartment can be regulated (by throttling the valve) to correspond to the varying hydraulic head within the tank so as to discharge a uniform amount of air throughout the length of the bottom and maintain a uniform agitation of the contents. The amount of air required is from 6 to 8 cu. ft. free air per minute at from 4 to 6 lb. pressure per square foot of porous medium. A 500-ton plant will require about 30 hp. to operate compressor, blower and pumps.

Each longitudinal edge of the tank is provided with a lip and an overflow gutter for the reception of the froth to be discharged. The lower end of the tank is furnished with a spigot discharge fitted with a plug valve, operated by a float, for the purpose of maintaining a uniform water level within the tank and thus in turn maintaining a uniform and constant discharge of froth under all the varying conditions of feed supply incident to practical milling operations. The water level may, of course, be varied, but is usually maintained at about 10 to 12 in. below the level of the overflow lips. The tailings are discharged through the spigot and the frothy concentrates are conveyed by means of the side gutters to the pump *D* and thence to the cleaner separatory cell marked *C*. This cleaner cell is a machine of exactly the same construction as the rougher. In operation, however, it is usually run with a lower air pressure than that used on the rougher; the tailings from the cleaner are pumped by *D*2 back into the original feed and so maintain a closed circuit on this portion of the feed.

The concentrates from the cleaner are the shipping or finished concentrates. Pump *D* can be eliminated if desirable by setting the cleaner at a lower elevation and conveying the rougher froth to it by gravity.

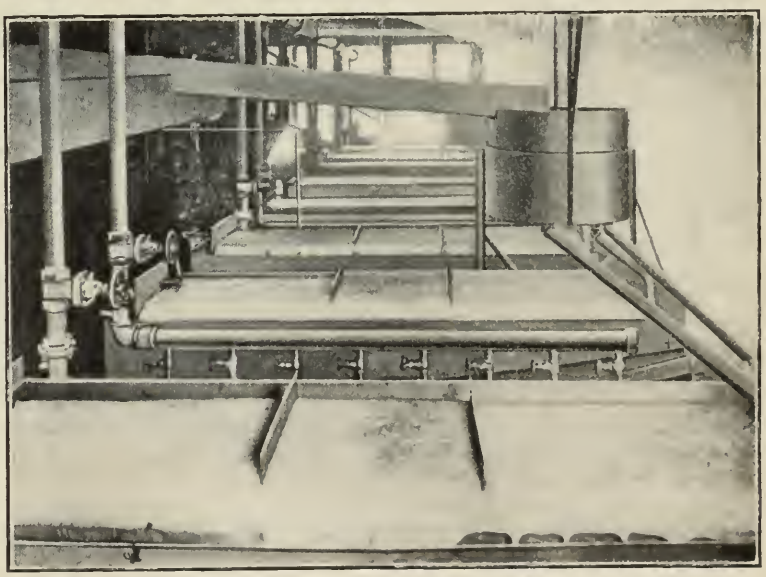

FIG. 2—500-TON INSTALLATION CALLOW PNEUMATIC FLOTATION MACHINES, NATIONAL COPPER MINING CO., MULLAN, IDAHO

Usually one cleaner will be sufficient to take care of four roughers. The froth formation and pulp density will now be considered.

Froth Formation

The froth is generated as the result of injecting the finely divided air into the bottom of the already emulsified pulp, and it continues to form and to overflow so long as it is furnished with pulp of the proper consistency, properly mixed, and with the right quantity and kind of oil or frothing agent. Measured from the water level within the tank, the froth produced may be from 14 to 16 in. in depth or thickness, and according to the kind of ore, kind and quantity of oil introduced will be more or less voluminous, coarse or fine grained, dry or watery, all of these conditions being adjusted by the regulation of the kind or quantity of oil and the quantity of air injected.

On some ores, rich in sulphides, and where a comparatively low grade concentrate will suffice, the cleaner

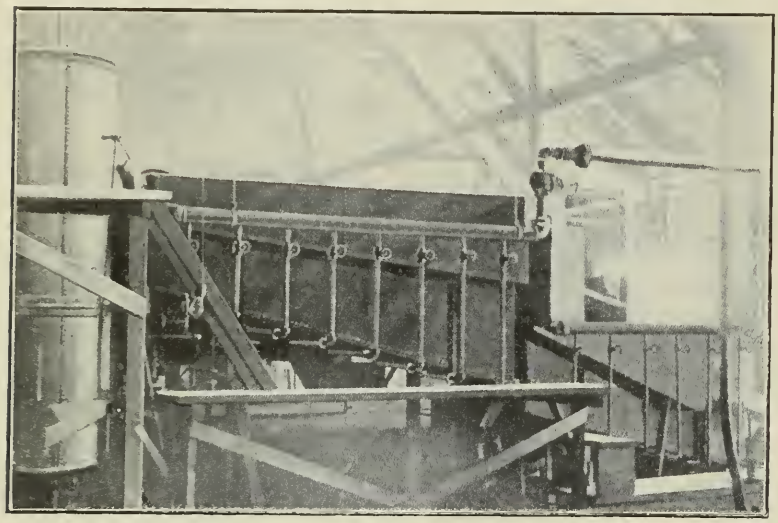

FIG. 3—30-TON EXPERIMENTAL UNIT, CALLOW PNEUMATIC FLOTATION MACHINES, DALY-JUDGE MILL, PARK CITY, UTAH

may not be necessary, but on low grade ores having a high ratio of concentration and where a concentrate of extreme cleanness and of maximum grade is required, a cleaner is desirable.

Pulp Density

The pulp to be treated may be of varying density from $2\frac{1}{2}$ water to 1 ore, up to 6 or 7 to 1. For a mixture of sand and slime the former ratio is preferable, but for a pure slime mixture (minus 200 mesh) a larger proportion of water is allowable. The particular density is not a matter of so much importance as that the supply of pulp shall be uniform as to its density, since each variation in the density of the pulp requires a readjustment of the oil supply, the quantity of oil increasing in proportion to the increased volume of the pulp independent of the solid contents.

Oils

The oils used may be broadly divided into "frothers" and "collectors." The pine oils are good frothers and coal tar and its various subdivisions are good collectors. On some ores, crude pine-tar will in itself combine both the property of frothing and collecting. On others this may have to be enriched by the addition of some one of its more volatile constituents such as refined pine oil, turpentine or wood creosote.

Generally speaking the coal-tar products are poor frothers, and to get a sufficient volume of froth to insure a high recovery it is often necessary to add refined pine oil, creosote, etc. At Inspiration, for instance, the mixture is 85 per cent crude coal-tar, 15 per cent light oil or creosote, 5 per cent pine oil. At Daly-Judge, 40 per cent crude coal-tar, 40 per cent creosote, 20 per cent pine oil. In the Coeur d'Alenes, on zinc ore, straight wood creosote; on the National copper ore plain turpentine will work, but pine oil is better. At Inspiration it required from $1\frac{1}{2}$ to 2 lb. of the mixture per ton of ore; at Daly-Judge 1 to $1\frac{1}{2}$ lb. and at the National 3/10 of a pound of oil is sufficient. The proper kind or kinds of oil and the quantity requisite can only be determined at present by tentative experiment; so far there is no scientific way known.

Character of Froth

The nature of the froth made by the pneumatic process has the distinctive characteristic of being unstable or ephemeral; that is, it quickly dies when removed from the action of the injected air. The bubbles composing the froth being generated under a hydraulic pressure varying from 15 to 37 in., on rising above the water and to the froth level, burst by reason of the lower surrounding atmospheric pressure. On bursting they release the mineral coating them, but this in turn is caught up by those bubbles immediately following behind. The instability or stability of the bubbles will depend upon the oil used and the nature of the ore gangue. Pine oil makes a very brittle froth which dies immediately on arriving at the surface. Creosote and light oil make a very elastic envelope which at times will expand into bubbles 3 or 4 in. in diameter before bursting. The pine oil bubbles will rarely be over $\frac{1}{4}$ or $\frac{1}{2}$ in. in diameter. Castor oil, olive oil, candle makers' oil (oleic acid), palm oil, sperm oil and other oils of a lubricating nature have in general been replaced by oils more or less soluble or miscible in water, such as turpentine, pine oil, eucalyptus oil and all the other coal and wood-tar distillations. The very volatile oils such as naphtha, gasoline, ether and alcohol seem to serve very little purpose except as means for making the pitchy ingredients of coal and wood-tars more soluble or miscible.

With the present knowledge of the subject it is impossible to state by a visual examination or an analysis of the ore, whether or no it can be successfully treated by flotation. Only properly conducted tests can determine this. The General Engineering Company of 159 Pierpoint Street, Salt Lake City, Utah, has equipped its testing plant for conducting the necessary preliminary tests for which an average 100 to 150-lb. sample will generally suffice. Should the preliminary tests show encouraging results, it is advisable to follow them up by the installation of a 20 or 30-ton experimental unit in the plant, or where there is no plant in existence a 5-ton sample can be sent to the General Engineering Company for further and final investigation.

Materials of engineering construction will receive special attention in the proceedings and discussion of the International Engineering Congress to be held in San Francisco next September. The field will be treated under 18 or more topics, covering: Timber resources; preservative methods; brick and clay products in general; life of concrete structures; aggregates for concrete; water proofing; volume changes in concrete; world's supply of iron; life of iron and steel structures; special steels; status of copper and world's supply; alloys; aluminum; testing of metals, of full sized members, and of structures.

Magnetic Separation of Zinc-Iron Sulphide Ores

Some tests recently conducted by the Campbell Magnetic Separating Company of Boston, Mass., in its plant at Cuba City, Wis., on the separation of the sulphides of iron and zinc are described in a pamphlet issued by the above company. The process consists in roasting the ore in a special kiln for from three to five minutes, then feeding it over a table in a thin layer on which it is agitated and exposed to the magnet. The

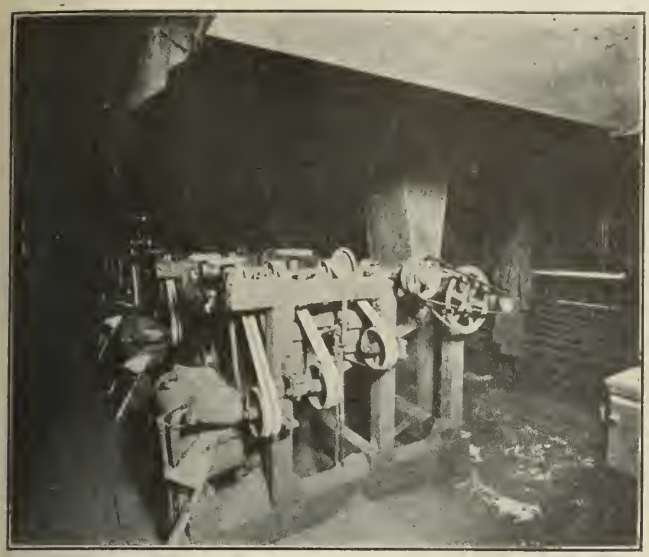

FIG. 1—VIEW OF EIGHT CAMPBELL MAGNETIC SEPARATORS INSTALLED IN THE COMPANY'S PLANT IN CUBA CITY, WIS.

iron is removed and the zinc flows on over the end of the table.

The following figures give the results of a seven-day test made upon the plant at Cuba City by Mr. Charles L. Constant of New York City.

Assay of raw ore:

Moisture	3.75 per cent
Zinc	16.50 per cent
Iron	33.00 per cent
Sulphur	42.49 per cent
Lime	1.95 per cent

Assay after roasting:

Zinc	19.20 per cent
Iron	37.80 per cent
Sulphur	35.30 per cent
Lime	1.12 per cent

Zinc concentrate after separating:

Zinc	60.75 per cent
Iron	2.05 per cent
Sulphur	29.95 per cent
Lime	2.00 per cent

Iron concentrate after separating:

Zinc	1.25 per cent
Iron	53.30 per cent
Sulphur	37.35 per cent
Lime	1.05 per cent

Further information is taken from the records of the Linden Zinc Co., Linden, Wis., who are using the Campbell system. Its average recovery of metallic zinc for 1914 was 95.4 per cent, the zinc in the iron varying between 0.60 per cent to 4 per cent and the average percentage of sulphur in the iron being about 35 per cent. Low operating costs and the small amount of labor required are other advantages claimed for this process and also its adaptability to the lowest-grade zinc ores, and table middlings and treatment of chalcopyrite.

At St. Louis University the gold medal for the best essay on the "nitrogen problem" has been awarded to Mr. Sylvester Flottemesh.

Titanium

"Geology of the Titanium and Apatite Deposits of Virginia," by THOMAS LEONARD WATSON and STEPHEN TABER, is the title of Bulletin 3A of the Virginia Geological Survey. This beautifully illustrated description of exhaustive field work and laboratory investigation on the Virginia deposits is without doubt the most complete work yet published on titanium ores. It also includes a large amount of general information on titanium which should make the volume one of great value to those interested in this subject. The commercial value of some of the Virginia deposits makes the discussion not only of scientific but also of economic importance.

The first chapter of the bulletin discusses the history, chemistry and ores of titanium with their distribution and occurrence, including a complete table of titanium minerals. The second chapter describes the occurrence and geographic distribution of rutile with descriptions of the areas in which it is found. This includes foreign countries, the principal ones being Canada, Norway and South Australia. Photomicrographs of specimens from Australia and Norway show the nature of these rutile-bearing rocks.

Chapter III begins the main portion of the volume, giving the results of the field and laboratory work in Virginia on the ore deposits of the Amherst-Nelson counties region. Topographical maps, photographs and photomicrographs interspersed throughout the text explain the rock formations, and analyses are given to show the chemical composition. "The region is shown to be a comagmatic area of unusual scientific interest, many of the rock-types of which are new and described in detail for the first time." This is the most important district commercially and its description takes up about two-thirds of the volume. Included in this chapter are also individual descriptions of mining properties in this district, the principal mine being that of the American Rutile Company. This is followed by a description of the general petrology of this region.

The fourth chapter discusses the ilmenite-apatite deposits in Roanoke County. These are also commercially important, as are those which were recently discovered in Goochland and Hanover counties and described in Chapter V. Chapters VI and VII describe the occurrence of rutile in Charlotte and Buckingham counties, in which the deposits are of scientific interest only. In the last two chapters economic considerations are discussed, mining methods are suggested and possible by-products mentioned. It is stated that the future of rutile mining in Virginia looks very encouraging as there is practically an unlimited supply of very pure rutile in the Amherst-Nelson counties area, and with the prospecting in the other districts and the development of new uses for titanium an increasing demand is expected which ought to stimulate production.

The utilization of heat from slag, under the Vautin and Johnson patents, is described in a booklet issued by Slag Power, Ltd., Salisbury House, London, England. The method of operation is illustrated and described, and the results of experiments are given showing the available heat that may be obtained from copper and iron slags. Tests indicate that 1000 kilos of copper slag contain from 318 to 350 calories of available heat, and upwards of 500 kilos of water have been evaporated per 1000 kilos of slag. In the case of iron slag the available heat per 1000 kilos is 550 calories, and upwards of 740 kilos of water have been evaporated per 1000 kilos of slag.

National Exposition of Chemical Industries

The opening of America's first National Exposition of Chemical Industries on Monday, Sept. 20, is looked forward to with great interest, as it is an event which cannot fail to be far reaching in its results. It will bring into closer contact than ever before the manufacturers, financiers, dealers and consumers. Elaborate exhibits are arranged, many of them working units, giving visitors the opportunity of seeing the processes in actual work. The character of the exhibitors assures the success of the undertaking.

An invitation has been extended by the advisory committee to President Wilson to be present and participate in the opening of the exposition.

Among the institutions which have co-operated to make this exposition a success are the American Chemical Society, American Electrochemical Society, American Institute of Mining Engineers, American Institute of Electrical Engineers, American Pulp and Paper Associations' Technical Section, and the Bureau of Commercial Economics. Following is an incomplete program which will have numerous other papers and addresses added:

Monday, Sept. 20

Opening day.

Tuesday, Sept. 21

D. P. Pierce (Barber Asphalt Company), "Work with the Ultra Microscope."

Howard H. Gross (president Tariff Commission League) will lead a discussion on the tariff question in which other members of the league will participate.

R. S. Frinck (president Frinck Pyrometer Company), "The Relation of Chemistry and Mechanical Manipulation to the Evolution of the Glass Industry."

Harrington Emerson (the Emerson Company), "Efficiency."

Meeting of the New York Section of the American Electrochemical Society

Wednesday, Sept. 22

Thomas H. Norton (U. S. Department of Commerce), "Foreign Markets for American Chemicals."

F. W. Keough (president National Association of Manufacturers), "Accident Prevention in the Chemical Industries."

Welding Ring (president American Exporters' Association), "Transportation and Shipping Facilities with Foreign Countries."

I. F. Stone (president National Aniline & Chemical Company), "The Aniline Dye Situation."

J. L. Lightner (Hershey Chocolate Company), "The Manufacture of Chocolate."

Thursday, Sept. 23

J. L. Taylor (U. S. Bureau of Mines), "Explosives."

H. A. Huston (German Kali. Co.), "Potash."

Linn Bradley (the Research Corporation), "Solution of Smoke, Dust and Fume Nuisances by Electrical Precipitation."

Percy Wilson (secretary Association of American Portland Cement Manufacturers), "The History of Cement."

Meeting of the American Paper and Pulp Association (Technical Section)

Friday, Sept. 24

S. P. Sadtler (S. P. Sadtler & Sons), "American Contributions to Industrial Chemistry."

W. D. Coolidge (General Electric Company), "The X-Ray."

Joint Meeting of the New York Section American Chemical Society and the American Institute of Chemical Engineers

Saturday, Sept. 25

John Barrett (director Pan-American Union), "South American Opportunities."

Geo. Frank Lord (DuPont DeNemours Powder Company), "Farming with Dynamite."

G. B. Heckel (New Jersey Zinc Company), "Zinc."

A motion-picture program has been arranged for by the Bureau of Commercial Economics at Washington. This will include various manufacturing processes, mining industries, uses of electricity, and general factory management, and should prove an exceedingly interesting and instructive feature. Many of the exhibitors will also have speakers in the auditorium, who will lecture and display by motion and slide pictures the work of their respective companies.

This lecture and picture program will be announced from day to day on the exposition bulletin boards.

Under the auspices of the Bureau of Foreign and Domestic Commerce, some eight bureaus in the Departments of Commerce, Interior and Agriculture are now arranging noteworthy and instructive exhibits, each of which will be typical and demonstrative of the work of that bureau.

Among the exhibitors at this exposition are the following:

Abbé Engineering Co.
American Hard Rubber Co.
American Chemical Society.
American Bitumastic Enamels Co.
Automatic Weighing Machine Co.
J. T. Baker Chemical Co.
Brown Instrument Co.
W. Beckers Aniline & Chemical Works, Inc.
Bethlehem Foundry & Machine Co.
Buffalo Foundry & Machine Co.
Boonton Rubber Mfg. Co.
Christian Becker.
Condensite Co. of America.
Chemical Process Co.
Chadwick Boston Lead Co.
Department of Commerce, Washington, D. C.
J. P. Devine Co.
Driver-Harris Wire Co.
DuPont DeNemours Powder Co.
Duriron Castings Co.
Dorr-Cyanide Machine Co.
Detroit Range Boiler Co.
Thos. A. Edison.
Elyria Enameled Products Co.
Eimer & Amend.
Fairview Fluorspar & Lead Co.
General Bakelite Co.
General Chemical Co.
Gerdes & Co.
Glens Falls Machine Co.
Emil Greiner & Co.
Hanovia Chemical & Mfg. Co.
Heller & Merz.
Huyck & Sons, F. C.
Huff Electrostatic Co.
International Instrument Co.
Kieselguhr Co. of Amer.
Koven & Bro., L. O.
Lead Lined Iron Pipe Co.
Lenz & Nauman (Scientific Specialties Co.).
Lungwitz, Emil
Metallurgical & Chemical Engineering.
Macbeth-Evans Glass Co.
Moore Filter Co.
Monsanto Chemical Works.
J. L. Mott Iron Works.
National Aniline & Chem. Co.
Norton Co.
Pfaudler Co.
Raritan Copper Works.
Schaefer & Budenberg.
Schaum & Uhlinger, Inc.
Scott & Co., Ernest.
Standard Aniline Products, Inc.
Sweetland Filter Press Co.
Swenson Evaporator Co.
Thwing Instrument Co.
Tolhurst Machine Co.
Troegerlith Tile Co.
United Lead Co.
Valley Iron Works
Wilson-Maeulen Co.
Zaremba Evaporator Co.

Supply of Manganese Ore and Ferro-manganese Statistics

From a statement issued by Mr. C. B. Morgan, secretary of the Noble Electric Steel Company of San Francisco, we take the following interesting statistics on manganese ore and ferro-manganese:

MANGANESE ORE

	1913 Tons	1914 Tons	1915 Tons
Imports into the United States	345,090	283,294	.....
Average per month	28,757	23,608	.....
Imports first half 1915	.....	.....	52,007
Average per month	.....	.....	8,700
Imports into England	601,177	479,435	.....
Five months ending May, 1915	.....	.....	107,297
Imports, May, 1915			5,278
Or at a yearly rate of			63,000

FERROMANGANESE

Average imports in the United States, embracing 1910-1914	100,793 tons
Production from imported ore	99,363 tons
Total available yearly supply	200,156 tons
Average imports per month	8,399 tons
Production	8,280 tons
Total available monthly supply	16,679 tons
Imports first half 1915	20,542 tons
Possible production	15,500 tons
Total available supply	36,042 tons
Total available monthly supply	6,000 tons

It will be observed that the first half of 1915 the supply has been 10,000 tons per month less than the average of the preceding five years, or a deficit of 60,000 tons.

Before the war 90 per cent of the importations of ferromanganese came from England, which is now the only foreign source of supply, and as the imports of ore into England are on a diminishing scale, it becomes an interesting question, to what extent England can fill the growing void in the United States. Upon the scale of imports of manganese ore into the United States shown in the first half of this year only a partial relief can be expected from domestic production.

Personal

Mr C. W. **Badgley**, of the El Paso Smelting Works, has been spending his vacation in Denver, Col.

Mr. **Walter E. Burlingame** announces that the business of E. E. Burlingame & Co., assayers and chemists, will hereafter be conducted under his name at the old location, 1736 Lawrence Street, Denver, Col.

Messrs. **F. G. Cottrell** and **Dorsey A. Lyon**, of the Bureau of Mines, have been in the Coeur d'Alene district, Idaho, preparing for some technical studies in local ore treatment under a co-operative arrangement between the bureau and local operators.

Mr. **Justin H.Haynes** has returned to Denver after four months' professional work near Searchlight, Nevada, and will be engaged in metallurgical work in Colorado.

Dr. **F. W. McNair**, president of the Michigan College of Mines, recently made a trip through Ontario, visiting Cobalt, Porcupine and Sudbury, where he was entertained by alumni of the college.

Mr. **H. C. Parmelee**, Western editor of METALLURGICAL AND CHEMICAL ENGINEERING, has been appointed by the Governor of Colorado as a trustee of the Colorado School of Mines. The other appointees are Mr. **Orvil R. Whitaker** of Denver and Mr. **H. M. Rubey** of Golden.

Mr. **W. H. Staver** is in charge of mining and milling operations on the Suffolk property, Ophir, Col.

Mr. **H. L. Sulman** has been elected president of the Mining & Metallurgical Club, London.

Obituary

In memory of **Albert Plaut**, the late president of Lehn & Fink, and treasurer of The Chemists' Club of New York City, the Board of Trustees of The Chemists' Club has adopted the following minute: The death of our treasurer, Albert Plaut, inflicts on The Chemists' Club and its members a very great loss. His unflinching interest in the club's affairs, his generous helpfulness on every occasion that offered itself, his keen interest in the work of chemists and his encouraging appreciation of these efforts, his sturdy maintenance of what he regarded as right, together with his gracious good fellowship, all endeared him to the large number of us who knew him. And while we record our poignant grief at his passing, we acknowledge both appreciation and pleasure in that ours was the privilege to be associated with one who ordered his life to such good ends and whose friendship was indeed a benediction to those who shared it.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath, Anodes

546,483, September 17, 1895, Henry L. Bridgman, of Blue Island, Illinois.

Relates to anodes for electrolysis and consists of a frame which may be of insulating material, or of lead, copper, or other conductor that is not attacked by the electrolyte. The frame supports a plurality of V-shaped pockets separated at the bottom, and placed one above the other, spaced apart a distance approximately equal to the depth of the pocket. Above the pockets is a hopper, and below a movable board serving as a stop for the anode material supplied to the hopper. A pipe is provided to supply electrolyte to the anode material, to wash out any sludge, also a stirring rod to prevent the anode material from becoming too compact. The kind of anode material used is not described.

553,464, January 21, 1896, Eugene Hermite, of London, England, assignor of two-thirds to Edward James Paterson and Charles Friend Cooper, of same place.

Relates to anodes, and describes securing a network of platinum wires to a glass plate. The plate is drilled with a plurality of holes, all over the plate, and platinum wire is either threaded through the holes, so as to produce as complete a net-work as possible, or insulating studs are inserted in the holes, and the platinum wire supported by the studs. The net-work of wire may be on one side or both sides of the plate.

568,229, September 22, 1896, Henry Blackman, of New York, N. Y.

Relates to anodes for electrolysis of alkali chlorids, preferably for making bleaching liquor, and contains a reference to a copending application which became patent 568,231. The anode consists of an oxid of iron, or a mixture of oxids, bonded with a suitable binding or fluxing material. The material preferred is known as "black slag," a residue from pig-iron furnaces; it is fusible, and may be cast into any desired shape. The

black slag may, if desired, be mixed with magnetite, or other oxids of iron, or pulverized carbon.

568,230, September 22, 1896, Henry Blackman, of New York, N. Y.

Relates to anodes for electrolysis of alkali chlorids and describes making the anode from the mineral "ilmenite" or titanium-iron-oxid. The material is either sawed into shape, as is a block of granite, or may be melted with the aid of a small quantity of fluxing material and cast.

568,231, September 22, 1896, Henry Blackman, of New York, N. Y.

Relates to anodes for electrolysis of alkali chlorids, and describes magnetite and ilmenite, which may be shaped by sawing, melting and casting, or pulverizing and mixing with a binding material such as tar and molasses, pressing into the desired shape and baking.

572,472, December 1, 1896, Hamilton Young Castner, of London, England.

Relates to anodes for electrolytic purposes, and describes heating a piece of gas-retort carbon, eighteen inches long by one inch square cross section to an immeasurable temperature by passing an electric current of about five hundred amperes for a few minutes, the carbon rod being covered by powdered charcoal to protect it from oxidation. After cooling the rod possessed decreased density and increased conductivity, and was less susceptible to chemical action than before treatment.

578,070, March 2, 1897, Albert E. Woolf, of New York, N. Y., assignor to Rosamond Woolf, of same place.

Relates to anodes for electrolysis and describes a sheet of platinum or similar difficultly corrodible metal or alloy, about one one-thousandth of an inch thick, comparatively narrow, and having a length several times its width, secured at one of its longer edges and two short edges to a base metal such as copper, iron, etc.; the base metal serving as the conductor and insulated with glass, enamel, etc. The electrode thus insulated may be safely immersed in an electrolyte and used as an anode at which corrosive gases are liberated.

621,121, March 14, 1899, John T. Morrow, of Great Falls, Montana.

Relates to a supporting means for copper and similar anodes, used in copper-refining. The supporting means consists of folded straps of pure rolled sheet copper having their ends cast into the impure anode. The straps serve as supports and conductors and effect an economy in the amount of copper to be remelted when the anode is consumed.

627,573, June 27, 1899, Charles Cunningham Connor, of Belfast, Ireland.

Relates to anodes for electrolysis and describes uniting pieces of gas-carbon, graphite, coke, etc., together by lead. The carbon blocks of carbon may be drilled, supported in a frame, separated by asbestos washers and lead poured into the drilled holes and washers. Or the carbon blocks may be thrust part way into sand, and a layer of molten lead poured on the sand securing the carbons in such a position that they project equally on each side of the lead layer, the latter serving as the conductor. Or the carbons may be drilled and bolted on the sides of a lead plate having projecting lugs. In each case the lead plate, etc., is insulated with enamel, pitch, etc.

633,056, September 12, 1899, Arthur L. Walker, of Perth Amboy, New Jersey.

Relates to a supporting and connecting means for copper anodes and consists in casting the crude anodes with holes or perforations in the "ears" or lugs, in which supporting bolts or "eyes" may be secured, thereby effecting an economy in the amount of undissolved anode to be recast.

639,811, December 26, 1899, Harry L. Haas, of New York, N. Y., assignor to the Zucker & Levett & Loeb Company, of same place.

Relates to a supporting hook for anodes, which is integral with the anode, and is provided with broad flat square-jointed faces or surfaces by which the anode is suspended, and by which electrical contact is made.

658,891, October 2, 1900, Henry Carmichael, of Malden, Massachusetts, assignor to S. D. Warren & Co., of Boston, Massachusetts.

Relates to an anode consisting of a net-work of platinum wire the wire supported upon and secured to projecting pins of platinum, which in turn pass through and are sealed in the ends of glass tubes, the tubes passing through the cover of the electrolytic cell. Connection is made to the inner ends of the platinum pins by copper or other wire, the tube then being filled with pitch, etc. Instead of the net-work of platinum wire, each glass tube may support a long piece of platinum wire folded into a plurality of loops. Instead of glass tubes, vitrified porcelain may be used, which is said to be more durable in contact with chlorin than the glass.

667,421, February 5, 1901, Henry Blackman, of New York, N. Y.

Relates to means for making electrical connection with anodes or other electrodes, and consists in boring a hole in the top of the electrode down into its mass, as large in diameter as its thickness will permit. In the hole is inserted preferably a zinc rod having a spiral roll of hard rolled sheet zinc secured to it and wound tightly upon it. The rod and spiral roll are forced down into the hole, the spiral making good contact with the walls of the hole. Upon the rod and into the hole is forced a hard rubber tube, carrying upon its lower end a soft rubber ring, the soft rubber making a tight joint with the walls of the hole, the lower part of the hard rubber being beveled to make a tight joint with the upper edges of the hole. The hard rubber tube projects above the level of the electrolyte and is provided with a screw-threaded ring or cap which compresses a packing tightly against it and the conductor to prevent access of liquids to the interior of the tube.

667,498, February 5, 1901, William Thomas Chapman, of Manchester, England, assignor to the American Alkali Company, of Philadelphia, Pennsylvania.

Relates to means for vertically adjusting the height of electrodes in a cell, to allow for wear, breakage, etc. The upper end of the electrode has attached to it a threaded conductor rod by which it is supported from a threaded sleeve, which permits raising or lowering as may be desired.

673,453, May 7, 1901, Isaiah L. Roberts, of Brooklyn, New York, assignor to the Roberts Chemical Company, of New Jersey.

Relates to a connector for granulated carbon electrodes, such as are used in porous cups. The connector consists of a metallic plate embedded in a conducting cement, made of resin, asphaltum, and a conducting material, preferably carbon; between the cement and the granulated carbon electrode is a layer of powdered carbon such as coked anthracite coal, to improve the electrical contact. For large electrodes several contacts may be placed at different positions. The entire top is then covered with asphalt or similar seal.

689,877, December 31, 1901, Luke Hargreaves and William Stubbs, of Farnworth in Widnes, England.

Relates to anodes and provides means for protecting the metallic part thereof from corrosion by the electro-

lyte. Where blocks of carbon are secured to a vertical metallic conductor, the latter is encased in a tube of protecting material, the tube being filled with a suitable oil, such as a resin oil containing resin dissolved in it, the oil completely covering the metallic parts, and penetrating by capillarity the pores of the carbon. With electrodes suspended from a horizontal metallic conductor, they pass through a shallow tray containing the oil, the tray resting upon the cell.

715,684, December 9, 1902, Frank McDonald, of Johnsonburg, Pennsylvania.

Relates to anodes and consists of a plurality of strips of thin ribbon platinum-foil, which may be two inches wide in some cases and of suitable length, sealed into the end of a glass tube, containing mercury, into the upper end of which projects a conductor. The tube may be closed by a plug of cement forming an air-tight and liquid-tight joint.

(Complete prior to 1903.)

Notes

The Lack of Coke and Iron in Italy.—According to the Chamber of Commerce of the U. S. (Riggs Building, Washington, D. C.) the war has stopped in Italy entirely the arrival of foundry coke and low-grade pig iron from Germany, and the local Italian producers (Solvay Process Works at Vado and Savona near Genoa) are closed because they have no coal, and until the war is over very little coal and coke will come from England from which country Italy has been importing about 70,000 tons of coke per year. The imports from Germany, Austria and Belgium amounted to 220,000 tons of coke per year. The metallurgical or hard foundry coke which has come from Westphalia in the past was delivered in Milan at from $11 to $12 a ton, and at the present those who have any coke in stock are getting anywhere from $20 upward a ton. The unloading and putting on cars at Genoa and Savona is about 50 cents a ton, and the freight from these ports to Milan is just under $2 a ton. The port of Savona has special facilities for unloading coal and coke. There is a big demand for iron in Italy that compares in analysis with English hematite. American pig iron for malleable use, as well as the more ordinary quality, in the general foundry business, is also wanted. If the makers of pig iron care to investigate what appears to be an opening in Italy, the American Chamber of Commerce in Milan will be pleased to have them send over their analysis together with prices at the seaboard in America, as well as in Genoa. The hematite which sold before the war at about $21 delivered in Milan is not to be had now at less than $45 to $50, as the only iron ore available is Spanish hematite, of which the quantity is limited. The landing charges, freight and duty from steamer to delivery in Turin or Milan are about $4.50, of which $2 is freight, $2 duty and the rest handling and unloading.

The standard riffles on a Wilfley table vary progressively in length from 4 ft. 6 in. to 13 ft. 10 in. In depth they are tapered from ¼ in. to 1/16 in. in the shorter rifles, and from ⅜ in. to 1/16 in. in the long ones.

The price of tungsten concentrates in the Boulder county field, Colorado, has advanced to $10 per unit for 60 per cent WO_3, or $600 per ton. According to a consular report, the price for ferrotungsten in England has advanced to $1.34 per pound of tungsten contained in the alloy, and tungsten powder to $1.46 per pound.

The Petroleum Industry of California is the subject of a 600-page book, with a separate folio of maps, issued by the California State Mining Bureau, Ferry Building, San Francisco, Cal. The price is $2.

The study of sanitary conditions in and about mining and metallurgical plants has been undertaken by the Bureau of Mines. Some results of an investigation by Joseph H. White are embodied in *Bulletin* 87, entitled "Houses for Mining Towns." The bulletin contains illustrations and designs, showing good and bad conditions, and outlines the work done by large companies in laying out and maintaining mining settlements.

Book Reviews

Chemical Theory and Calculations. By F. J. Wilson and I. M. Heilbron. Price $1.00 net. New York City: D. Van Nostrand Company.

A first-class little book for beginners, if used under a good teacher. The explanations of fundamental chemical quantitative relations (such as of equivalent weights) are clear and convincing. The only drawback is that here and there a word is used loosely, or a necessary qualifying phrase omitted, which would need the attention of a sharp-eyed teacher to straighten out and thus prevent the student getting a fragmentary or faulty idea. The problem method is the only method to make absolutely certain that a student has mastered the fundamentals; for, if a student can work out a complicated problem correctly one may be sure that he is properly master of the principles involved.

Details of Cyanide Practice. By Herbert A. Megraw. Octavo (15 x 22 cm.), 215 pages, numerous flow sheets, drawings and illustrations; price $2 (8/4). New York and London: McGraw-Hill Book Company, Inc.

The work describes cyanide practice at fifteen important mills in North America, the facts being gathered from a tour which was intended to include Mexico, but this was prevented by the revolution in progress there. The chapters have already appeared as a series of descriptive articles in the *Engineering and Mining Journal*. The work presents the author's observations and personal opinions, and criticisms intended to promote discussion respecting details involving diverging practice.

Cyanide Practice, 1910 to 1913. Edited by M. W. von Bernewitz. Octavo (15 x 23 cm.), 732 pages, 133 illustrations. Price, $3. San Francisco: Mining and Scientific Press.

This a reprint of 205 articles which appeared in the *Mining and Scientific Press* from July, 1910 to January, 1913. It is a continuation of two similar compilations printed in 1907 and 1910. A great improvement over its predecessors is the classification of the articles under fifteen headings, conforming to the arrangement of the ordinary treatise on the cyanide process, instead of merely arranging them chronologically.

There is an immense amount of up-to-date information on the cyanide process in this book, written from many different standpoints and, therefore, of greater suggestiveness and value than if written by a single author. Incidentally, when one reflects that this mass of useful information was furnished by one single journal, from week to week, in timely installments, and that this is only one of several subjects covered by that journal, one obtains a vivid idea of the immense value given, at relatively small cost, by the columns of the active technical journals. This book is valuable in and of itself, but it proves the still greater value of the

periodical scientific press to the wide-awake technologist.

Methods in Metallurgical Analysis. By **Charles H. White.** Duodecimo (12 x 18½ cm.), 356 pages, 106 illustrations; price $2.50. New York: D. Van Nostrand Company.

The author is assistant professor of mining and metallurgy in Harvard University and the Massachusetts Institute of Technology. The book is intended for the use of students who have had adequate preparation in qualitative analysis and gives them the methods which have been most generally adopted in American metallurgical laboratories. The details are clearly stated in a manner indicating the author's long practice in teaching; the style is good, the methods well chosen, the printer's work first class. It is undoubtedly a very welcome book for the use of metallurgical students.

Metallurgy. By **Henry Wysor.** Second edition, revised and enlarged. 392 pages, 104 illus. Price, $3. Easton, Pa.: The Chemical Publishing Company.

A condensed treatise for the use of college students and the general reader. The bulk of it is good, though some parts less so; it is all necessarily brief. There is a very large amount of information in the book, of a kind adapted to give the reader a general idea of every phase of the subject. It is essentially a textbook, adapted for use as such by assigning lessons in it from cover to cover. For those who are so placed that they must teach metallurgy merely as a branch of industrial chemistry, this is probably as good a textbook as could be selected; but some omissions would need to be supplied and some errors corrected: *e.g.*, omission of petroleum among the fuels, explanation of *how* mercury ore is decomposed by heat, or the kind of electrodes in aluminium reduction pot. It is a book which might be satisfactorily used in giving an elementary course.

Steel Working and Tool Dressing. By **Warren S. Casterlin.** 12 mo., 207 pages. Price, $2. New York: M. T. Richardson Company.

The sub-title reads "A Manual of Practical Informationo for Blacksmiths and All Other Workers in Steel and Iron." The author is a practical blacksmith who has spent fifty-seven years at the anvil. He says in the preface: "I have worked in more different shops, done more traveling, and spent more time and money to perfect myself in the art of steel working than any other man on the continent." Again he says: "I shall never revise this book again. I have tried to do my duty. I have been cautious at every stroke of the pen."

It is difficult to criticise such an honest bit of writing. It is written in absolute sincerity, and it contains the quintessence of the experience and beliefs of the old, old school. Peace be to their ashes! No one can read it without learning some items of practical information; yet it is the duty of the reviewer to caution readers against the limitations of the author and the many errors in the book. The uninstructed would learn from it much that is questionable and some things that are wrong; they had better, therefore, leave it alone until they know more about steel from more reliable sources. Those initiated in steel will find it an interesting human document, and may find in it some crumbs of useful information.

Heat-Treatment of Steel. Collected from articles in *Machinery*. Octavo, 278 pages, illustrated; price $2.50. New York: The Industrial Press. London: The Machinery Publishing Co., Ltd.

This book is mainly compiled from articles published in *Machinery*, with amplifications and additions. It contains a large amount of information and some misinformation, thrown together in a miscellaneous receipt-book sort of way. At places it is quite good, but at others it is pretty poor. A reader well acquainted with the subject might glean some useful information by reading it through critically; one unacquainted with the subject will run the risk of learning it in a disjointed, unsystematic manner which will give him but little real mastery over it. It may be possible that mechanics need to have an art presented to them in this sketchy, jumbled sort of way in order to read it understandingly, but we doubt it.

The Sampling and Assay of the Precious Metals: Comprising Gold, Silver, Platinum, and the Platinum Group Metals in Ores, Bullion, and Products. By **Ernest A. Smith.** Octavo (15 by 22 cm), xv + 460 pages, 166 illustrations; price, $4.50 net.

The author is connected with the Sheffield Assay Office, but was formerly teaching the subject at the Royal School of Mines, London; he dedicated the work to his father, Richard Smith, one of the original staff of the Royal School of Mines, on its formation in 1851.

The author's aim has been to make the book exhaustive and comprehensive. Particular attention is given to sampling. We would describe the treatment as being less scientific than Fulton's "Manual of Fire Assaying," and therefore less instructive to the student. A curious misnomer exists in the title: assay is *"for"* the precious metals, not *"of"* them.

Blowpipe assaying for gold and silver is acknowledged to be useful, particularly to the prospector, and therefore deserved a chapter instead of three-fourths of a page. The miscroscopic measurement of small assay buttons from small amounts of ore or from very lean ores, is not mentioned; also, methods particularly adapted to assaying country rock or sea-water are not given, yet should be considered in a comprehensive treatise.

It is a fine book, but could be improved in a few respects.

Gemeinfassliche Darstellung des Eisenhüttenwesens. Compiled and published by the Verein deutscher Eisenhüttenleute. Ninth edition, octavo. xii + 438 pages, 68 illustrations, many diagrams; price, bound in cloth, 5 marks (retail in New York $1.65). Düsseldorf: Verlag Stahleisen.

A well-written, beautifully printed and illustrated exposition of the present methods of manufacturing iron and steel. The space given to each topic is necessarily brief, but it is utilized most skillfully. To those reading German easily it gives a very readable and instructive picture of the iron industry. Over one-third of the book is devoted to statistics of the iron industry in all parts of the world and nearly one-fifth to an exhaustive list of all the firms making and working upon iron and steel in Germany.

Einführung in die Metallographie und Wärme Behandlung. Von H. Hanemann. 16 x 24 cm., 128 pages, 25 diagrams in the text, 110 photomicrographs on plate paper. Price 10 marks (retail price in New York $3.35). Berlin: Gebrüder Borntraeger.

The author is director of the metallograph division of the iron and steel laboratory at the Technical High School in Berlin. This book embodies twelve lectures given by him to metallurgical, chemical and mechanical engineers in a summer school course. It is, therefore, not a comprehensive text-book, but merely a clear-cut statement of the best of present methods and results in the microscopic study of metals and their improvement by heat treatment. It is clearly written, and the photographs are excellent and most instructive.

Metallurgical and Chemical Engineering

A Consolidation of
Electrochemical and Metallurgical Industry and Iron and Steel Magazine

Vol. XIII NEW YORK, SEPTEMBER 15, 1915 No. 10

Published Semi-monthly on the First and Fifteenth of Each Month by the

California and the International Engineering Congress

Next week, from Sept. 20 to 25, the International Engineering Congress, to which sunkissed California has invited the engineers of the world, will meet in San Francisco. That it will be a great success is assured by the simple fact that San Francisco is the hostess and the national societies of civil, electrical, mechanical, and mining engineers stand sponsor. But it is a melancholy reflection to think that this is the only survivor of so many congresses planned.

The year 1915 was intended to be one of promotion of international good will and friendship by international congresses. It was not so to be. There has been no International Congress of Applied Chemistry in St. Petersburg or Petrograd, no International Congress of Mining, Metallurgy, Engineering and Economic Geology in London. Even the International Electrical Congress which had been planned for San Francisco was called off, and this is characteristic. The Electrical Congress was managed in the East and was called off; the Engineering Congress was managed from San Francisco, and its managers with true Californian spirit stuck to their purpose and carried it through and will achieve the success which their courage deserves.

That in number of members and in international character the International Engineering Congress will seriously suffer from the European war goes without saying. That it can nevertheless be made a real success San Francisco will prove. It is true that the conditions resulting from the European war even in neutral countries have greatly reduced the anticipated enrollment of members, but they have not resulted in a proportionate reduction in either the quality or the quantity of the papers offered for publication in the Transactions. And the Transactions are, after all, the final test of the success of the Congress. But that the Congress and its Transactions should be of the greatest possible benefit to the engineering professions, it is essential that it should enroll the greatest possible number of members.

It is not yet too late to join the Congress. The address of the International Engineering Congress is Foxcroft Building, San Francisco, and the membership fee is five dollars, which entitles the member to full participation in the Congress, a volume reporting the general proceedings, and any single volume of the Transactions which the member may select out of the set of ten volumes. These ten volumes relate to (1) Panama Canal; (2) Waterways and Irrigation; (3) Municipal Engineering; (4) Railways and Railway En-

gineering; (5) Materials of Engineering Construction; (6) Mechanical Engineering; (7) Electrical and Mechanical Engineering; (8) Mining and Metallurgy; (9) Naval Architecture and Marine Engineering; (10) Military Engineering. It may finally be mentioned that for the section of metallurgy five symposia have been arranged on iron and steel, copper, gold and silver, zinc, and the utilization of fuels in metallurgy, the editors being Henry M. Howe, E. P. Mathewson, C. W. Merrill, W. R. Ingalls and C. H. Fulton respectively.

So much may be said as to what may be expected in return for the membership fee. But to look at the Congress in this way shows a rather narrow viewpoint, as the idealistic side of the whole undertaking is entirely lost sight of. The Congress was organized to commemorate and celebrate one of the greatest peaceful engineering achievements of recent times—the completion of the Panama Canal. In these frightfully distressing war times, the Engineering Congress will emphasize the triumph of the peaceful work of the engineer. To enroll as a member means to avow the truth of this idea and is but a small tribute to the Californians who have made the congress a reality.

* * *

Yet the courageous manner in which the International Engineering Congress has been organized is but one single expression of the general spirit that moves the whole Californian people. They mind their own business and in that trait alone they are almost without competitors, and that is one reason why Californians can do things that seem impossible elsewhere. And they mind their own business with the full-blooded enthusiasm and never-dying optimism which they inherited from their pioneer ancestors. With the simple faith in the righteousness of their doings, they perform miracles. After the fire of 1906 how could they have built up otherwise in a few years a new and more beautiful San Francisco? How could they have organized otherwise nine years later a World's Fair and make a success of it—a big success, aesthetic, industrial, cultural, and even financial? In these distressing days when the rest of the world is in flames or is shaking, San Francisco stands firm and strong and happy—an inspiration to all who go and see and wonder.

It is a pity that the East in its troubles does not seem able to derive from the West that inspiration which it needs and could get abundantly. At least if it is true that the newspapers give the people what the people want, it is distressing to see in Eastern newspapers nothing but glaring headlines on the European war. Has anyone seen in any New York newspaper a headline on the wonderful success which San Francisco is making, even beyond her own expectations? Must we always look backward toward Europe? Have the people of the East lost the spirit of those pioneers who followed the course of the sun and conquered the West? Can't we learn to look westward and forward toward the Golden Gate and the great empire at the Pacific Coast? Never has been the name of the *Pacific* Coast as true as to-day.

Of course, the one encouraging feature in this situation is obvious; it is that the situation has produced automatically its own remedy. What no argument about the wisdom or decency of Americans seeing America first could have done, has been practically forced upon American travelers by the European war and by the San Francisco and San Diego Expositions. And every Eastern traveler comes back to the East as an enthusiastic voluntary advertising agent of the greatness of the Pacific Coast.

This is a big gain for the East, but it is not the main point for the West. What are as much important for the West as the very large number of average sight-seeing travelers, are the visits of technical and engineering societies. This week, from September 16 to 18, San Francisco has the meetings of the American Society of Civil Engineers, the American Society of Mechanical Engineers, the American Institute of Mining Engineers, the American Institute of Electrical Engineers, the Society of Naval Architects and Marine Engineers, and the American Electrochemical Society, previous to the International Engineering Congress next week. Many other societies have met and will meet on the Coast. Of the trip of the American Institute of Chemical Engineers from San Diego to San Francisco and Seattle and of the trip of the American Chemical Society in counter current from Seattle to San Francisco we give quite a full account in this issue. But the interesting point in this connection is this: What has the Pacific Coast for the chemist and what has the chemist for the Pacific Coast?

The mining engineer blazed the trail and the metallurgist followed, and the more the mineral resources of the Pacific Coast will be utilized the more will the chemical training be needed in the metallurgist. This is obvious. The Bully Hill mine is a famous case in point. But outside of metallurgy the chemist's work in California is restricted at present chiefly to oil and gas and to sugar. These are big fields, very big fields. But they seem small compared with the unlimited possibilities not yet touched.

One single example may explain what we mean. A few years ago, a strong-hearted man was shown the immense kieselguhr deposits at Lompoc in Santa Barbara County and the prospects of oil wells were pointed out to him. This did not appeal to him, as any other rich man could have tackled that proposition. What appealed to him was the creation of a new American industry—that of kieselguhr; he had become a true Californian on California soil. The mining problem was simple enough, but the chemical problem of utilization for heat insulation, sugar filtration, oil refining, and we don't know what else, was everything.

There are unnumbered opportunities of this kind for the chemist in the development of the natural resources of the Pacific Coast. Mr. Baruch's paper on the Southwest, like Dr. Benson's paper on the Northwest, will prove suggestive. If the first semimonthly edition of this journal has become almost completely a Pacific Coast issue, let us hope that this is a happy omen on the future interrelation between chemistry and the Pacific Coast.

A Bit of Economic Mineralogy

If you see it in *The Sun*, it's so. We cull the following contribution to economic mineralogy from *The Sun* of Aug. 20:

> One of the effects of the war upon this country has been to develop resources of which we before had no knowledge. This has been shown in the development of dye, potash and certain mineral industries. Now it has been discovered that there are immense deposits of silica in the sand hills of western Kansas, and so great has grown the demand for the substance since the supply from Germany has been cut off that several large plants have been built for treating and marketing it. We have thus been able not only largely to supply our own demand, but to transform what was once considered waste land into productiveness.

The still more important discovery that the coal deposits of Pennsylvania contain large quantities of carbon has rendered that state, at least, independent of imported fuels; and since the scientific application of the oxometer has demonstrated the presence of not inconsiderable quantities of oxygen in the atmosphere of the western hemisphere it is anticipated that before very long respiration may be possible in this country without the use of European oxygen.

The Iron Trade's Divergences Under War Demand

It may be interesting to recount some of the divergences, amounting occasionally to definite dislocations, produced in the iron trade by the demand for war material. As is doubtless quite well recognized, nearly all if not quite all the increased demand for steel, as compared with that of last year, is due to the war. The measure of the demand upon the steel mills is not merely the quantity of war material they are producing, for ordinary domestic buyers, jobbers and manufacturing consumers have been moved to purchase ahead, and to increase their stocks, because the magnitude of the war demand made them fear they would not find themselves with all the material needed unless they were forehanded in their purchases.

An outstanding divergence is the fact that the steel works are producing pig iron at a rate fully 5 per cent in excess of their best previous rate, reached early in 1913, while the merchant furnaces are producing 20 per cent less than at that time. The demand has run to steel, not to iron castings. The iron cannon ball is far in the past.

The demand for steel has run very strongly to open-hearth, but open-hearth steel has become so scarce that many consumers who ordinarily use open-hearth have been induced to take Bessemer. Very likely they are finding it more suited to their purpose than they expected.

For the first time in their history a large use has been found for the rail mills, apart from the rolling of rails. Of course there have been interchangeable mills, rolling billets or rails at will, but few such have been built in recent years. Now a very large tonnage of rounds, over 3 in. in diameter, is being rolled on rail mills, the section being approximately the same weight as that of standard rails. At least half a dozen rail mills are so engaged. The railroads, which have had no occasion since 1907 to worry about securing any delivery desired upon rails, are now seriously concerned over the prospect, and are beginning to buy rails for 1916 delivery.

The rise in the price of spelter, due to the combined influence of England's supplies from Germany and Belgium, equal to 15 or 20 per cent of the world's normal requirements, being shut off, and the large consumption in the manufacture of war material, has almost killed the galvanized sheet industry. About one-eighth the weight of the average gage galvanized sheet is spelter, while over a period of years spelter sold per pound at about three times the price of the uncoated steel sheet. In recent months spelter has been fluctuating between three and five times its former cost. When spelter has advanced the mills were afraid to sell galvanized sheets; when it declined the buyers were afraid to buy and the current production of galvanized sheets is only about one-third normal.

Various price relations in finished steel products have been disturbed. For many years steel plates brought from $1 to $2 a ton more than steel bars, but in the past few months the divergence has been as much in the other direction.

During the first six months of this year finished steel prices rose steadily, by an average not far from $3 a ton, while pig iron fluctuated within narrow limits and showed no general advance. The pig-iron market was largely a function of foundry activity, which was light. Since July 1 there have been sharp advances in pig iron prices. These advances, while harmonizing with the rise in steel prices, have occurred with a much smaller turnover in the pig-iron market than ever before occurred during a similar rise in price, and the advance may perhaps be attributed more to sentiment than to an operation of the law of supply and demand.

The large steel rounds being rolled in tens of thousands of tons a week involve unprecedentedly heavy cropping, the extreme being 35 per cent from the top and 5 per cent from the bottom. Incidentally this cropping is usually required to be done from the ingot and by sawing, which has necessitated some rearrangements in equipment. What to do with the crops is furnishing a more important problem. The markets have probably not yet felt all the influences which this large production of crops is likely to exert. Scrap, pig iron and billets may within a few months be found in new relations with each other. The measure of production is the capacity of the open-hearth furnace, and if all the crops are charged into the furnace, together with other scrap produced by the mill, the supply of scrap otherwise drawn from the mill is not required, and even the consumption of pig iron may be curtailed. Open-hearth steel billets are now very scarce, but if the crops should find their way largely into billets this situation might be very markedly altered. The situation merely presents possibilities. The specifications vary greatly with different orders and the various mills that have accepted the orders may work out their problems in very different ways.

Readers' Views and Comments

The Potash Situation

To the Editor of Metallurgical & Chemical Engineering:

Sir: Mr. Dolbear, in his instructive article on the potash situation in your August number, apparently overlooks altogether the only potash resource in the United States that at present promises to produce potash to any extent at an early date.

The Searles Lake project in Southern California is unfortunately slow in its development, and the other prospective potash sources mentioned are none of them being worked on a scale much beyond the experimental, if they are worked at all.

The potash source which Mr. Dolbear has overlooked is the alunite deposits in Utah. These promise to deliver at an early date a marketable soluble potash salt.

Alunite, being an insoluble hydrous potassium sulphate, can readily be dehydrated and partly decomposed by calcination. In doing this the water is driven off and the aluminum sulphate is decomposed, leaving insoluble aluminum oxide and the soluble potassium sulphate.

Active development work is going on in the alunite deposits in Utah. New veins are being found, and one mill is under construction, and still a couple of others are projected, and the construction of these is expected to start at an early date.

The mill in which the ore is to be calcined, now under construction, is owned by the Minerals Products Company of New York City, and it is generally understood that the products from the mill will be disposed of by the Armour Company.

One hundred tons of alunite per day the plant is planned to take care of, and this amount of alunite will, on calcination, produce twenty tons of potassium sulphate, and thirty-seven tons aluminum oxide.

Considering the total consumption of potash per year in the United States for fertilizer purposes, it is apparent that twenty tons per day is only a very small fraction of the total fertilizer needs of the country, but, at the same time it certainly indicates a good start, and the existence of a domestic source of potash readily made available.

The aluminum oxide obtained in the calcining of the alunite is a by-product, and contains about 99 per cent of Al_2O_3, and approximately 1 per cent of impurities, such as silica and other metallic oxides.

This aluminum oxide can with slight expense and with some care be further purified, and in such condition it may be used in the manufacture of metallic aluminum.

The output of aluminum oxide from even a moderately sized potassium sulphate plant would be considerable, and if all the oxide of this first installation were reduced into metal, some eighteen tons of aluminum would be produced daily, or close to one-fifth of the total aluminum production in the United States per day during 1913.

The thought has been launched that by obtaining this aluminum oxide as a by-product at practically no cost it would be feasible to manufacture aluminum so cheaply that it could be sold at such a low price that the usages for aluminum would be very materially broadened.

The potash situation could well be considered alarming at present in the United States, with the German supply altogether eliminated, but fortunately there are stored enormous quantities of potash all through the country.

It is unfortunate that the chemical combination in which the potash occurs is, with the exception of alunite, such that it involves considerable amount of expense and labor to obtain it in a soluble condition.

There are many processes evolved for the purpose of making these potash resources available, but so far none has been successful enough to justify its operating on a scale much beyond the experimental stage.

This does not eliminate the possibilities that all the potash stored in the Lencite Hills in Wyoming and in the feldspathic rock deposits all through the country cannot be made available at an early date, but it is "up to the chemists" of the country to economically sever the pernicious hold silica has on the much needed and coveted potash.

It has struck me that the chemical profession could in no better way serve our country to-day than assist in solving the potash situation, expedite the liberation of the fettered potash which in reality represents our nation's daily bread, and possibly in years to come the daily bread of many of our European neighbors.

To accomplish the expeditious solving of this problem, I ask you whether a joint committee could not be formed among the leading chemists of the United States, immaterial if they belong to any chemical societies or not, for the purpose of discussing this matter and evolving methods by which to accomplish this. The co-operation of the people and the Government of the United States could certainly be counted upon, financially as well as otherwise.

Any valuable inventions made and processes developed by this committee should be patented, but these patents would all be turned over to the United States Government, making the use of patents and processes free to everybody.

The successful solving of this problem at this time, under these conditions, would build a monument to the chemical profession which time could never obliterate.

J. W. Beckman.

San Francisco, Cal.

Repairing Furnace Linings with Compressed-Air Gun and Torch

To the Editor of Metallurgical & Chemical Engineering:

Sir:—In your issue for April, 1915, page 250, I note reference to my patented process for forming and repairing furnace linings by means of a compressed-air gun combined with a torch, the object being to form a dense vitrified lining. As I am not financially interested in this patent in any way my opinion on the process may be considered unbiased. The idea of using a compressed-air gun to project materials into a furnace is not new; but from my experience with processes I have come to realize that there is a vast difference between ideas and their practical application. I have built and operated reverberatory furnaces and it was for this reason that it occurred to me, while I was engaged in some engineering work for the Cement Gun Co. that their machine could be used for the purpose indicated above. In my connection with the Cement Gun Co. I had an opportunity to study the development of the machine from the time it was first conceived by Mr. Ackley up to its present development, and I would say that the idea of blowing a solid against a surface is one thing and carrying out the idea is another.

Volumes could be written on the difficulty of doing

that very thing, and I myself have spent the better part of two years in solving the problems connected therewith. It can, therefore, be very easily understood that anyone merely wishing to apply this idea to furnace work, without having knowledge gained from experience, would run against great difficulties in a mechanical way. This is probably the reason why the matter has never been prosecuted farther.

A furnace built by this process whereby the proper screen combination is used to produce a mixture which can settle into place with practically no voids, would give enormous metallurgical advantages. The absorption of the bottoms would be reduced to a minimum, and with it, of course, the necessity of smelting old bottoms and placing new ones would be reduced in proportion. The furnace up-keep can not only be reduced to a low cost, but a furnace can be made to last practically indefinitely, because an absolute bond can be obtained between the material in place and the new material, and repairs can be made without interfering with the operation. Thus, if the proverbial "stitch in time" is applied whenever needed, the furnace should be kept constantly in first class repair with very little cost. If anyone wishes to try this process and is willing to go into detail, I would be glad to furnish any advice I am able to give as to details of operation.

Joplin, Mo. ALFRED SCHWARZ.

Metallurgical and Chemical Engineering in Great Britain

(By Our London Correspondent)

Concerning Things in General

All mental and industrial activity here (in London) is now dominated by one thing, and one thing only. The war and the demands incidental to it determine not only civilian occupations and movements, but our diverse pre-occupations. We talk very little about what we shall do when the war is done—although perhaps we are doing more "thinking ahead" about commercial and economic matters then than we were wont to do in the easy days when in their relentless, inevitable but unsuspected ways, uncontrollable forces were insuring the advent of a colossal war.

We are now mainly preoccupied with a very big problem—the national regrouping and reorganization of all activity. Save for those who wear the king's uniform here or in the field, there are before us here many questions centering round the fact that we must either answer them successfully or make way for a race with the brain to translate the co-ordinated activity of the anthill or the hive into the every-day facts of existence and racial persistence.

Individualism has played its part, and a very valuable part, in our development hitherto, but there has been a nemesis of individualism. When every man does "what seemeth right in his own eyes" without regard to discipline grave risks are run. Equally, too, superorganization with the elimination of individual thought or initiative has in it all the potentialities of atrophy and decay. Modern Germany, with all its wealth of organized knowledge, yet suggests in some degree a feeble imitation of the complex and highly organized civilization of the Incas. Safety obviously lies in avoiding the pitfalls on either side, and possibly some of its innate inclination for compromise will help the British race to surmount its obstacles.

The manufacture of rifles, field guns, cartridges, high explosives, aeroplanes, boots, uniforms, vehicles, and the feeding of the army is only one of many problems. The transport of men and munitions must be carried on simultaneously with the transport of foodstuffs and raw materials for the civil population. Military activity alone cannot suffice for any race barring, say, a race of freebooters content with an ephemeral existence of short but not necessarily jubilant span. Civilization demands synchronism between military effort and non-military activity when everything is referred to the arbitrament of the sword.

We are improvizing as we go along, and reckon to make a success of our improvization, although the cost of improvization will give us a bad national headache when the show is over.

Writing in a khaki uniform, one hesitates to prophesy. Yet your correspondent feels constrained to make a duplex prophecy which will fit either event that the fates yield to Europe. If militarism triumphs, it will be morally conquered by the adoption of a part of the individualism of the conquered nations. If the individualist and hitherto non-militarist races come out on top they, too, will be morally conquered by their adoption of semi-militarist tendencies and by an imitative co-ordination and national organization of the industrial activity of the race which they must now break or else be themselves broken.

Metallurgical Work at the National Physical Laboratory 1914-1915

The annual report of the National Physical Laboratory, now in my hands, is a chronical of diverse activities, all more or less influenced by the war. Twenty-five per cent of the staff—some fifty members—are now on military service, some of them in the same corps as your correspondent, doing similar garrison duties. Of course, the financial results of the year's work at the laboratory have been adversely affected by the war. Up to the end of June, the receipts for work done were considerably in excess of those for the corresponding three months of last year; during the next three months there was a heavy fall, amounting to some £2,100, but subsequently there has been a considerable recovery, the net result is that the accounts show a credit balance of £80.13.8.

So far as the present letter is concerned, I propose only to refer to the report of the department of metallurgy and metallurgical chemistry, leaving other matters for a later letter.

New apparatus has been added, including (1) a new vacuum pump—Gaede's piston type—for use in connection with the research on the melting point of iron in vacuo; (2) a large induction coil, intended primarily for use in connection with the cathode-ray furnace; (3) the remodelling of the plotting chronograph; (4) a microscope levelling device intended to supersede the older mechanical devices for setting the prepared surface of the specimen at right angles to the optic axis of the microscope; (5) an experimental rolling mill. This mill has been designed primarily for the purpose of providing facilities for rolling ingots of light alloys (alloys of aluminium) into bars and sheets for the purpose, in the first place, of ascertaining the suitability of various alloys for mechanical use, principally in connection with aeronautics, and, in the second place, for the purpose of determining the exact conditions under which various promising alloys can be rolled in a satisfactory manner. The mill, however, has been so designed that other alloys can also be handled in it. The need for an experimental equipment of this kind has arisen, in the first instance, from the circumstance that it has been found very difficult to obtain satisfactory rolling results in existing industrial mills with certain alloys which showed a high promise of usefulness. Although several bars of such alloys have been rolled by using extreme care and special precautions, it was quite

obvious that industrial success could not be obtained until the exact conditions demanded by the peculiarities of these alloys had been thoroughly studied. By equipping a full size rolling plant, in which the various conditions of speeds, draft and temperature are under exact control, it will be possible to ascertain within what limits these various factors must be kept in order to secure uniformly successful production. Experience has already shown that the conditions suitable for the rolling either of pure aluminium or of brass or steel are not satisfactory for these new materials.

Apart from these special questions, the rolling mill equipment promises to be of particular value for facilitating research on many questions connected with this important manufacturing process, since measurements of power, temperature, etc., can be carried out in the laboratory plant in a manner quite unattainable in most existing industrial establishments.

As regards research work, this was almost entirely confined to the first three or four months. After the outbreak of the war, this department was so short handed that it was found difficult to do much more than cope with the investigatory test work. The work actually done referred to the constitution of the Aluminium Zinc-Copper series. Considerable difficulty has, however, arisen in interpreting the indications of thermal curves and of microscopic examination relating to the alloys lying near the aluminium corner of the ternary triangle. This difficulty has now been traced to the fact that the accepted constitutional diagram for the copper aluminium alloys containing 90 per cent of aluminium and over is incomplete in regard to an important reaction which occurs in the alloys at a temperature of 560 deg. C. It has, however, been found difficult to discover the exact nature of this reaction, and since it is of fundamental importance to the understanding of the ternary alloys containing up to 5 per cent of copper, considerable time has been devoted to the study of this special point. This difficulty is an example of a class which is frequently met with when ternary alloy systems come to be investigated in an accurate manner. It is then frequently discovered that a very minute transformation which occurs in one of the binary systems has escaped observation, but that the evidences of this occurrence, such as thermal arrest points and microscopic changes, become considerably intensified by the addition of a few per cent of the third metal. Although in themselves of considerable interest, the discovery of these points often requires a very extensive investigation before the work on the ternary system can proceed satisfactorily, so that the labor—already very extensive—of investigating ternary systems is thereby very largely increased. It is, however, considered that the studies of ternary systems undertaken at the laboratory should not be merely of an approximate or exploratory nature, but the full treatment necessarily involves considerable delay in the attainment of results suitable for publication. This is the principal reason why it has not been found possible to issue a further alloys research report during the past year. It is hoped, however, to carry the work to a stage where publication becomes possible before the end of the present calendar year.

Experiments on the physical properties of the ternary alloys have been largely postponed until the rolling of the alloys could be carried out in the experimental roling mill at the laboratory itself. A large number of ingots for the purpose of carrying out these rolling experiments have, however, been prepared, and as soon as the equipment of the mill is complete a large quantity of results will rapidly become available.

The scheme for the extended investigation of the permanence of light alloys in regard to supposed spontaneous disintegration, which was set out in the previous report, has been steadily pursued as far as the adverse circumstances already noted have permitted. The preparation of the very large number of test pieces has proceeded and is now approaching completion, while a considerable number of measurements have been made.

Other research work has included some work on low carbon steel as to the effects of strain at high temperatures, on the intercrystalline cohesion of metals, on the melting point of iron. With reference to Dr. Rosenhain's new re-agent for etching steel, it is pointed out that an example of the usefulness of this re-agent has recently occurred in connection with steel required for war materials. In this steel, minute cracks and fissures, which inevitably led to the rejection of the final product, have been found to be definitely associated with the presence of phospheric bands, whose presence was clearly revealed by the re-agent. A further interesting observation, which has been carefully confirmed, illustrates the manner in which the phospheric banding of steel persists even after drastic heat treatment. This observation was made by examining a banded steel in the ordinary annealed condition and again after quenching from 800 deg. C. In the latter condition, while the bulk of the steel was in the condition of martensite-troostite, certain regions were found to consist of ferrite, and this could readily be identified with the bands of phospheric ferrite revealed by the new re-agent in the annealed steel. This observation shows clearly how the presence of a relatively high proportion of dissolved phosphorus prevents the diffusion of iron carbide even at a temperature as high as 800 deg. C. A further inference may be drawn to the effect that the presence of marked phosphorus banding is a very serious disadvantage to steels which have to be hardened, and incidentally also to materials intended for case hardening, since phosphoferrite resists diffusion of carbon, and this leads to the production of soft spots, and even of cracks, after hardening.

Reference is also made to the Research on Magnet Steels conducted under the auspices of the Research Committee of Magnet Steel.

A detailed study of the constitution of the Alloys of Copper and Tin has been begun with a view to utilizing the most accurate available methods for clearing up the points which still remain in doubt in regard to the constitution of these alloys.

The work so far undertaken has dealt with alloys containing 55 to 65 per cent of tin, and the results have been published in a paper read at the March (1915) meeting of the Institute of Metals. Incidentally, for the purposes of this research, a new form of thermostat has been developed (Mr. Haughton and Mr. Hanson), which allows specimens to be annealed in electrically heated furnaces for long periods at a temperature maintained constant within + 1 deg. C. As yet the apparatus has only been constructed of glass, and is, therefore, only available up to a temperature of about 450 deg. C., but it is hoped to extend its usefulness by having it constructed in silica, or, possibly, even in metal. It will then be very useful in the metallographic study of many alloy systems.

There has been much activity in regard to investigatory test work. The work which has been carried out may be roughly divided into three groups:

(1) Investigation of cases of failure.

(2) Investigations in connection with manufacturing processes, the manufacture of specific articles, or the use of special materials.

(3) Investigations connected with aeronautics.

Cases coming under group (1) have been more numerous than usual. The examples dealt with cover a very wide range of metals (ferrous as well as non-ferrous)

and a wide range of objects. As regards group (2), while several of the cases ivestigated have been those arising out of industrial difficulties of an ordinary nature, several have arisen, during the last few months from circumstances due to the industrial conditions caused by the war. The laboratory has been, in several instances, in a position to overcome the difficulties of manufacturers arising from shortage of customary materials, etc. Owing to the confidential character of the work of this kind detailed reference to it is obviously impossible.

The investigation of failures and breakages occurring in connection with aeronautical work, principally in regard to engine parts and in some cases structural parts of aeroplanes, has occupied a very large amount of time and attention from the superintendent and staff of the department. Particular attention has been devoted to the question of the effect upon steel of acetylene welding, and the research which has been undertaken in consequence of the questions raised in this connection is being carried out jointly with the engineering department. The materials involved in these aeronautical questions are in many cases special alloy steels of peculiar properties and microstructure. The peculiarities in question have in many cases required special experimental investigation; so much so is this the case, that it is becoming desirable that a systematic study of the more usual types of alloy steels should be undertaken by the department, and, as indicated in the outline program for future work, it is hoped to undertake such a systematic study as soon as the pressure of the work of the staff of the department may permit.

Market Prices

JULY, 1915

Copper opened at £82, and fell rapidly to £79.10 (2nd), recovered to £80 (6th), then declined to £78 (12th), and after a slight improvement to £78.10 (13th), it fell away to £74.15 (18th); it then rose to £76 (21st), and after declining to £75 (23rd), fell sharply to £72 (25th), recovered slightly to £72.10 (26th), and continuing to fall closed at £71.10.

Tin opened at £172.10, falling to £171 (2nd). It then improved to £173 (3rd), declined to £170.10 (8th), and after again touching £173 (13th) fell rapidly to £165 (20th). After a slight recovery to £166 (21st), it continued to fall steadily, closing at £155.

Haematite opened at 95/- and remained at this price throughout the month.

Scotch Pig opened at 72/6, improving to 74/- (7th). It then declined, again reaching 72/6 (20th), and after recovering slightly to 73/- (22nd), continued to fall to 72/3 (27th), after which it remained fairly steady, closing at 72/6.

Cleveland opened at 66/6, improving to 67/6 (2nd). After a slight decline to 67/3 (3rd), it continued to rise to 68/- (7th). It then fell slowly again, reaching 66/6 (20th), recovered to 67/- (22nd), but afterward lowered to 66/3 (27th). It then improved slightly, closing at 66/6.

Lead opened at £26.15, and after falling away to £25 (8th), it recovered to £26.5 (26th), at which price it remained steady till the 15th; it then declined to £25.15 (16th), and again remained steady till the 24th, after which it continued to fall, closing at £24.10.

	£	s.	d.

Notes

Electrolytic Oxygen and Hydrogen.—The International Oxygen Company, 115 Broadway, New York City, has issued a 24-page booklet on "I. O. C. System, Production Pure Oxygen and Hydrogen." It deals with the I. O. C. system of welding and cutting and is profusely illustrated, showing installations in various parts of this country and abroad.

Converter practice at Hayden, Ariz., has given the following results, according to Manager J. J. Ormsbee: Throughout November, 1914, a daily average of over 81 tons of copper was produced from a 42 per cent matte, with a standard size Pierce-Smith converter. During the first half of February, 1915, a daily average of 85 tons was maintained.

The Dome mill, at Porcupine, established a new record in May, when 26,000 tons of ore was treated, having an average value of $4.28. The gold produced was valued at $111,261. This tonnage is the largest in the history of the mill; the value was approximated in April, when it was $4.20 per ton.

The Ohio Copper Company's mine and mill at Bingham and Lark, Utah, have been leased to the General Exploration Co., of Salt Lake City. The mill will be put in condition to handle 2000 tons of ore daily.

Stratton's Independence, Ltd., treated during the month of April 8387 tons of low-grade dump and mine ore, netting the company $8,000.

Porcupine Crown Gold Mining Co. is preparing to retreat the tailings from its experimental amalgamation mill. The dump contains about 19,000 tons valued at $3.50 per ton, and was accumulated prior to the erection of the cyanide mill.

The Tropenas Converter Co., of 50 Church St., New York, is erecting a new office and laboratory building of its own in Brooklyn, N. Y. This will include a small experimental plant in which a novel steel-producing method is to be perfected.

The Bucyrus Company, of South Milwaukee, Wis., has moved its Southern sales office from Birmingham to New Orleans, La. Mr. E. L. Byron, Southern sales manager, will remain in charge, and will have associated with him, Mr. R. S. Byron. His office will be 1105 Hennen Building.

The price of ferromanganese in the United States fluctuated widely in 1914, on account of the European war. Prior to August the price of standard 80 per cent ferromanganese was about $40 a long ton. During August prices ranged from $110 to $140 a ton, while quotations dropped as low as $62 in November and advanced again to $80 in December.

The establishment of platinum refineries in Russia has not been encouraged as a result of the order forbidding the exportation of platinum in quantities valued above 500 rubles ($257.50). Not a single refinery has been opened, and producers find themselves with large quantities of metal on hand which they cannot market. The bureau for gold and platinum industries has been asked to ascertain whether sales can be effected in this country, and if so the producers will ask for a modification of the embargo. Representatives of the gold mining industry in Russia have petitioned the government for the establishment of a concern to manufacture potassium cyanide.

Tanks.—The Walter A. Zelnicker Supply Company of St. Louis has sent us its recent bulletins on used tank car tanks.

The Link-Belt Company, of Chicago, has issued its new Portable Wagon Loader Catalog 210, which de-

scribes the machine that will load a wagon or truck with material carried on the ground at the rate of one ton per minute.

Gas and Gasoline Engines.—The Chicago Pneumatic Tool Co. has issued a bulletin describing their class A-G Giant Engines for the utilization of natural or producer gas or gasoline.

DeLaval Centrifugal Blowers and Compressors are described in a catalog recently issued by the DeLaval Steam Turbine Company of Trenton, N. J. This is a profusely illustrated catalog containing illustrations, diagrams, and descriptions of their products.

The Mesta Machine Company of Pittsburgh reports a recent shipment of a four-arm low-type sheet pickling machine to the Alan Wood Iron and Steel Co., Philadelphia, and orders from the McKeesport Tin Plate Company for three of these machines.

Costs in the Steel Foundry is the title of Steel Castings for July, 1915, a small bulletin issued by the Tropenas Converters Company. This bulletin discusses costs systems and gives special attention to overhead costs and the determination of selling prices.

The Snyder Electric Furnace Co. of Chicago is installing a Snyder steel furnace for the Canadian Brakeshoe Company, Ltd., of Sherbrooke, Quebec. This furnace will melt and refine cold material and will deliver 24 tons in 24 hours.

Glass Enameled Products.—The Elyria Enameled Products Company of Elyria, Ohio, has issued Catalog *B* describing seamless one-piece enameled apparatus. This includes open and closed tanks, steam and water jacketed kettles, vacuum pans, etc. The glass enamels used are claimed to be acid, alkali, and rust resistant, and the seams are welded by the autogenous welding process.

The National Screen Separator is described in a bulletin recently issued by the National Engineering Co. of Chicago. The feature of this separator is a device for keeping the screen from clogging up. This is accomplished by having wires stretched underneath the screen which are alternately drawn taut and released by suitable mechanism, thus forming a vibrating devise striking the screen.

Conductivity of Electrolytes.—The accurate measurement of the conductivity of electrolytes is discussed, and improved apparatus for this purpose described, in catalog No. 48 recently issued by the Leeds & Northrup Company, Philadelphia, Pa. The development of this apparatus was made with the assistance of Dr. E. W. Washburn of the University of Illinois. The catalog contains, besides the description of apparatus, much valuable technical information on conductivity measurements, comprising about 29 pages of discussion, diagrams and illustrations.

The **National Tube Company**, Pittsburgh, Pa., has issued Catalog J, comprising material manufactured at the Kewanee Works of the National Tube Company, embracing "National" pipe for steam, gas, water and air; cast iron, malleable iron and brass fittings; "Kewanee" unions and "Kewanee" specialties; brass and iron body valves and cocks; radiators and coils; drive well points and well supplies. The catalog is a beautifully illustrated volume of 394 pages, and very elaborate and detailed in its information, giving lists of the different sizes of the materials manufactured, with drawings and in part colored illustrations.

The debt of Chilean nitrate producers to the government on May 15, as a result of loans advanced by the government to keep the industry going, amounted to $2,880,000.

Ultraviolet Rays.—A reference list of 317 articles, etc., on ultraviolet rays, available in the New York Public Library has been published in form of a pamphlet by this Library.

The output of recoverable zinc in New Jersey in 1914 was 148,506,500 lb., as compared with 144,312,560 lb. in 1913. Owing to the lower average price of spelter, the estimated value of the 1914 product was only $7,515,914, as against $8,081,502 in 1913.

Antimony shipments from Central China during the first three months of 1915, according to the Hankow *Times*, consisted in 1067 tons of antimony regulus and 2560 tons of crude antimony. The price for regulus has practically quadrupled since last August, and the high price has greatly stimulated production.

The production of Portland cement in the United States in 1914 was 88,230,170 barrels, valued at $81,789,368, according to the U. S. Geological Survey. The output represented a decrease in quantity of 3,866,961 barrels, and a decrease in value of $10,768,249, as compared with 1913.

A Government Corner in Chinese Blue.—According to a Washington newspaper story, Mr. Joseph E. Ralph, director of the Bureau of Engineering and Printing, has bought up in New York all the available supply of Chinese blue and other special colors needed in the preparation of stamps, seals and paper money.

Methods of determing total sulphur in rubber have been studied by the Bureau of Standards. The results have been published in Technologic Paper No. 45, recently issued. Copies may be had free of charge on application to Bureau of Standards, Department of Commerce, Washington, D. C.

The ash of the seaweed collected on the shore of Manila Bay in Tondo is reported to yield 15 per cent of potash. No data are available to show the quantity of seaweed that can be gathered, but it is considered to be abundant. The discovery has aroused considerable interest owing to the present scarcity of potash.

The American Shop Equipment Co. of Chicago has issued a bulletin on Shop Furnaces describing their rivet forges for oil or gas fuel, flue welding furnace and forge furnaces, also heat treating furnaces and pot furnaces, all for oil or gas fuel. The bulletin also gives complete export shipping data.

The Hardinge Conical Mill Co. is installing for the Nevada Consolidated Copper Co. two 8-feet dia. Hardinge mills, to be used with iron balls. Also an order from the Dome Mines Co., Ltd., of South Porcupine, Ont., Canada, for two 8-feet dia. ball mills. These ball mills are to take the place of stamps now in use at the Dome Co.'s plant.

The **Superior Chemical Corporation** has recently been organized, with factory and office at 170 Tillary Street, Brooklyn. The officers are John E. Muhlfeld, president, and Samuel G. Allen, secretary and treasurer. The operation of the plant will be under the supervision of J. L. Danziger. The company will manufacture chemical and allied products, with especial attention devoted to photographic developers.

Natural Gas.—The Bureau of Mines has just issued Technical Paper 109, which deals with the chemical and physical properties of the natural gases used in twenty-five cities in the United States. The authors are G. A. Burell and G. G. Oberfell. Five of the samples contain methane only, as the combustible gas. The others contain in addition to methane higher members of the series of paraffin hydrocarbons. The heating values range from 735 to 1312 B.t.u. per cubic foot at 0 deg. C. and 760 m.m. pressure.

Seattle Meeting of the American Chemical Society

THE fifty-first meeting of the American Chemical Society was held at Seattle, Washington, from Tuesday, Aug. 31, to Friday, Sept. 3, and proved unusually successful and enjoyable. It was a somewhat "old-fashioned" meeting in the best sense of the word, with a preponderance of general meetings over sectional sessions, with the attendance always held well together, and a true, congenial happy spirit prevailing all around.

Immense credit is due to the local committees, with chairmen H. G. Byers of the executive committee, H. K. Benson of the finance committee, E. J. Bartels of the excursions committee, L. A. White of the press committee, J. H. Linton of the reception and registration committee, R. W. Clough of the banquet committee, M. J. Falkenberg of the smoker committee, and Mrs. C. A. Newhall of the ladies' committee. With Seattle extending its fullest hospitality to the society everyone felt at once at home. But for the fine and truly happy spirit which prevailed full credit must also be given to the president of the American Chemical Society, Dr. Charles H. Herty, who impressed his charming personality on the whole meeting and even succeeded in eliciting some excellent and lively discussions in the technical sessions.

The attendance during the general meetings was nearly 200. From the East a party of about forty members had come in a special car personally conducted by President Herty and Secretary Parsons. A stay at Glacier National Park on Saturday and Sunday, preceding the Seattle meeting, was delightful. The party arrived at Seattle on Monday. Simultaneously another party of a score of members arrived in countercurrent from San Francisco, having attended the meeting of the American Institute of Chemical Engineers the week before.

On Monday night there was a meeting of the council of the American Chemical Society, preceded by a complimentary dinner. The general meeting started on Tuesday morning in the chemical laboratory of the University of Washington with general registration. The registration officials were not only charming to look at, but the office had a 100 per cent efficiency as a semipermeable diaphragm. Members having registered and received the very pretty totem-pole badges found themselves in the lecture room, with no way left to the outside. And the meeting that followed was enjoyed by all in fullest measure.

Open Meeting

The meeting was opened by Dr. H. G. BYERS, professor of chemistry at the University of Washington. He introduced Dean ARTHUR PRIEST, who as personal representative of the president of the University and of the Mayor of Seattle extended the welcome of university and city to the society in a felicitous little speech.

Dr. CHARLES H. HERTY, president of the American Chemical Society, in his reply referred to the reception which the society had from the Seattle section five years ago on its Western trip. He spoke of the Pacific Coast as a land that has been built by "boosters" in the best sense of the word. The confidence in the future of this country is our rich inheritance from the pioneers who built up the empire at the Pacific Coast. Dr. Herty paid a tribute to the daily newspapers of Seattle which show so much interest in science and industry in general and in the University of Washington in particular, and as newspapers give the people what they want, this fact proves the great interest which the people of the State of Washington take in their University. Dr. Herty concluded with a reference to the great developments right before us now and the immense opportunities of the American chemist. Mutual helpfulness must be the keyword.

CHEMICAL INDUSTRY

The opening address related to "Chemical Industry," the author being Dr. L. H. Baekeland. In his absence the address was read by the secretary, Dr. Parsons. As this address is to be delivered again next week by the author himself in connection with the National Exposition of Chemical Industries, in New York, we reserve its publication in full to our next issue.

Dr. Baekeland referred to the present European war as a chemists' war. But "do not imagine that this is the first chemical war. The art of kiling and robbing each other became chemical the day gun powder was invented; at that time, however, the existing knowledge of chemistry was just of pinhead size. Napoleon knew very well how to use adroitly exact knowledge and chemistry for furthering his insatiable ambition to dominate the world; so he surrounded himself with the most able chemical advisers and scientists. Ever since then science, technology and chemistry in particular have played a rôle of increasing importance in the armament of nations. . . .

"Do not reproach chemistry with the fact that nitrocellulose, of which the first application was to heal wounds and to advance the art of photography, was stolen away from these ultrapacific purposes for making smokeless powder and for loading torpedoes. Do not curse the chemist when phenol, which revolutionized surgery, turned from a blessing to humanity into a fearful explosive, after it had been discovered that nitration changes it into picric acid.

"Let us hope in the meantime that war carried to its modern logical gruesomeness, shorn of all its false clamor, deceptive picturesqueness and rhetorical Bombast, exposed in all the nakedness of its nasty horrors, may hurry along the day when we shall be compelled to accept means for avoiding its repetition."

After his introductory remarks on the war, Dr. Baekeland reviewed the peaceful work of the chemists in the industry, especially the work of the American chemists who, he emphasized, are a more potent factor in the world's progress now than those of Germany or England. He emphasized the importance of the achievements of American electrochemical industries, compared with which the dyestuff industry is almost insignificant. He defended in a strong and able manner the American chemist against the claim that he was to be blamed for the lack of an American dyestuff industry.

But Dr. Baekeland also agreed that in the past, chemists, as a general rule, had been too much analytical and not enough constructive. "Successful engineering is essentially constructive. The most urgent work for the chemist of to-day must be constructive—he must learn how to cement together the vast amount of data which already lie at his disposal, even if he, himself, has to produce this very cement by further research."

THE PACIFIC NORTHWFST

Dr. H. K. Benson, of the University of Washington, followed with an address on the "Industrial Resources and Opportunities of the Pacific Northwest." This address is published in full at the end of this report.

SYMPOSIUM ON THE CONTRIBUTIONS OF THE CHEMIST TO VARIOUS AMERICAN INDUSTRIES

After these two addresses of general interest, the symposium of papers on contributions of the chemist to various American industries was taken up, in continuation of the series of papers presented at the New Orleans meeting (this journal, May, 1915, p. 283).

John E. Teeple's paper on "The Contributions of the Chemist to the Naval Stores Industry" was read by Professor Frankforter.

George W. Sargent's and A. L. Cushman's two papers on "The Contributions of the Chemist to the Iron and Steel Industry" were read by Professor Franklin.

M. H. Ittner's paper on "Contributions of the Chemist to the Art of Soap Making" was read by Dr. Richardson.

E. T. Beiser's paper on "Contributions of the Chemist to the Perfumery Industry" was read by Dr. Byers.

G. W. Thompson's paper on "Contributions of the Chemist to the Lead Industry," was read by Professor Withrow.

Maximilian Toch's paper on "Contributions of the Chemist to the Paint and Varnish Industry" was read by Dr. Parsons.

Dr. John R. M. Klotz, chief chemist of the Barrett Manufacturing Company, then presented a very interesting paper on "Contributions of the Chemist to the Coal Tar Industries," which we reserve for publication in full in our next issue. This paper elicited an extended and lively discussion in which Dr. Klotz gave additional information on the particular conditions of this industry created by the war.

Mr. R. F. Max Michael then read an illustrated paper on a new viscosimeter.

The balance of the program for this afternoon comprised the following three papers:

Francis C. Frary, "Contributions of the Chemist to the Photographic Industry."

Frank R. Eldred, "Contributions of the Chemist to the Pharmaceutical Products Industry."

S. W. Katzenstein, "Contributions of the Chemist to the Hardwood Distillation Industry."

Sessions of Wednesday

While the afternoon of Wednesday was devoted to section meetings, the forenoon was given over to a very interesting symposium on wood distillation in general session.

Professor James R. Withrow of Ohio State University gave an illustrated lecture on "Chemical Engineering Features of the Hardwood Distillation Industry. Dr. S. F. Acree of the Forest Products Laboratory of Madison, Wis., discussed "What Chemistry Had Done to Help the Utilization of Wood."

The other papers on the program for this session were:

H. K. Benson and T. G. Thompson, "The Study of the Tannin Content of Douglas Fir Sawmill Waste."

H. K. Benson and Marc Darrin, "Yield of By-Products from the Destructive Distillation of Some Western Conifers."

H. K. Benson and Newton Crites, "The Extraction of Resinous Wood by Ammonia."

Roy C. Judd, "Discoloration of Maple in the Kiln."

R. E. Rose and A. G. Bissell, "The Chemical Composition of the Light Oil from the Destructive Distillation of Resinous Woods."

F. W. Kressmann, "Manufacture of Ethyl Alcohol from Wood Waste. II. The Hydrolysis of White Spruce."

Homer Cloukey, "The Application of the Davis Spot Test in the Preliminary Examination of Creosotes."

A. W. Schorger and Ralph Sayre, "Isoprene from Beta-pinene."

Bailey Tremper, "The Distillation of Douglas Fir at High Temperatures."

F. W. Kressmann, "The Manufacture of Ethyl Alcohol from Wood Waste: III Western Larch as a Possible Raw Material."

Marc Darrin, "The Production of Acetone from Pyroligneous Acid."

An account of this symposium is reserved for our next issue.

PRESIDENTIAL ADDRESS

Dr. CHARLES H. HERTY'S presidential address on "Co-operation in Matters Chemical," delivered on Wednesday evening, was one of the ablest presidential addresses delivered before the American Chemical Society.

Dr. Herty pointed out how regrettable it was that the three-year-old determination of international co-operation of chemists, conceived at the International Congress of Applied Chemistry in New York City in 1912, had so early been forgotten, due to the war.

Research, whether "pure" or "applied," is identical. Pure enrichment means enrichment of the soil, applied research means crop production. There is no dignity or lack of dignity involved. "Pure" and "applied" research are just terms of convenience.

Dr. Herty emphasized the responsibility of professors of chemistry in universities, especially head professors, in bringing out the national point of view, through their attitude toward research.

The war situation has called public attention too acutely to certain special applications of chemistry, at the expense of the deserved appreciation of the quiet workers who have in the past built up our science.

Dr. Herty made a plea to all chemists for some little research with no hope of pay so that all of us may thus repay our obligation to our science.

University research should be greatly encouraged. This raises the question whether there exists the proper co-operation between the universities and the industries.

Do university professors have the proper attitude toward the problems of the industry? Do they emphasize sufficiently "chemistry in service of mankind?"

On the other hand, do men in the industries appreciate properly the rationale of the university professor's point of view in establishing fundamental facts and drawing accurate deductions therefrom?

Dr. Herty emphasized the stimulating and broadening influence of the general meetings of the American Chemical Society held in different parts of the country. He warned against the dangers of local sectionalism in the society.

Chemical preparedness for national defense puts an important responsibility upon the chemist, who derives in return the valuable benefit of the proper development of certain needed industries which might otherwise be neglected.

That the nation should be self-contained is a matter of most fundamental importance.

Our visible supply of sodium nitrate is slight. We have depended too much on Chile saltpeter and perpetual peace. We should acquire, with government help, a sufficient supply to tide us over an extra year until factories could makes nitrates from air in case of war.

Ammunition is important enough, but have we acquired chemical preparedness in industrial chemistry?

Dr. Herty then discussed our patent system and where it is deficient. He called attention to the failure of the nation to understand the asset value of a patent and to the failure to protect him who creates. The nation, through its laws, should be the guardian of the patentee.

Dr. Herty mentioned the throttling of the early aniline oil industry in this country by foreign competition. He emphasized the viciousness of dumping and the necessity of the adoption by Congress of an anti-dumping clause.

Dr. Herty pointed out the value which an American dyestuff industry would have as a reserve for the explosive industry.

In concluding his able analysis of the present industrial chemical situation in this country, Dr. Herty emphasized that the chemist has made good. What we need is wise legislation.

Social Functions and Entertainments

The entertainment program was delightful.

The special program for the ladies contained an extensive automobile trip, a theatre party, and a fine exhibition of folk dances by co-eds of the university.

The Council was entertained at a complimentary dinner on Monday night.

The feature of the smoker given to the Society on Tuesday evening at the Seattle Commercial Club was an illustrated lecture by Professor Edmond S. Meay, president of the Mountaineers, on Mount Rainier. There were also some vaudeville entertainments and the whole occasion was greatly enjoyed.

On Wednesday afternoon there were automobile rides, on Thursday a fine excursion on Puget Sound for the inspection of the shipping and fishing industry, and a banquet in the evening of Thursday. As the writer had already left Seattle, he is unable to say from his own experience how the following feature of the banquet program, quoted from the Seattle *Daily Times*, worked out: "So that the local chemists will have a little first-hand information on the quality of the beverages to be consumed after the prohibition law goes into effect in this State, a number of 'wines' and other non-alcoholic drinks, invented by the local chemists, will be served to the visiting scientists at a dinner to be given in their honor at the Hotel Washington on Thursday evening. The sub-committee, Charles A. Newhall and Professor Benson, thought this would be a good opportunity to ascertain from the members of their own profession whether the new concoctions have any 'pep.'"

After completion of the Seattle meeting, the program provided an excursion to Mount Rainier National Park, a visit to Portland, Ore., with luncheon and excursion on the Columbia River, the party being the guests of the Oregon Section, and finally at San Francisco, an entertainment by the California Section at a smoker at Techau Tavern. Dr. Franklin and Dr. Duschak had come from San Francisco, to welcome the society to California.

* * *

The Industrial Resources and Opportunities of the Northwest

An Address Made at the Seattle Meeting of the American Chemical Society

BY H. K. BENSON

In an address* upon a similar topic dealing with the Southern States, our mutual friend and co-worker, A. D. Little, expressed his temerity for a visitor to enumerate the potentialities of the South. For an entirely different reason the speaker faces a similar temerity. Inasmuch as he must remain in the locality after the attendants of the convention have departed, he must stay with the facts and representations here made. If, therefore, the figures are not as large and the possibilities not as boundless as those to which you became accustomed at the New Orleans meeting, your disappointment must be attributed to the fear, and not to the enthusiasm, of the speaker. In the brief compass of this address it is hoped, however, to call attention to the great store of natural resources and latent opportunities for development which constitute the heritage of those who labor in the Pacific Northwest.

The industrial aspect of the Northwest has been toward the East. From thence flowed the great streams of capital which have furrowed the conti-

*This journal, May, 1915, p. 281.

nental barriers and spread a network of transportation to every storehouse of natural treasures; or locked in mountain fastnesses have generated the power with which the wheels of industry may be driven. The time is coming and is now here when we may well turn from the broader phases of external development to a more minute and critical inspection of the resources about us on every hand and utilize them in the greater intensification of industry and commerce.

The Pacific Northwest constitutes an industrial unit which comprises the States of Oregon, Idaho and Washington, the province of British Columbia in Canada, and the territory of Alaska. Although composed of different political parts, whereby the natural course of industry may be hindered or benefited, yet the ultimate outlet for commodities is largely confined to the cities touching the waters of the Pacific Ocean. Material development of any portion of this area is felt throughout all of it. While it would be of great interest to comprehensively discuss the potentialities of the Pacific Northwest as a whole, the lack of published data would make it necessary to collect and compile at first hand much of this information. Time does not permit of such an extended investigation of this at present, and it is proposed therefore to present in some detail the resources of the State of Washington as a typical example of what may be found in varying degrees throughout the entire Pacific Northwest.

The total area of the Pacific Northwest includes nearly a million and a quarter square miles distributed as follows:

Oregon	96,607	sq. mi.
Washington	69,180	" "
Idaho	83,888	" "
British Columbia	395,500	" "
Alaska	586,400	" "
	1,234,575	sq. mi.

Harney County alone, in Oregon, contains as much tillable land as the State of Maryland, while the area of Alaska is greater than that of Norway, Sweden, Finland, England, Scotland and Ireland taken together. While a large portion of Alaska is mountainous, less than 1 per cent of its area consists of permanent snow fields, and its agricultural valleys contains as much tillable land as is cultivated in the States of New York, Pennsylvania and Ohio.

LUMBER INDUSTRY

We call Washington the "Evergreen" State, because its hills and mountains are enveloped with forests of fir, cedar, spruce and hemlock. With the pines of Oregon and Idaho, these forest species represent the greatest resource of the Pacific Northwest. In the States of Oregon, Washington and Idaho there are still uncut more than 50,000,000 acres of merchantable timber, from which it is estimated that over 850,000,000,000 ft., board measure, of lumber may be cut. This is more than one-third of the standing timber of the United States. The annual cut of lumber in the two States of Oregon and Washington is slightly in excess of 5,000,000,000 ft. in lumber and 8,500,000,000 shingles. Over 2000 wood manufacturing establishments, employing about 65,000 men are required in the production of the lumber and timber products of Oregon and Washington annually. The value of the timber product annually manufactured exceeds $80,000,000, of which 80 per cent is paid out for wages, taxes, rent and other production costs. When there is added to these forest areas, the 180,000,000 acres of forest lands in British Columbia with its annual cut of 1 1/3 billion ft. and an estimated stand of merchantable timber amounting to 130,000,000,000 ft. and the more or less indefinite content 20,000,000 acres of merchantable timber in Alaska, it becomes apparent that the timber products of the Northwest will continue for many years as an asset of great importance.

FERTILIZER INDUSTRY

The fertilizer resources of the Pacific Northwest are almost of equal importance as its forest products. From the waters of Puget Sound and the North Pacific the annual harvest of fisheries products exceeds $53,000,000. In 1913 the fisheries products of British Columbia were almost one-half of the total production of the Dominion, amounting to $14,500,000, and twice the value of those of Nova Scotia. The salmon industry of Alaska now extends from Ketichan in Southeastern Alaska for a distance of 2000 miles to beyond Bristol Bay in Bering Sea. In 1913 the seventy-nine salmon canneries of Alaska represented an invested capital of $31,341,670, and the annual catch of halibut, codfish, herring and whales requires an additional investment of over $6,000,000.

From the annual packing of 8,000,000 cases of salmon on the Pacific Coast results an annual production of 140,210 tons of cannery waste, which might be augmented considerably by the non-edible fish which are rejected and never reach the cannery. This waste contains in the fresh condition 10 per cent oil, 3.5 per cent bone phosphate, 1.5 per cent phosphoric acid and 3 per cent nitrogen. Of the total waste in 1913, only 16,300 tons were utilized on the Pacific Coast of the United States. From this waste were obtained 1630 tons of dry scrap and 293,000 gal. of oil. More complete utilization would increase the possible output of fertilizer and oil by tenfold.

Floating upon these same waters are the great beds of the giant kelps or seaweeds. These have been mapped by the United States Bureau of Soils, and according to this survey they yield annually over 20,000,000 tons of kelp equivalent to 750,000 tons of potassium chloride. The total imports of potash salts of all kinds in normal time is equivalent to about 400,000 tons annually. From the kelps of the North Pacific waters may be extracted not only the potash salts for domestic consumption but a surplus as well, which eventually may enable this country to export potash salts to other countries.

Until the discovery of the rock phosphate deposits of the Northwest the only commercial quantities that were known to exist in the United States were found in Florida and Tennessee. The phosphate deposits of Idaho are thirty times greater than the other known deposits of the United States. In the areas thus far surveyed by the United States Geological Survey it is estimated that over 2,500,000,000 tons of phosphate rock with 35 to 37 per cent phosphoric acid (P_2O_5) may be found.

In the ultimate utilization of cannery waste and of non-edible fish, of the potash in kelps and of phosphate rock, the Pacific Northwest offers a most promising field for the upbuilding of a great fertilizer industry.

COAL AND OIL

In the past the industrial welfare of a community was dependent upon its nearness to a coal deposit, but in the Northwest coal has competitors in the great quantities of oil from California and the electrical power of the mountain streams of the Northwest. The annual production of coal in the State of Washington is nearly 4,000,000 tons, while that of British Columbia is 2,500,000 tons. The total supply of coal in

the Pacific Coast States is estimated by Campbell and Parker at 22,000,000,000 tons, of which 20,000,000,000 are located in the State of Washington. The coal fields of Alaska cover 12,667 square miles. The estimate of the Geological survey places minimum coal resources of Alaska at 150,000,000,000 tons, which are far in excess of the original coal supply of Pennsylvania. Unlike the latter, however, much of this coal consists of lignites, the utilization of which calls for new methods and processes. Even in the State of Washington and adjacent to the coal fields themselves fuel oil is transported from California displacing annually a quantity of coal greater than that consumed.

WATER POWER

The water power resources of the Pacific Northwest constitute an important factor in power productions. The estimated developed water power of the Pacific Northwest exclusive of Alaska, exceeds 650,000 hp. The estimated undeveloped power of the Columbia River Basin is approximately 20,000,000 hp. or one-third of all the undeveloped water power in the United States, and equivalent to all the water power found in the twenty-six States east of the Mississippi River. Within economical transmission of our larger cities on tide water may be generated at least one-fifth of the available water power of the United States, exclusive of Alaska. The water power resources of the latter are said to exceed those of the Pacific Coast States.

MINERAL INDUSTRY

Much has been written of the mineral industry of Alaska and the Northwest, and it would become tedious to particularize concerning its extent and importance. The annual production of gold and silver in normal times is approximately $35,000,000. For the year 1913 the production of copper was valued at $11,300,000, of lead at $15,600,000, and of zinc at $2,500,000. The development of deposits of minor minerals has not been extensive, due to their remoteness from suitable smelting facilities. On the Seward Peninsula is a tin-bearing district of 450 square miles. Alaska has produced since 1902 over 560 tons of tin. Antimony ores are found in Alaska and Washington, molybdenum in British Colombia and Washington, tungsten in Alaska and Washington, while platinum is found in the sluice boxes of many of the placer camps of Alaska. Arsenic ores abound in the Monte Cristo district of Washington, and are smelted with the recovery of white arsenic at the Tacoma smelter.

Graphite, gypsum and barytes exist in commercial quantities in Alaska. In Washington and adjoining portions of British Columbia occur the only large deposits of limestone located on deep water along the entire Pacific Coast of the United States and Canada. Extension deposits occur in the northern tier of countries from Puget Sound to the Idaho boundary. These deposits constitute the sources for six Portland cement, one hydrated lime and numerous lime kiln plants now located within the State of Washington.

Clay deposits suitable for use in common brick manufacture are widely distributed throughout the Pacific Northwest, as are also those adapted to the manufacture of drain tile. In numerous places are also found deposits of clays which can be used for the manufacture of paving brick, sewer tile, terra cotta and firebrick. Both Washington and British Columbia are now producers of refractory brick of a high grade. Washington now ranks fifteenth in the production of clay products in the United States, forty-five firms being engaged in the industry and producing wares valued at over $2,000,000 annually.

Deposits of diatomaceous earth of superior quality have been investigated in five locations within the State of Washington. Apparently enormous quantities of this material exist in this State. Deposits of magnesium carbonate and other magnesium salts have been reported, but are not utilized. Among other raw materials available in the Pacific Northwest are iron ores suitable for mineral paints and perhaps for pig iron; talc for use as a filter in paper manufacture; silica for glass, and sand, lime, brick and large deposits of stone for structural purposes. Among the latter especial mention should be made of the Alaskan marble and of the granites and sandstones of Washington. At least three extension deposits of tufa rocks occur in Oregon and Washington.

THE OPPORTUNITIES OF THE PACIFIC NORTHWEST

The opportunities of the Pacific Northwest are to be found in the utilization and distribution of the resources heretofore recited. Less than 100,000 persons are now employed in manufacturing industries, which produce products valued at $400,000,000 in the States of Oregon and Washington. An inspection of the foodstuffs of the city of Seattle reveals what is typical of the entire Northwest. In this city of 300,000 population, during the past year 7207 cars of vegetables and fruit were shipped into the city. This is equivalent to a carload for every seven families. Of three million packages making up the total receipt, a million and a quarter came from outside the State of Washington.

Agriculture is a dormant, undeveloped industry. Less than 10 per cent of the agricultural land of Washington has been improved and is utilized for agriculture. More than 2,500,000 acres of logged-off land of agricultural character remain uncleared and idle. This is due chiefly to the high cost of clearing the land by the methods which are commonly in use. The farms which have been developed from the wilderness of débris left by the logger represent a monument of industry to those who have reclaimed them and made them factors of production. In eastern Washington the problem has been different. Instead of the jungle the desert must be overcome. Irrigation has transformed large areas into orchards and meadows of great beauty and wonderful productiveness. But even there, out of 2,000,000 acres of irrigable land not more than 25 per cent has thus far been reclaimed. In British Columbia the estimated acreage of tillable land is 253,000,000 acres, of which not more than 12 per cent is occupied, and only about one-fifth of that is under cultivation. The great need of the Pacific Northwest is settlement by colonists. Transportation is available, water and power are abundant, natural resources of unknown extent and character await development—in brief, the harvest is great, but the workers are few.

In the industries already established greater intensification and closer utilization are urgent. Fully as much timber as is manufactured into lumber is either wasted by burning or used in an uneconomic manner. As will be shown in papers presented before the convention, the fir slabs of the sawmills contain nearly as much tannin as the chestnut wood, which is the basis of the tannin extract industry of the United States. But no extract plant exists in the Northwest, and even tanneries have had hard struggles for existence in spite of the fact that great quantities of hides are readily available. Men have looked at our great forests and have seen nothing but lumber in them, and, following the line of least resistance, they have cut down these forests and manufactured a single product. In the fisheries industry the results have been largely similar. Mr. John N. Cobb,

editor of the *Pacific Fisherman*, calls attention to the neglected fishery resources of the Pacific Coast in an admirable paper presented before the first annual meeting of the Pacific Fisheries Society. In the 120,000 tons of salmon offal annually wasted are millions of pounds of salmon eggs. Siberia in 1913 prepared 500,000 lb. of salmon eggs as caviar, while 24,000 lb. were prepared upon the Pacific Coast of America in the same time. In Japan whale meat is of considerable economic importance as a food product. The whaling stations of the Pacific Coast ship certain portions to Japan, but by far the largest portion is either made into fertilizer or else wasted. Methods of processing whale meat so that it could be marketed as a food product should be worked out by the technical men of the fisheries industry whereby millions of pounds of meat might be added to our national supply annually.

These are random instances of the wasteful methods whereby our natural resources are being developed. A more complete study of existing conditions would simply tend to multiply the number of them. The Pacific Northwest needs to apply the methods of self-examination which have been so successfully applied to the industries and resources of the more congested sections of this and other countries. It needs a closer alignment with the technical thought and progress of the day. In a word, it needs, not capital, but captains of industry. With more care for the utility of natural resources and with the co-operation of the technical skill of the day, opportunities will spring from hidden places, and industries will multiply, and the Pacific Northwest will take its place in the moving streams of commerce and trade.

* * *

The following list comprises the names of those members which registered during the first day of the meeting, but it is not a complete list of the attendance:

W. H. Adolph, Tsinan, China; F. C. Atkinson, Indianapolis, Ind.; Edward Bartow, Urbana, Ill.; Stuart J. Bates, Pasadena, Cal.; J. H. Beal, Urbana, Ill.; R. C. Benner, Fremont, Ohio; J. E. Berkheimer, Tacoma, Wash.; Page R. Boyles, Salem, Ore.; C. M. Brewster, Pullman, Wash.; H. A. Bright, Washington, D. C.; C. A. Browne, New York City; H. W. Brubaker, Manhattan, Kan.; T. J. Bryan, Oak Park, Ill.; Miss M. G. Buckhous, Missoula, Mont.; G. H. Burrows, Burlington, Vt.; J. C. Butcher, Clackamas, Ore.; C. E. Coates, Baton Rouge, La.; Lillian Cohen, Minneapolis, Minn.; H. T. Corbett, Washington, D. C.; J. E. Darrah, Champaign, Ill.; J. A. Dawson, Vancouver, B. C., Canada; L. H. Duschak, San Francisco, Cal.; R. A. Dutcher, Corvallis, Ore.; R. C. Eccles, Brooklyn, N. Y.; John B. Ekeley, Boulder, Colo.; F. R. Eldred, Indianapolis, Ind.; H. C. Enders, New York City; Harry L. Fisher, New York City; Roy Fitch, Washington, D. C. Fred Flanders, Boston, Mass.; Frans Franken, Chicago, Ill.; George B. Frankforter, Minneapolis, Minn.; Edw. C. Franklin, Palo Alto, Cal.; John Fulton, Corvallis, Ore.; A. N. Gadsby, Washington, D. C.; E. D. Goldsmith, Tacoma, Wash.; George Grindrod, Kent, Wash.; W. J. Hale, Ann Arbor, Mich.; E. D. Heinrich, Tacoma, Wash.; Charles H. Herty, Chapel Hill, N. C.; E. Hockett, Columbus, Ohio; W. B. Holmes, Fremont, Ohio; J. S. Jones, Moscow, Idaho; James Kendall, New York City; J. R. M. Klotz, New York City; W. A. Lenenberger, Tacoma, Wash.; W. L. Lewis, Evanston, Ill.; J. K. Long, Evanston, Ill.; S. K. Loy, Laramie, Wyo.; Paul S. MacMichael, Auburn, Wash.; R. S. McBride, Washington, D. C.; J. F. McGregory, Hamilton, N. Y.; D. McIntosh, Vancouver, B. C., Canada; E. J. Mead, Everett, Wash; R. B. Moore, Denver, Colo.; Rokuro Nakaseko, Kyoto, Japan; Arthur C. Neish, New York City; W. A. Noyes, Urbana, Ill.; F. A. Olmsted, Oregon City, Ore.; J. C. Olsen, New York City; C. L. Parsons, Washington, D. C.; I. K. Phelps, Washington D. C.; R. W. Rea, Portland, Ore.; E. Emmet Reid, Baltimore, Md.; Clifford Richardsen, New York City; W. D. Richardson, Chicago, Ill.; E. F. Roeber, New York City; C. F. Rudmann, Ironton, Ohio; Edward Schramm, Washington, D. C.; E. Schwerdtfeger, Seattle, Wash.; R. D. Smith, Hamilton, N. Y.; O. F. Stafford, Eugene, Ore.; Frank Sternberg, Victoria, B. C., Canada; J. K. Takenaka, Portland, Ore.; Herman V. Tartor, Corvallis, Ore.; A. D. Thorburn, Indianapolis, Ind.; Bailey Tremper, Auburn, Wash.; Paul Van Horst, Tacoma, Wash.; Carl L. von Ende, Moscow, Idaho; R. G. Waltenburg, Washington, D. C.; B. L. Wehmhoff, Bremerton, Wash.; F. A. Wertz, Washington, D. C.; A. S. Wheeler, Chapel Hill, N. C.; H. H. Whiteside, Auburn, Wash.; A. M. Williamson, Niagara Falls, N. Y.; James R. Withrow, Columbus, Ohio; Frank Wright, Kent, Wash.; F. N. Yuill, Indianapolis, Ind.; Clarence Zischkan, Tacoma, Wash.; H. F. Zoller, Tacoma, Wash.

Oxy-benzyl-methyl-englycol-anhydride or "modern magic" is the title of a booklet issued by the General Bakelite Co. for distribution at the San Francisco Exposition. This booklet describes the various uses of Bakelite.

The Improvement of High Boiling Petroleum Oils, and the Manufacture of Gasoline as a By-Product Therefrom, by the Action of Aluminium Chloride[1]

BY A. M. McAFEE

The conversion of high boiling petroleum oils into lower boiling oils of greater commercial value is an old problem, and many solutions of it have been proposed. Formerly, when kerosene was worth more than gasoline, naturally the effort was to increase the yield of kerosene from crude oil; nowadays, gasoline is worth more than kerosene, and naturally the effort is to increase the yield of gasoline. But in principle, gasoline making and kerosene making from high boiling petroleum oils are the same, and most of the proposed methods make both products. With very little variation, most of them will make gas equally well. A careful examination of these methods will show, in nearly all cases, the same principle, namely, what is called cracking—heating to a sufficient temperature to cause the high boiling oils to become unstable and break down into lower boiling oils. If the heat be intense enough and the time be long enough the product will be gas; a less heat and a shorter time will make gasoline, and a still less heat and shorter time will make kerosene.

Cracking Methods

The inventors have rung the permutations on this simple idea; they heat under pressure and they heat under vacuum; they heat in the presence of gases; they heat in the presence of catalysts; they heat in tubes and they heat in boilers, etc., etc. It is safe to say that in 99 per cent of the methods which have been proposed for converting high boiling oils into lower boiling oils, "cracking" by heat is involved. Sometimes it is disguised in ornate language; sometimes it lurks behind intricate apparatus, but it is always there.

The difficulty, however, with all these cracking methods is a difficulty in principle. In breaking down the complex, high boiling hydrocarbons into several simpler ones, there is not enough hydrogen to saturate these newly formed bodies, and unsaturated hydrocarbons must necessarily result unless hydrogen be added or carbon subtracted. Hydrogen is too expensive and difficult to add, and, though a part of the carbon is readily enough subtracted and deposited, this subtraction and deposition never goes far enough, although the stillman might not be readily convinced of this. These cracked products are in large part unsaturated, and they are not desirable commercially. They are foul smelling; they are yellow in color and become rapidly more yellow on standing; they deposit large amounts of carbon on ignition in a gas engine; they burn with a smoky flame; they contain resinous bodies which cause gumming in use or on standing, etc., etc. They can, of course, be refined somewhat with sulphuric acid, but there must be too much of the acid used and too much of the oil is lost to permit in practice any thorough treatment with acid.

Aside from the poor quality of the liquid products obtained, the operation of the cracking process is attended with great difficulty where uniform results are desired. There are many variables on which the obtaining of such results depends—temperature, time, pressure and catalytic action of the walls of the containing vessel. A change in either of these variables makes a change in the products obtained. Using the same appa-

ratus, the same pressure, and consuming the same time, a difference of a comparatively few degrees of temperature in cracking operations makes marked differences in the yield and quality of liquid products.

In most of the cracking processes, pressure is employed. Sixty to 100 lb. is usual, and some have proposed much higher pressures. It is here that the greatest difficulty becomes manifest—the great danger to the operators and to the plant. There is always a deposition of hard (and flinty hard) coke on the inner walls of the heating element. Some who have had considerable experience in cracking oils have said that the coke is forced into combination with the iron making it brittle, and thus utterly unable to withstand the high temperature and pressure employed. At any rate, the deposition of the carbon occurs where the element is hottest, causing a local overheating at that point. Under such conditions the tensile strength of the steel becomes an unknown quantity—as likely as not it yields to the stress without any warning. Oil vapors of a temperature around 650 deg. Fahr. ignite spontaneously when they evolve from a still into the surrounding atmosphere. In cracking processes the temperature is 750 deg. to 850 deg. Fahr., and even higher, hence the manifest danger of cracking petroleum oils under such pressures.

Aluminium Chloride Process

When I took up the gasoline problem, some two and one-half years ago, I dismissed from consideration the idea of cracking oils. Up to this time, or since the Friedel and Crafts British patent, No. 4769 of 1877, there had been some degree of mild interest shown as regards the effect which aluminium chloride might have on petroleum oils, but no positive results had followed from this interest. It appeared to me that this reaction might have far more significance than was then apparent; I trust this paper may in a measure exemplify its significance.

I have found that with proper control of the vapors leaving the distilling system and entering the final condenser, and with sufficient time given the aluminium chloride, high boiling oils can be completely broken down into lower boiling oils, and no matter how unsaturated the high boiling hydrocarbons may be, the low boiling oils produced therefrom are sweet smelling, water white and saturated. The reaction gives little gas and only about the right amount of carbon to allow production of saturated products. The carbon is deposited not in the form of a hard baked-on carbon, but as a granular, coky mass, easily removed from the still.

But there are other products than gasoline that can be made from petroleum which are commercially worth while, although in our efforts to increase the supply of gasoline we have apparently forgotten this fact. If the market value of the various products which can be obtained from crude petroleum be plotted, it will be found that there is a peak at the low boiling end and another at the high boiling end. Gasoline is worth more than kerosene and kerosene is worth more than gas oil, while the products following gas oil, paraffin and lubricating oils are worth as much or more than the gasoline.

The problem before me, therefore, knowing the reactive power of aluminium chloride, was to apply it to crude petroleum so that good heavy oils could be obtained while at the same time converting the less valuable portions of the crude into gasoline. The solution of this problem is found in my patent.

In the practical operation of this process, crude petroleum of any kind is first distilled until the naturally occurring gasoline and kerosene, if there be any present, is distilled off. As you are probably aware, in many of our crude oils, and especially some of those from Texas, California and Mexico, there is substantially no gasoline present, and very little kerosene. But in any event, the crude is first heated to free it of any moisture which it may contain, since the oil must be perfectly dry before adding the aluminium chloride.

The next step is to add anhydrous aluminium chloride to the remaining residual oil, and then bring the mixture to boiling in the still. Boiling is usually around 500 deg. Fahr., and generally remains between 500 and 550 deg. Fahr. during the entire distillation, extending over a period of twenty-four to forty-eight hours. There is no need of employing extra pressure or vacuum or special apparatus; any still with a stirrer in it suffices.

Granted sufficient time for the aluminium chloride to get in its work, the success or failure of this process depends upon the proper control of the temperature at which the oil vapors are allowed to leave the distilling system to enter the final condenser. Between the still and the final condenser are placed two air-cooled condensers connected in series, which separate the low boiling oils from the high boiling oils, returning the latter together with any volatilized aluminium chloride to the still. For a 1000-bbl. still the air condensers which we are now using are drums of oval cross-section, 3 ft. x 6 ft. x 6 ft. high. In addition to the air condensers, a 3-ft. dome is attached to the top of the still which serves to return most of the volatilized aluminium chloride and its compounds. The operation is so controlled that the vapor is kept at the desired temperature, as indicated by a thermometer placed in the vapor line at the point of exit of vapor into the final or water-cooled condenser. The temperature at this point should not exceed 350 deg. Fahr., otherwise not only will heavy oils distil over, but the aluminium chloride (or its compounds with hydrocarbons) will enter the condenser and clog it up. Under the first named condition, the distillate obtained will be a mixture of gasoline, solvent oil and kerosene, which are afterward separated by fractional distillation. There products are all water white, sweet smelling, saturated and need no refining with sulphuric acid. In practice, no treatment is given them, except a washing with alkali, followed with water, to remove hydrogen sulphide. With proper back-trapping of high boiling oils into the still from the air-cooled condensers, and a temperature of 300 deg. Fahr. in the vapor line, the distillate obtained will be gasoline alone, which is ready for the market when washed with an alkaline solution.

I have spoken of the time which should be given the aluminium chloride for the accomplishment of the desired results. It is a mistake to assume that with a given amount of aluminium chloride and boiling it up with oil the desired results will be obtained. That is far from the truth. I do not wish to impose upon your patience by dismissing consideration of the mechanism of this reaction by simply saying it is catalytic. I am fairly well satisfied that it is one of association or combination in the liquid phase and dissociation in the vapor phase. It is well known that aluminium chloride exists in the solid and liquid states as Al_2Cl_6 and in the vapor state as $AlCl_3$. It is also well known with what avidity aluminium chloride in the solid or liquid state will combine with other salts to form double salts. The most common of these double salts is that of aluminium and sodium chloride, which, at one time, as you know, was the source of metallic aluminium (Castner process). Aluminium chloride probably combines with these high boiling complex hydrocarbons in much the same way as it combines with sodium chloride, and when the boiling temperature is reached these double com-
